Host immune responses to parasites are geared to eliminate the foreign organism, and include both innate and specific immune responses. Innate responses involve complement-mediated lysis and macrophage/neutrophil phagocytosis and killing. Some parasites evade complement-mediated lysis by altering surface molecules that bind complement or by acquiring host proteins that inhibit complement pathways (e.g. CD55, decay accelerating factor). The tegument of helminths makes them resistant to neutrophil and macrophage cytocidal mechanisms.

Specific immune responses appear to segregate into two groups: cellular immunity against protozoa mediated through CD4-driven macrophage activation or CTL (cytotoxic T-lymphocyte) responses, and antibody (IgE) or eosinophil (major basic protein)-mediated defence against helminthic infections.

Immune responses against parasites may in fact produce some of the damage seen in the host. Examples include the fibrosis and granuloma formation in schistosomiasis, immune complex deposition in malaria and schistosomiasis, autoimmune myocarditis, and neuropathy in Chagas' disease caused by *Trypanosoma cruzi*.[3] Autoimmune disease in chronic parasitic infections may be associated with molecular mimicry.[4]

Parasites use a number of mechanisms to evade the host immune system (Box 105.1). These are crucial adaptations in ensuring the survival of the species from the point of view of the parasite, but equally may contribute significantly to the pathology seen in the host.

Epidemiology

Parasitic infections are a particular problem in developing countries. In developed countries, they usually occur in isolated outbreaks or in people who have been travelling to endemic areas. An increased incidence of parasitic disease is found throughout the

---

Box 105.1 Immune evasive mechanisms

Anatomic sequestration

- Intracellular replication (malaria, toxoplasma)
- Cyst formation (entamoeba)
- Residence within the intestinal lumen (helminths)

Antigen masking

- Parasite acquires surface coat of host proteins (schistosomiasis)

Antigenic variation

- Antigenic shift with stages of parasitaemia (malaria)
- Continuous variation of surface antigens (African trypanosomiasis)

Antigen shedding

- Loss of surface antigen spontaneously or after antibody binding (*E. histolytica*, trypanosomes, schistosome larvae)

Resistance to host immune effector mechanisms

- Development of tegument (resistant to antibodies, complement, or CTL attack)
- Inhibition of complement (various mechanisms)
- Resistance to phagocytosis (various mechanisms)
- Resistance to antibody (production of ectoenzymes)

---

world amongst patients infected with HIV.[5] Even in endemic areas, direct parasitic involvement of the musculoskeletal system is relatively rare. Systematic epidemiologic studies are lacking and therefore the true prevalence of rheumatic manifestations in parasitic infections remains unknown. No specific manifestations or rheumatic syndromes have been identified in association with parasitic infection. Diagnostic criteria for 'parasitic rheumatism' have been suggested, but because of its relatively low prevalence, together with other problems related to conducting epidemiological studies in

developing countries, there has not been a rigorous study of 'parasitic rheumatism' and its diagnostic criteria. Where data is available, the musculoskeletal manifestations are varied and the outcome usually very good either with or without therapy.[6]

Differential diagnosis and investigations

Parasitic infection as a cause of rheumatic disease is not frequently considered in the primary differential diagnosis. Factors that must alert the clinician to a parasitic association include:

- patients from endemic areas
- patients who have travelled to endemic areas
- elevation of eosinophil count
- failure to respond to anti-inflammatory therapy
- coincidental identification of parasitic infection in index patient.

Initiation of relevant investigations for parasitic infection depends on the clinician having a heightened level of awareness for the association of parasitic infection and musculoskeletal disease. An appropriate search for parasites and/or their immune phenomena may assist in making a diagnosis. This includes a search in blood, urine, and faeces, and where appropriate, tissue for histological analysis.[7] Direct identification of parasitic material in muscle, synovium, and bone has highlighted the role of parasitic infections in causing musculoskeletal disease. However, it is rare to find parasites at the site of pathology and this depends on the type of parasite involved. Parasitic material has been identified at the site of musculoskeletal pathology in cases with cysticercosis, gnathostomiasis, filariasis, Guinea worm infestation, hydatid disease, malaria, schistosomiasis, strongyloidiasis, toxocariasis, toxoplasmosis, trichinella infections, and trypanosomiasis. With the advent of molecular methods of identification of parasites, including specific polymerase chain reaction (PCR) techniques, the percentage of cases with identifiable 'parasitic material' may increase in future.[8] Developments in imaging techniques may also aid diagnosis. Typical ultrasonographic and MRI features have been described for certain parasites, e.g. muscular cysticercosis.[9]

More often, rheumatic syndromes are associated as a remote manifestation accompanying a parasitic infection elsewhere in a given individual. In this case, parasitic material may be identified at a site remote from the musculoskeletal system, or immune phenomena may indicate the possibility of a parasitic infection. These include elevated blood eosinophils (usually with nematode infections), infiltration of eosinophils into tissue, specific anti-parasitic antibodies, deposition of immune complexes, and signs of immune damage such as granuloma formation or fibrosis.

Parasites are broadly classified into two groups, protozoa and helminths. A wide variety of parasites from both groups have been associated with rheumatic manifestations (Tables 105.1 and 105.2). These include oligoarthritis, polyarthritis resembling rheumatoid arthritis, enthesitis, myositis and myopathic syndromes, and vasculitis, either localized or systemic. However, no specific 'parasitic syndrome' has been identified, and the pathogenesis remains uncertain. Evidence exists for both direct parasitic involvement of musculoskeletal tissue as well as possible reactive arthritis or immune-mediated mechanisms causing the rheumatic manifestations.

Treatment

The optimal approach to therapy has not been firmly established for many of the parasitic musculoskeletal manifestations and therapy remains largely empirical. Some patients only require non-steroidal anti-inflammatory drugs (NSAIDs) to control symptoms while others need specific anti-parasitic therapy or direct removal of the parasite (Tables 105.1 and 105.2). Complete resolution of symptoms and signs has been reported with anti-parasitic therapy, particularly where strong evidence of infection has been found. No formal studies have been conducted to assess the need for anti-parasitic therapy in all patients. Several of the anti-parasitic agents are relatively toxic, so a trial of therapy should not be undertaken lightly. Where clinical suspicion is high, and particularly where evidence exists for parasitic infestation, a trial of therapy may be undertaken under close supervision. Typically, therapeutic responses to anti-parasitic therapy occurs where standard anti-inflammatory therapy and/or steroids have previously failed.

Infections due to amoebae and *Blastocystis* spp. can be treated with metronidazole[56] or tinidazole. *Blastocystis* spp. also respond to nitazoxanide.[57] Flagellates (e.g. *Giardia*) generally respond to metronidazole or tinidazole.[58] The benzimidazole albendazole is a useful alternative. Therapeutic choices for malaria are complicated by resistance to traditional therapies such as chloroquine, particularly for *Plasmodium falciparum*. Chloroquine usually followed by primaquine remains effective, however, for most forms of non-falciparum malaria. Falciparum malaria in areas of chloroquine resistance requires combination therapy based on artemesinin derivatives, atovaquone–proguanil, quinine, or mefloquine.

Intestinal nematodes are generally sensitive to benzimidazoles such as albendazole or mebendazole. However, the response to therapy is variable. Pyrantel pamoate is effective against *Ascaris* spp. and *Ancylostoma* spp. Ivermectin is also effective against several nematodes although not considered the drug of choice. The treatment of filarial worms has traditionally been based on the use of diethylcarbamazine or ivermectin, particularly for endemic disease. However, these agents are associated with significant side effects. An alternative initial agent for the individual patient is doxycycline, which targets endosymbiotic bacteria.[59]

Intestinal cestode infestations due to *Taenia solium* and *T. saginata* usually respond to praziquantel which remains the drug of choice. Niclosamide and albendazole may also be effective. Tissue cestodes (larval forms) may respond to a number of agents including benzimidazoles. However, the need for specific anthelmintic therapy is unclear in these cases. In addition, other measures such as steroid therapy and surgical removal of cysts are often required.[46] Schistosomes and many trematodes are sensitive to praziquantel. The drug of choice for the liver fluke *Fasciola hepatica* is triclabendazole. Newer anthelmintics include nitazoxanide, tribendimidine, and artemisinine derivatives; however, their role is yet to be determined in treatment of rheumatic manifestations of parasitic infections.

In addition to uncertainty related to outcome measures, there is the possibility of exacerbating musculoskeletal symptoms on initiation of anti-parasitic therapy. This is more of a problem when treating tissue-invasive parasites, and varies with type of parasite, parasite load, and the drug used.[60] A policy of 'start low and go slow' should help avoid most major complications of therapy but there may be a need for concomitant steroids, particularly in the Mazzotti reaction described in the treatment of filariasis with diethylcarbazine or ivermectin.[61,62]

Table 105.1 Protozoa have been associated with a variety of musculoskeletal manifestations. Therapeutic choices and references of case reports or case series are indicated

Protozoa	Musculoskeletal manifestations	Therapy	Reference	
Blastocystis spp	Asymmetric oligoarthritis Infectious arthritis	Metronidazole Iodoquinol	Tejera et al. (2012)	10
Cryptosporidium	Reactive arthritis	Nsaids Paromomycin	Hay et al. (1987)	11

CHAPTER 106

Fungal arthritis

Carol A. Kemper and Stanley C. Deresinski

Introduction

Fungal infection of joints is an uncommon but challenging clinical problem whose recognition and management is often belated. A high degree of suspicion for fungal infection must be maintained in the face of persistent monoarticular or, less commonly, asymmetric polyarticular, arthritis, especially in an immunosuppressed host. Fungal joint infection most often results from the haematogenous dissemination of the pathogen from a primary portal of infection (usually pulmonary) directly to the synovial tissue, or occurs as the result of infection of para-articular bone with subsequent rupture into a joint space. Less commonly, such infection occurs as the result of direct inoculation of the organism into the joint space or synovial tissue. An inflammatory, aseptic arthritis may also occur in association with certain fungal infections (e.g. coccidioidomycosis,histoplasmosis) as a consequence of the immune response to the organism, rather than a result of infection of the joint space itself.

Epidemiology

Only a handful of fungi, perhaps five or six species at most, are responsible for most human mycotic musculoskeletal infections (Table 106.1),[1,2] but virtually all of the approximately 100 fungi pathogenic in humans have been reported to cause infection of bones and/or joints. The frequency with which fungal arthritis occurs, its clinical presentation, and its outcome varies depending on the specific pathogen as well as upon host variables. For example, fungal arthritis due to the endemic dimorphic fungi, such as *Histoplasmosis capsulatum*, *Blastomycosis dermatiditis*, and *Coccidioides immitis*, is often seen in patients without overt immunodeficiency. In contrast, infection due to candida species is usually found in association with intravascular infection in individuals with readily apparent host factors, such as indwelling central venous catheters (often in association with the administration of long-term antibiotic therapy and/or parenteral nutrition), haemodialysis, or intravenous drug use. Defects in cellular immunity are critical to the dissemination of certain fungi from their initial portal of infection and the secondary infection of joint spaces. Patients with haematological malignancy, haematopoietic and organ transplant recipients, and those receiving long-term corticosteroids and immunosuppressive therapy (including biological agents for rheumatoid arthritis) are especially at risk for fungal arthritis due to candida. Rarely, joint infection occurs secondary to direct inoculation of the organism into the joint during aspiration or injection, trauma, or surgical intervention. Unlike the other fungi, infection with *C. albicans* and related yeasts is ordinarily the consequence of host invasion by endogenous colonizing organisms. In contrast, exposure to *B. dermatiditis*, *C. immitis*, *H. capsulatum*, or *Paracoccidioides brasiliensis* primarily occurs because of exposure within an endemic area (see Table 106.1). Two of the more common fungi found in joint space infections, *C. neoformans* and *Sporothrix schenckii*, have a worldwide distribution.

Clinical picture

The clinical presentation of joint infection is generally indolent, although the onset of some infections, such as those due to *B. dermatiditis*, candida species, and occasionally other fungi, may be acute, with hot, erythematous, tender joints and accompanying fever. The presentation may thus resemble an acute bacterial septic arthritis. Most cases, however, present with the usual findings of monoarticular (or occasionally asymmetric polyarticular) arthritis with decreased range of motion, tenderness, and swelling. There is often evidence of joint effusion; but in some cases of chronic infection due to *C. immitis*, joint swelling may be due to synovial proliferation rather than the accumulation of fluid. The initial list of differential diagnoses may therefore be quite broad, and includes septic arthritis, rheumatoid arthritis, mycobacterial infection, brucellosis, and pigmented villonodular synovitis. While fungal arthritis may present in the setting of widespread fungal infection, in many instances there is little clinical evidence of extra-articular infection. Large weightbearing joints, particularly the knee, are the usual targets. Radiographic findings that may be seen with varied frequency, depending include erosion of juxta-articular cortex, osteoporosis, and associated para-articular osteomyelitis. Clinically important information about joint integrity and the presence of otherwise unapparent para-articular osteomyelitis may be provided by MRI, which has greater sensitivity and resolution than other conventional techniques (see Chapter 68). Synovial fluid examination reveals an elevated white blood cell count. Although candidal and blastomycotic joint infections typically present with frankly purulent synovial fluid with a predominance of polymorphonuclear leucocytes, the other fungi often cause lesser degrees of inflammation with lower cell counts and variable predominance of either polymorphonuclear leucocytes or lymphocytes. The protein concentration is usually in excess of 3.0 g/dL while the glucose concentration is

Table 106.1 Risk factors for infection and the clinical setting of fungal joint infection

Organism	Endemicity	Host risk factors	Mode of infection	Joint involvement
Candida spp.	Normal human commensal	Haematological malignancy, immunodeficiency, neonates, indwelling catheters, central catheters, long-term antibioticuse, exogenous steroids	Haematogenous, rarely direct inoculation from trauma or injections	Monoarticular; predominately large joints (knee 70%)
Coccidioides immitis	Arizona, New Mexico, California	Usually immunocompetent host	Haematogenous	Monoarticular (90%); predominately knee and ankle
Blastomyces dermatitidis	Ohio, Missouri, Mississippi river valley, south-eastern USA, Africa, Middle East	Usually immunocompetent host (>90%)	Haematogenous rarely direct inoculation	Monoarticular (90%); knee ankle, elbow, and wrist
Sporothrix schenkii	Worldwide	Alcoholic, diabetic, rarely severely immunocompromised	Haematogenous, may be direct inoculation	Monoarticular (50%), polyarticular (50%); knee, ankle, wrist, small joints of the hand
Histoplasma capsulatum	Ohio, Missouri, Mississippi river valleys, Central and South America	Both normal and immuno- deficient hosts (e.g. AIDS)	Haematogenous	Monoarticular; knee, wrist, small joints of the hand
Cryptococcus neoformans	Worldwide	Organ transplant, AIDS, haematological, malignancy, diabetes, exogenous steroids	Haematogenous	Monoarticular (65%), polyarticular (35%); knee(60%), ankle, wrist, sterno/acromio-clavicular
Paracoccidioides brasiliensis	Central and South America	Immunocompetent host	Haematogenous	

low to normal. Routine direct examination (e.g. Gram stain) usually does not reveal the organism, but cytological preparations are useful in the diagnosis of blastomycosis, cryptococcus, and, to a lesser degree, coccidioidomycosis. Culture of synovial fluid or synovial tissue usually yields the organism. Synovial tissue histopathology is variable and often non-specific, as in infection due to *S. schenckii* in which the organisms are few and difficult to visualize. A granulomatous reaction is most commonly observed. The use of additional diagnostic procedures, such as blood cultures, bone marrow examination and culture, antibody tests, or tests for the detection of fungal antigen in serum or other body fluids, depends upon the clinical setting and the suspected aetiology. Tests of delayed dermal hypersensitivity to fungal antigens are generally not useful for diagnostic purposes. Some infections may cause tenosynovitis in the absence of osteomyelitis or arthritis. Tenosynovitis may occur as the result of haematogenous dissemination or direct inoculation, and is most often associated with *S. schenckii* infection, and less frequently, with infections due to *C. immitis* and *C. neoformans*. During the primary pulmonary infection with *C. immitis*, an acute self-limiting arthritis or periarthritis, commonly referred to as 'desert rheumatism', may be seen in association with erythema nodosum, erythema multiforme, and occasionally hilar adenopathy. Thus, the clinical picture may resemble sarcoidosis.

Management

Amphotericin B remains the initial therapeutic agent of choice for many serious fungal infections, especially for those who are severely immunosuppressed, have life-threatening or central nervous system disease, or who have failed azole therapy. Lipid-associated or -complexed formulations of amphotericin allow the administration of higher dosages of drug with less toxicity than the conventional

formulation, but are substantially more expensive. The triazoles, fluconazole and itraconazole, especially in the outpatient setting, have similar efficacy but reduced toxicity and morbidity compared to amphotericin B. Newer azoles, voriconazole and posaconazole, are available. The echinocandins caspofungin, anidulafungin, and micafungin may prove to have a role in the treatment of selected infections. 5-fluoroctosine (5-FC) is used much less frequently.

Individual mycoses

Aspergillus

Aspergillus rarely results in joint space infection. Severely immunosuppressed hosts, such as those with haematopoetic and organ transplants, haematological malignancy and intra-articular steroid injection, are at greatest risk for aspergillus infection.[3] Clinically apparent pulmonary infection is present in two-thirds of patients with disseminated aspergillus. Haematogenous dissemination of the organism is implicated in most cases, although introduction of the organism into the joint space has occurred during surgical or arthroscopic procedures, or as a result of trauma.

Voriconazole is the treatment of choice for life-threatening invasive aspergillus infection, but amphotericin B, caspofungin, posaconazole, and micafungin are alternatives.

Blastomycosis

Blastomycosis is an uncommonly encountered mycotic infection endemic in parts of the United States (Table 106.1). *B. dermatiditis* is a thermal dimorph whose mycelial phase is thought to reside in soil. Primary pulmonary infection maybe acute, subacute, or subclinical, but is usually self-limited; chronic infections are unusual. Haematogenous dissemination is relatively frequent during the initial phase of the disease, leading to infection at almost

any body site. Skin and bones are the most frequent sites of dissemination (25–60%), and only 2.5–8% of patients develop joint infection.[4] Patients with particularly severe pulmonary disease or miliary involvement, or those who are immunocompromised, are at the greatest risk for dissemination.[5] Myalgias and arthralgias are common during the acute pulmonary phase of the disease, but erythema nodosum is not. The arthritis is monoarticular in more than 95% of cases with the knee most commonly involved (see Table 106.2). Joint pain is often acute in onset and patients usually appear toxic. In contrast to coccidioidal arthritis, active pulmonary disease is present in more than 90% of patients with joint involvement, and more than 70% have evidence of additional dissemination. Synovial fluid findings are similar to those seen in candida arthritis. Definitive diagnosis requires growth of the organism. A presumptive diagnosis may be made by visualization of the yeast in synovial biopsy specimens.

Itraconazole is the drug of choice for most forms of the disease; amphotericin B is reserved for the more severe forms. Newer azoles such as voriconazole and posaconazole have a limited role in the treatment of pulmonary blastomycosis.[6]

Candida species

C. albicans is a normal commensal of humans, and endogenous colonization is the source of most infections by candida species. Deep tissue infection generally occurs after amplification of colonization during an intervening immunodeficient state or during administration of broad-spectrum antibacterial therapy coupled with breaches in integumentary and mucosal barriers. Candida infection of joints is typically the consequence of haematogenous dissemination (often from indwelling intravenous catheters in predisposed immunodeficient hosts or in intravenous drug users).[7] Joints previously afflicted by rheumatoid arthritis appear to be at increased risk of infection with candidal organisms (Table 106.1).

Candida joint infection is acute in approximately two-thirds of cases. The large joints are most commonly affected. Synovial fluid examination demonstrates a markedly elevated white blood cell count with a predominance of polymorphonuclear leucocytes (Table 106.2). Candida can be observed on Gram stain. Histological examination of synovium reveals mononuclear cell infiltration but usually an absence of granulomata. Synovial fluid or tissue consistently yield the organism in culture. Recovery of the organism from blood cultures may provide an important clue to the aetiology of the joint process.

Intravenously administered amphotericin B, with or without 5-FC, remains the standard of treatment for immediately life-threatening infection.[8] Fungal susceptibility studies, performed by a reliable laboratory, may help to guide therapy in more complicated cases. Caspofungin may also prove efficacious. Repeated joint aspiration is usually indicated. Surgical debridement, both to confirm the diagnosis and to remove infected tissues, is often necessary (in addition to antifungal chemotherapy), particularly in cases of hip joint infection.

Prosthetic joint infection

Fungal infection of total joint arthroplasties is rare.[9] Infection is a consequence of implantation of skin microflora during surgery. The infections are clinically low-grade, and indolent. Pain, decreased range of motion, and peri-articular swelling are common. Sinus tracts may be seen. Radiographs show evidence of loosening and adjacent areas of osteolysis indicative of osteomyelitis.

Technetium pyrophosphate and gallium nitrate scans are not useful, since they are often positive in the presence of a loosened prosthesis, regardless of the presence of infection. Consistent with a more subacute presentation, synovial fluid white blood cell counts are less inflammatory than that typically seen in native joint infections (4000–15 000/mm^3).

Table 106.2 Clinical and laboratory data helpful in the diagnosis of fungal joint infection

Organism	Serology	Synovial fluid white cell count	Synovial glucose	Synovial fluid examination	Culture
Candida spp.	Not useful	Frankly purulent, <100 000/mm^3	Variable, low to normal	20% positive	Blood and/or synovial fluid, >95% positive
Coccidioides immitis	Complement fixation, immunodiffusion diagnostic	<50 000/mm^3, mononuclear cells	Low	Rarely positive	Synovial fluid, >95% positive
Blastomyces dermatitidis	Low sensitivity, low specificity	Frankly purulent, <100 000/mm^3 polymorphonuclear	Variable, low to normal	By cytological preparation, 90% positive	Synovial fluid, 50% positive
Sporothrix schenkii	Not available	2000–60 000/mm^3 lymphocytes and polymorphonuclear	Variable, low to normal	Rarely positive	Synovial tissue more often positive than synovial fluid
Histoplasma capsulatum	Complement fixation, immunodiffusion diagnostic			Not helpful	Blood and/or synovial fluid, 20–25% positive
Cryptococcus neoformans	Cryptococcal antigen diagnostic	200–5000/mm^3	Variable, usually normal	Indian ink very helpful	Blood and/or synovial fluid, 80% positive
Paracoccidioides brasiliensis	Serum antibody			Not helpful	Usually positive, slow growth (>4 weeks)

Amphotericin B, with or without fluconazole,[9] in combination with removal of the prosthesis and other foreign material, and debridement of affected tissue is the initial treatment of choice.

Coccidioidomycosis

Coccidioides immitis is endemic to soils, with most cases resulting from exposure to airborne arthroconidia (Table 106.1). Risk factors include ethnicity (especially African and Pacific Island ancestry), male gender, and immunosuppression (Table 106.1). Upon reaching the alveoli of the infected host, the organism, a tissue dimorph, converts to the spherule–endospore phase. Approximately one-half of infected patients become symptomatic and, in the vast majority of these, the infection is self-limiting with influenza-like symptoms. Transient arthralgias or aseptic inflammatory arthritis, which probably represents an immunologically mediated inflammatory process similar to erythema nodosum, occur in 3–5% of patients with primary pulmonary coccidioidomycosis. Treatment consists of the administration of non-steroidal anti-inflammatory agents.

Clinically important extrapulmonary dissemination occurs in fewer than 0.5% of cases. Most cases that occur outside an endemic area are the result of travel to an endemic area by someone with no pre-existing immunity.

Skeletal infection occurs in up to 10–50% of patients with disseminated disease, and is frequently multicentric with axial involvement.[10,11] Monoarticular arthritis occurs in more than 90% of cases, with large weightbearing joints, particularly the knee and ankle, being most frequently affected. Although the larger joints are more commonly involved in adults, the small joints of the hand appear to be more commonly affected in children. At the time of presentation with joint disease, occult sites of dissemination are present in up to 25% of cases. Extrapulmonary sites of infection, including meningeal, bone, and joint infection, should, therefore, be avidly sought for in any patient with disseminated coccidioidomycosis. Some patients may initially present with an acutely inflamed joint, but most infections are indolent with progressive effusion and synovial thickening. The diagnosis of joint infection is often delayed, and chronic infection frequently results in significant articular and bony destruction with resultant loss of joint function (see Figure 106.1a). Occasionally, chronic arthrocutaneous fistulas develop with drainage of synovial fluid (Figure 106.1b). Radiographic examination may be unremarkable during the initial phase of infection; effusion, and erosion of articular cortex and adjacent osteoporosis are commonly seen as the infection progresses. MRI in adults with coccidioidal arthritis frequently reveals synovitis, subarticular bone loss, and loss of cartilage, but less frequent marrow involvement.[11]

Synovial fluid is inflammatory with total white blood cell counts as high as 50 000/mm^3 (Table 106.2). Culture of synovial fluid yields the organism in approximately 50% of cases, usually within 3–6 days. Greater yield is seen with culture and histological examination of synovial tissue. The affected proliferative synovium, which often invades cartilage and articular surfaces, exhibits granulomatous villonodular inflammatory changes with the characteristic endosporulating spherules visible on microscopic examination. Most importantly, if coccidioidomycosis infection is suspected, the microbiology laboratory must be notified because of the significant biohazard represented by this organism in culture. Several serological techniques are available for establishing the diagnosis.

Among the endemic fungal infections, coccidioidomycosis is the most recalcitrant to therapy. Patient prognosis depends upon the extent of dissemination to other sites, particularly the central nervous system. Treatment consists of systemic administration of antifungal agents. Amphotericin B remains the treatment of choice in many cases, especially for those with life-threatening disease, central nervous system involvement, and immunosuppression, as well as those who have failed appropriate azole therapy. Patients with disseminated disease often receive a total of 1.0–2.5 g of amphotericin B.[12] Patients with skeletal infection may do better in response to itraconazole rather than fluconazole.[13] Continued therapy is indicated until remission has been achieved, as defined by objective clinical measures, and improvement in serological and radiographic data. Lifelong therapy for disseminated infection is often necessary. The need for synovectomy and debridement of infected bone and tissue remain controversial. Despite appropriate medical and surgical intervention, the joint infection often remains progressive and disabling.

Cryptococcosis

Cryptococcus neoformans is worldwide in distribution. Skin test surveys suggest that subclinical infection is quite common in normal
Fig. 106.1 (a) Radiograph of the right elbow demonstrating destruction of the articular cortex and osteomyelitis of contiguous bone, and (b) sinus formation in an elderly woman with chronic coccidioidal arthritis of many years' duration despite multiple courses of antifungal therapy.

hosts. Clinical disease occurs predominantly, but not exclusively, in individuals with defects in cellular immunity (Table 106.1). Patients with renal failure and HIV infection are especially vulnerable to infection with this encapsulated yeast. The primary portal of entry for the organism is believed to be the respiratory tract, although clinical recognizable pulmonary infection is infrequent. Haematogenous dissemination leads to varying organ involvement, although the organism has a particular predilection for the brain and meninges.

Cryptococcal arthritis, frequently associated with areas of contiguous osteomyelitis and osteomyelitis, occurs in up to 10% of patients with systemic disease.[14] Although soft tissue swelling, inflammation, and frank cellulitis have been reported in cases of cryptococcal joint infection, most cases are indolent in presentation. The knee is involved in approximately 60% of reported cases, followed by an equal number of cases in the sternoclavicular and acromioclavicular joints, elbow, wrist, and ankle (Table 106.2). Approximately one-third of the cases are polyarticular. Radiographs demonstrate an erosive arthritis and juxta-articular osteomyelitis. CT scans often show evidence of surrounding soft tissue inflammation. *C. neoformans* can be visualized using Indian ink. Examination of the synovial fluid reveals a white blood cell count of 200–20 000/mm^3, with a predominance of mononuclear cells. The peripheral white blood cell count and erythrocyte sedimentation rate are often normal.

Amphotericin B may be administered as initial therapy in most cases of life-threatening, disseminated infection. Many experts advocate the concomitant administration of 5-FC for approximately 4 weeks for more severe infection. Once the systemic disease is under control and the joint disease is improving, consideration can be given to completing treatment with fluconazole. Debridement may be useful, especially in cases with significant synovial thickening and peri-articular extension of infection.

Histoplasmosis

Histoplasmosis capsulatum is endemic to many areas within the temperate zones of the world, but is most heavily concentrated in the Ohio, Mississippi, and Missouri River valleys of the United States (Table 106.1). The organism is a thermal dimorph with the mycelial phase existing in soil, generally in association with bird and bat guano. Large outbreaks occur in urban endemic areas. Speleologists throughout the world may be at risk. Upon inhalation by the human or animal host, microconidia reach the alveoli where they convert to the yeast phase. While more than 95% of infections are subclinical, a flu-like respiratory illness may result from infection. Haematogenous dissemination is rare and occurs most commonly in patients with impaired cellular immunity. People with HIV infection who travel to or have previously lived in an endemic area are at risk for reactivation disease.

Immunologically mediated arthralgias and aseptic inflammatory arthritis, similar to that reported for coccidioidomycosis, are common in primary histoplasmosis.[15] Erythema nodosum and erythema multiforme may also occur. During a single outbreak of acute histoplasmosis in 381 symptomatic patients, 16 (4.1%) developed arthralgias and 6 (1.6%) developed aseptic arthritis.[15] The knees, ankles, wrists, and small joints of the hands were the most common sites of involvement; approximately 50% of the cases were polyarticular. The synovial fluid is inflammatory. This clinical problem is self-limited and is treated with non-steroidal anti-inflammatory agents. In contrast to candidiasis and

coccidioidomycosis, infection of the synovium or joint space by *H. capsulatum* is exceedingly rare.[16] Juxta-articular osteomyelitis is often present. Joint involvement is usually monoarticular and has been reported in both apparently immunologically normal and compromised hosts.

The diagnosis of histoplasmosis can be made by culture of both blood and infected sites, including synovial fluid, and histologic demonstration of the infecting organism. The organism is readily cultivated on a variety of media. Detection of histoplasma antigen in serum or urine is useful in the diagnosis of disseminated histoplasmosis. Although both false-positive and false-negative results occur, antibody tests may be useful.

Amphotericin B remains the initial treatment of choice for severe, life-threatening forms of histoplasmosis. Itraconazole, is effective for mild to moderately severe infection.[17]

Paracoccidioidomycosis

Paracoccidioidomycosis is endemic only to areas of Central and South America where it is the most commonly encountered respiratory mycotic infection. *Paracoccidioides brasiliensis* is thermally dimorphic, and as is true for the other dimorphic fungi, conidia released by the mycelial phase of the fungus are inhaled and convert to the yeast phase in the alveoli. Acute, self-limited pulmonary infection may occur, although most patients present with chronic pulmonary disease and evidence of chronic haematogenous dissemination, including painful granulomata of the skin, lymphadenopathy, and ulceration of mucous membranes. Osteoarticular infection is typically multifocal with osteomyelitis of long bones; lesions are ostelytic without sclerosis or periosteal reaction.[18] Articular involvement occurs in one-third, but primary arthritis is rare. Infection is most common in children and adolescents. The diagnosis is usually made on the basis of visualization of the organisms in synovial fluid or tissues, or by culture. Serological tests have been utilized with varying success.

Although the disease is rarely encountered outside endemic areas, the diagnosis should be suspected in any individual at epidemiological risk. Paracoccidioidomycosis primarily occurs in individuals without evidence of immune dysfunction,

Amphotericin B is effective in the treatment of disseminated paracoccidioidomycosis, although itraconazole (and ketoconazole) appear as effective in the treatment of less severe cases.[19] Relapses after treatment are common, and chronic suppressive therapy with one of the azoles or a sulfonamide is therefore recommended.

Sporotrichosis

Sporothrix schenckii, a tissue dimorph, is commonly found on decaying vegetation and in soil in many areas of the world. Infections are both sporadic and epidemic. In contrast to the other soil fungi, cutaneous disease occurs secondary to the inoculation of the organism as a result of trauma to the skin. The lymphocutaneous form, with the development of an ulcer at the site of cutaneous inoculation and proximal nodules in the area of lymphatic drainage, is the most common manifestation of infection.[20] People at particular risk for this infection include rose cultivators and those who handle soil and sphagnum moss.

While arthralgias occur in approximately 2% of those with acute cutaneous or lymphocutaneous disease, infection of the joint space with *S. schenkii* is rare, having occurred in only 1 of 3300 patients (0.03%) in a large outbreak of sporotrichosis.[21] Arthritis may occur

in the presence of widespread dissemination to other sites, but is much more common as an isolated finding.[22] Bayer and colleagues described 44 cases of sporotrichal joint infection, 20% of which were associated with systemic and pulmonary disease.[22] Most cases of sporotrichal arthritis are, therefore, believed to be due to haematogenous dissemination of the organism, although some cases may be the result of articular extension of infection from an adjacent site of osteomyelitis or skin infection or, occasionally, from direct inoculation of the organism into the joint. The majority of patients with systemic infection have predisposing underlying disease, including myeloproliferative disorders, malignancy, chronic corticosteroid use, and alcoholism.

Sporotrichal arthritis is an indolent and slowly progressive infectious process that predominantly affects the knee and other large weightbearing joints, although the small joints of the hand and wrist are also commonly affected. Calhoun and colleagues described 11 cases of systemic sporotrichosis; 8 involved the skeletal system with a total of 12 joints being affected, including the wrist (63%), knee (%), ankle (25%), and elbow and phalanx (13% each).[23] Monoarticular and polyarticular involvement occurs with equal frequency. Most cases present as a slowly progressive synovitis or tenosynovitis with pain, warmth, swelling, and restricted range of motion.[22,24]

Radiographic abnormalities are seen in more than 90% of cases, possibly reflecting the chronicity of infection prior to diagnosis. Osteoporosis of contiguous bone is the most common radiographic finding, followed by soft tissue swelling with effusion, punched-out osteolytic lesions, articular cartilage erosion, and joint space narrowing (Figure 106.2b,c).[22,25]

Synovial fluid white blood cell count is reported to range from 2800 to 60 000/mm^3 (Table 106.2). The diagnosis may be delayed because of the isolated nature of the infection, the rarity of visualizing the organism on smears of synovial fluid, the often non-specific nature of synovial histopathology (which may resemble that of rheumatoid or tuberculous arthritis), and the paucity of organisms in tissue (see Figure 106.2d). Asteroid bodies, often said to be pathognomonic of sporotrichosis, may, in fact, be seen in other infections. Isolation of the organism in culture is the cornerstone of diagnosis. Synovial tissue is more likely to yield the organism (usually within 5 days) than is synovial fluid.

Itraconazole is recommended for osteoarticular sporotrichosis, with amphotericin B as a second-line agent. Surgical debridement may also be necessary on occasion, but should be reserved for persistent culture positivity and in cases of tenosynovitis.
Fig. 106.2 (a) Bone scintigraphy, using technetium-99m, demonstrating intense uptake of the radionuclide in the left knee of a patient with synovitis due to Sporothrix schenckii. (b and c) Radiographs of the left knee from a patient with Sporothrix schenckii, demonstrating only patchy osteopenia of the distal femur and proximal tibia. (d) Granulomatous reaction with typical giant cells of synovium obtained from the same patient. Organisms were not visualized with this stain or with Gomori–methamine silver or periodic acid–Schiff (PAS) stains and the diagnosis was made by recovery of the organism in culture from the synovial tissue. Opportunistic infection

Saraswathi Murthy and Susan Hopkins

Introduction

Approximately 400 000 adults (>600 per 100 000) living in the United Kingdom are affected by rheumatological diseases.[1] Infections in patients with rheumatological disease are common and contribute to morbidity and mortality in this group. This is largely due to an intrinsic immunomodulatory effect of the disease itself and end-organ damage; or due to the use of corticosteroids, disease-modifying anti-rheumatic drugs (DMARDs), and now more commonly biological agents.

Progression of rheumatoid arthritis (RA) disease has been associated with a greater likelihood of developing infection[2,3]; greater than twice the risk of the general population with risk of respiratory and skin and soft tissue infections most likely.[4] A recent European study looking at a cohort of 1000 systemic lupus erythematosus (SLE) patients found that 25% of patient deaths were due to infection alone.[5] Among patients with systemic sclerosis a recent study found that one-third of deaths not directly related to the disease itself were due to infection.[6]

The potential to acquire any infection relates to alterations in the host immune system, damage to epithelial barriers, and organ dysfunction related to the disease process. Low complement levels, impaired lymphocyte response and activation, as well as defective apoptosis and phagocytosis play a role in the immunodeficient state related to rheumatological disease. Skin damage from vasculitic disease or systemic sclerosis creates an impaired barrier in the normal defence innate defence system allowing for skin and soft tissue infection. Lung fibrosis related to RA, vasculitides, or systemic sclerosis (SSc) may alter the immunological milieu and increase the likelihood of pulmonary infection.

The use of biological agents continues to increase and although they have proven effective in controlling these disease processes they are unfortunately associated with an increase in bacterial, fungal, and viral infections including tuberculosis (TB) and non-tuberculous mycobacteria. The frequent use of corticosteroids in rheumatological disease has been consistently shown to increase the rate of bacterial, fungal, and viral infections. There appears to be a dose-related and cumulative dose relationship to this which needs to be taken into account with each patient.

There is therefore an increasing need for guidance in managing the patient with rheumatological disease who develops infection and, moreover, guidance on the prevention of developing infection is of paramount importance. This may be in the form of screening tests at the time of diagnosis, line care, vaccination, or secondary prophylaxis. This chapter provides an overview of the factors that potentiate infection risk within rheumatological diseases and with pharmacological therapies, the common infections encountered, their initial management, and preventable measures that should be undertaken.

Role of underlying disease in infection

RA has been shown to be an independent risk factor for hospitalization with a serious infection.[4] All infections are more common in RA patients than in the general population.[2–4] RA almost doubles the risk of developing community-acquired pneumonia, the likelihood of which correlates directly with disease activity.[7] Atrophic skin over affected joints allows microbial penetration of the skin and soft tissue. Rheumatoid vasculitis can result in ulceration of the skin, distal ischaemia of the digits, and ultimately gangrenous changes with resultant infection.

Neutropenia and splenomegaly, such as occurs in Felty's syndrome, results in splenic sequestration of immune complexes and neutrophils and renders the patients susceptible to encapsulated bacterial organisms (*Streptococcus pneumoniae*, *Haemophilus influenzae*, *Neisseria meningitidis*).

Other forms of arthritic disease such as psoriatic arthritis, ankylosing spondylitis, and enteropathic arthritis have a lower intrinsic risk of infection.[8]

SLE is associated with a significant risk of developing infection, and 50% of hospitalizations are related to infection.[9] One-quarter of deaths in lupus patients are caused by infection,[5] and infection is the second most common cause of death in the first 5 years after disease diagnosis.[10] Infection occurs predominantly in the respiratory, urinary, and skin systems and to organisms that take advantage of the gaps in the innate immune system posed by lupus itself.[5,9–13] A greater risk of developing infections in SLE has been shown with a SLE disease activity index (SLEDAI) score over 12, longer disease duration, renal involvement, and serological markers such as positive anti-dsDNA antibody levels.[9,11,14–17] Hypocomplementaemia and hyposplenism especially associated with lupus render the active lupus patient susceptible to infections with encapsulated organisms and non-typhoidal salmonella.[10] Mannose-binding lectin (MBL) polymorphism in SLE has been shown to increase the infection risk.[10,18] The active lupus patient is therefore more susceptible to viruses, mycobacterial disease, and fungal and protozoal infections.[9,18–20] Diagnosis of infection in the lupus patient may

prove difficult as both infection and lupus flares cause a systemic inflammatory response and clinicians must be vigilant to intervene early in sepsis to improve outcome.

A recent large, multicentre prospective study[6] demonstrated that 33% of non-systemic sclerosis-related deaths were from infection or, put another way, in the overall cohort more than 1 in 8 deaths were infection related. Polymyositis and dermatomyositis are not commonly studied with regard to risk of infection but recent studies show that infection is also one of the leading causes of death in this patient group, representing approximately 30% of all patient deaths.[12,21]

Luqmani et al.[22] showed that the mortality within the first year of diagnosing Wegener's granulomatosis is nine times greater than in the general population and the most common cause of death is infection(32%) followed by active vasculitis and renal disease. In another study[23] looking at the long-term survival in 535 ANCA-positive vasculitis patients (Wegener's granulomatosis and microscopic polyangiitis) most deaths occurred within the first year and almost one-half of these deaths were infection related. It is important to note that all of the patients were on a combination of immunosuppressants.

Role of immunosuppressant treatment in infection

Glucocorticoids have a vital role in the management of patients with rheumatological disease,[1] to various degrees at different points in the disease history. They inhibit synthesis of the majority of cytokines including interleukin(IL)-1, interferon-gamma (INFγ) and tumour necrosis factor alpha (TNFα) while also reducing the production and impairing the function of macrophages. Although neutrophilia is a common feature of steroid use, this apparent increase in blood is related to the inability of these cells are to migrate to tissues where they are required. Leucocyte function is also impaired and is thought to be related to inhibition of endothelial adhesion. As a result, patients treated with glucocorticoids are at significant risk of developing infection with bacterial fungal or viral pathogens.[24,25] In a large cohort study, glucocorticoids use increased the relative risk of serious infection (requiring intravenous antibiotics or hospitalization) almost threefold.[26] The risk of opportunistic infections with doses equivalent to more than 10 mg of prednisolone daily or intravenous boluses of corticosteroids is clearly demonstrated.[25,27] Developing active TB infection on a DMARD is almost twice as likely if it is in combination with steroid rather than DMARD monotherapy.[28] Low-dose corticosteroids (<5–10 mg prednisolone) appear to have little or no significant infection risk whereas high daily doses (>20–30 mg) are associated with significant risk.[24,29–31] Few studies have looked at what the cut-off for the 'safe' dose of steroid would be and this would invariably depend on multiple factors related to the individual and disease.

The DMARDs have varying effects on the immune system and as a consequence some are much more strongly associated with different infections than others. Methotrexate is particularly associated with infections. Greenberg et al.[27] demonstrated an infection rate of 30.9 per 100 person-years in methotrexate users compared to other DMARDs (24.4 per 100 person-years). A recent systematic review[31] looking at methotrexate monotherapy for RA showed the greatest risk of infection is within the first 2 years of use.

Cyclophosphamide causes bone marrow suppression, reduced lymphocyte proliferation, and hypogammaglobulinaemia. In one study, it increased the risk of infection even more than glucocorticoids(relative risk of 3.3 compared to 2.6 for steroids).[26] Azathioprine and lefluonamide are also associated with infection.[26,32] Other DMARDs including gold, antimalarials, D-penicillamine, and sulfasalazine generally cause a state of hypogammaglobulinaemia and have not been linked to significant risks for developing infection in comparison to glucocorticords.[26,32,33]

The use of biological agents is a rapidly evolving area targeting specific parts of the immune system, which has changed management of autoimmune and rheumatological disease profoundly. Consequently the effects that this has on the rate and types of infections that can be acquired or reactivated are still being determined, especially as new agents are being licensed for use continuously.

Monoclonal antibodies against TNFα, such as infliximab, adalimumab and golimumab, and the soluble TNFα receptor fusion protein etanercept have been associated with a high risk of infection.[25,27,28,34–40] Higher incidences of intracellular pathogen-related infections occur with anti-TNF.[25,37] Both new infections and reactivations of TB are strongly associated with anti-TNF drugs (RR 1.6–25.1).[34] Infliximab is currently the most associated with serious infections,[25,31,37] although the 2011 Cochrane review[41] demonstrated that certolizumab was also associated with a high risk of serious infections. Infliximab confers twice the risk of TB reactivation compared to etanercept[34] and has been shown to cause a much faster presentation with a median interval from commencing treatment of only 12 weeks.[36,42] Non-tuberculous mycobacterial infection, most commonly *Mycobacterium avium*, has also been strongly associated with anti-TNF use.[43]

Rituximab results in a state of hypogammaglobulinaemia.[44] There does not appear to be a significant risk of opportunistic infection and no association has been shown relating to TB infection.[39,45,46] Some association has been made with rituximab and cytomegalovirus (CMV) and JC virus, leading to progressive multifocal leucoencephelopathy (PML).[47]

Tocilizumab, a monoclonal IL-6 antibody, has shown greater rates of bacterial, not opportunistic, infection during its use than rituximab or anti-TNF agents at 5.3 per 100 patient-years, though this may be related to comorbidities or previous DMARD history.[48] The effect of abatacept and anakinra on the incidence of infection remains unclear.[46]

Changing biological agents has appears to confer a greater rate of developing infections requiring hospitalization,[39] although patients switching regimens tend to have a larger number of comorbidities. Infections occur more often at the start of treatment and the risk of developing serious infection reduces with time.[35,43] Particular care should be taken around the time of therapy switches and commencement of new therapies, especially as the effects of infection may mimic the adverse effects of the drugs.

Diagnosis and treatment of infections

When managing patients with chronic multisystem disease, and especially while using immunomodulatory therapies, the clinician must be ever vigilant for early signs of infection. These individuals may not present with conventional symptoms and signs: inflammatory response will be suppressed; blood inflammatory markers and cerebrospinal fluid (CSF) white cell counts may be low or normal. A thorough knowledge of the travel, occupational, and medical history is essential to develop an accurate differential diagnosis.

When an acute infective process occurs on immunosuppressants, where possible these should be stopped immediately and recommenced after the infection is treated. Corticosteroids should of course not be stopped suddenly and may even need to be increased during serious infections to compensate for adrenal suppression despite infection risk.

Infection empiric guidelines for specific organisms and syndromes are outlined in Tables 107.1 and 107.2. However, where a patient is slow to respond, or has a rapidly evolving clinical picture, consultation with the local infection expert is recommended.

The infections that are common in the community and hospitals are even more frequent in this population. These common infections are outlined in this section and summarized in Table 107.2.

Pneumonia

The most common causes of lower respiratory tract infections in patients with rheumatological illness are similar in aetiology to the general population. Aspiration pneumonia is included in the differential for many rheumatological patients with altered dysmotility syndromes, which most commonly becomes secondarily infected with anaerobic and Gram-negative species. Opportunistic infection is uncommon but must be considered when managing these patients: the most frequent opportunistic pathogens are *Pneumocystic jirovecii*, cryptococci, mycobacteria, and CMV. These should be considered if there is a poor clinical response to antibacaterials.

Appropriate clinical specimens should be taken prior to commencing antimicrobial therapy including: sputum samples, urinary antigens (pneumococcal and legionella), and acute and convalescent serology. When present, pleural effusions should be aspirated and sent for microbiological culture. Where individuals do not improve with empiric anti-bacterial treatment, further diagnostic samples such as bronchoalveolar lavage (BAL) should be performed especially to determine the presence of a fungal or viral pathogens. Empirical antibiotics according to the appropriate local and national guidelines are appropriate relating to the severity of infections—commonly amoxicillin or co-amoxiclav.[49] If clinical evidence of severe pneumonia is present then the addition of atypical cover with a macrolide is recommended (e.g. clarithromycin).

Skin, soft tissue, bone and joint infection

Cellulitis is most commonly caused by *Staphylococcus aureus* or streptococci (group A, C, or G). Initial therapy should treat these organisms: flucloxacillin with or without penicillin. Recent healthcare interactions, preceding trauma, animal bites or scratches, and fresh or salt water exposure are important historical aspects to consider in determining whether additional empirical antimicrobial treatments are required for Gram-negative pathogens or multidrug-resistant organisms. Blood cultures and/or samples from tissue and pus can assist in the microbiological diagnosis.

Osteomyelitis can either occur from haematogenous spread or, more commonly, is due to contiguous lesions that are infected. This occur commonly in individuals with chronic peripheral ulceration. MRI is the recommended imaging modality as it has excellent sensitivity of 81–100% and reasonable specificity (67–96%), allowing changes to be seen as early as 3–7 days from onset of infection.[50,51] Nuclear imaging modalities such as the three-phase bone scan, although sensitive (73–100%) can be poorly specific and often ambiguous when other inflammatory causes are present (presenting as false-positive results) or when vascular supply is poor (false-negative results).

Meningitis

CSF findings for the common types of meningitis are outlined in Table 107.3. In the immunocompromised, *Listeria monocytogenes* is an important additional pathogen. Encapsulated organisms are important pathogens in those with splenic dysfunction.

Table 107.1 Common infection syndromes and their management

Infection type	Management
Vascular access device	Send blood cultures, line site swab
	Remove VAD if SIRS
	Send catheter tip for culture
	Start empiric antimicrobials (e.g. vancomycin and gentamicin)
Lower respiratory tract	Obtain sputum for culture
	Consider nasopharyngeal swab for respiratory viruses
	Consider acute and convalescent serology
	Start empirical therapy according to local guidelines (e.g. amoxicillin and clarithromycin)
	Further investigations if not improving at day 3–4
Skin and soft tissue	MRSA screen
	Isolate suspected streptococcal infection for initial 24 h of treatment
	Obtain tissue samples for culture if exposed ulcer/bone
	Aspirate joint prior to antibiotics
	Empiric treatment according to local guidelines Tailor treatment with culture results
	Consider radiograph of affected limb ±MRI scan for deep collections/osteomyelitis
Urinary tract	Send urine culture prior to therapy
	Review previous cultures if available to tailor treatment (especially where multidrug-resistant organisms may be present)
	Initial treatment according to local empirical guidelines
Infective endocarditis	Await blood culture results
	Echo—determine effect and suitability for emergency valve replacement
	Chase MRSA screen
Meningitis	CT scan and lumbar puncture pre-antibiotics if this can happen within 2–4 h
	Send CSF for bacteria, viral, fungal, and TB culture
	Indian ink/cryptococcal antigen
	Aciclovir only if evidence of encephalitis
Disseminated infections (e.g. TB, viruses, fungi, tropical)	Discussion with specialist infection unit

CSF, cerebrospinal fluid; MRSA, methicillin-resistant *S. aureus*; SIRS, systemic inflammatory response syndrome; TB, tuberculosis.

Table 107.2 Common infection aetiologies in immunocompetent and suppressed hosts

Gram stain	Grouping	Important species	Infections	Focused treatments
Gram-positive cocci	Staphylococci	*Staphylococcus aureus* (MRSA and MSSA)	Skin and soft tissue infections, bacteraemia, endocarditis, osteomyelitis and septic arthritis	MSSA: Flucloxacillin MRSA: Glycopeptide
		CNS, e.g. *S. epidermidis*, *S. lugdenensis*	Device-associated infections: CVC, prosthetic joints	
	Streptococci and related organisms	Haemolytic streptococci	Skin and soft tissue infections, bacteraemia, endocarditis, osteomyelitis and septic arthritis, pharyngitis ('strep throat')	Penicillin
		Pneumococci	Pneumonia, meningitis, sinusitis	Penicillin, 3rd-generation cephalosporin
		Enterococci	Urinary tract and abdominal/biliary sepsis	Amoxicillin or glycopeptide
Gram-positive bacilli	Anaerobic bacteria	*Clostridium* spp. (e.g. *C. tetani, C. difficile*) *Actinomyces israelii*	Tetanus, *C. difficile* associated diarrhoea/ pseudomembranous colitis Actinomycosis—GI, dental, respiratory	
	Other important	*Listeria monocytogenes*	Bacteraemia, meningitis	Amoxicillin
Gram-negative bacilli	Enterobacteriaciae	**GI commensals** *Escherichia coli, Klebsiella* spp., *Proteus* spp., *Enterobacter* spp., *Citrobacter* spp.		According to sensitivities Co-amoxiclav, Ciprofloxacin, Cephalosproins, Carbopenems
		GI pathogens *Salmonella typhi & paratyphi* Non-typhoidal salmonella	Gastrointestinal disease, bacteraemia, biliary tract disease and recurrent infection	3rd generation cephalosporins, quinolones
		Shigella spp., *Campylobacter* spp.	Acute gastorenterintis	Ciprofloxacin, clarithromycin
	Non-enterobacteriacaie	*Pseudomonas aeriginosa* And other environmental organisms less frequently *Acinetobacter* spp *Stenotophomonas* spp	Healthcare-associated pneumonia (including ventilator), cellulitis (esp. in those with ulcers or underlying immunosuppressive condition) Device-associated UTI and bacteraemia	
Gram-negative cocci		*Neisseria meningitis*	Bacteraemia, meninigitis	
Fungal	Candida spp	*Candida albicans*	Mucositis, vaginitis Bacteraemia, device related infection, endocarditis	Fluconazole
		Non-albicans species: *Candida glabrata, krusii* etc		Caspofungin, amphotericin

CNS, coagulase-negative staphylococci; CVC, central venous catheter; GI, gastrointestinal; MRSA, methicillin-resistant *S. aureus*, MSSA. methicillin-sensitive *S. aureus*; UTI, urinary tract infection.

Table 107.3 Common cerebrospinal fluid findings

	Protein (g/L)	CSF glucose: serum glucose ratio	White cells (per µL)	White cell differential	Appearance	Added tests to CSF
Normal	0.18–0.45	0.6	<5	Mononuclear	clear	–
Viral	Raised (usually <1)	normal	Raised (usually <1000)	Mononuclear	clear	Viral NAAT (liaise with virology lab)
Bacterial	Raised (usually >1)	Low (<0.6)	Raised (often >1000)	neutrophils	turbid	Gram stain and culture
Tuberculosis	Raised	Low	Raised	Lymphocytes	Turbid/clear	Acid-fast bacilli smear TB culture NAAT (liaise with microbiologist)
Listeria	Raised	Normal/low	Raised	lymphocytes	Turbid/clear	Gram stain Culture
Cryptococcus	Raised/normal	Normal/low	Normal/raised	monocytes	clear	Indian ink Cryptococcal antigen

CSF, cerebrospinal fluid; NAAT, nucleic acid amplification techniques; TB, tuberculosis.

Cell-mediated immunodeficiency, often iatrogenic in rheumatology patients, weakens the response to other organisms, such as nocardia, mycobacteria, and cryptococci—which, although rare, may cause central nervous system (CNS) infection.

Immunocompromised individuals may not be able to mount the usual response to infection and often the CSF white cell count is not raised. Therefore clinicians must be prudent when diagnosing meningitis but also when managing these cases as low CSF white cell count is a poor prognostic factor in bacterial meningitis.[52]

Other multiorgan infections

Non-typhoidal salmonella

Non-typhoidal salmonella—facultative anaerobic Gram-negative rods—belong to the *Enterobacteriaceae* group and are spread via the faeco-oral route in contaminated water or food. Salmonella is the most common cause of bacteraemia in lupus patients.[17] Approximately one-third of infected individuals die from overwhelming sepsis.[14] The organism can easily be grown from blood cultures and once bacteraemia is confirmed metastatic infection should be considered, especially determining whether there is intra-abdominal or bone and joint infection. Treatment of disseminated diseases is guided by antimicrobial susceptibility testing but is usually with a fluoroquinolone or third-generation cephalosporin.

Tuberculosis

In 2010, TB accounted for 1.1 million deaths (in non-HIV-infected individuals) and there were 8.8 million new cases of TB.[53] The bacilli replicate relatively slowly and eventually the host mounts a significant cell-mediated response which destroys cells and surrounding tissues. In untreated or uncontained infection the bacilli spread by eruption of the caseating granulomas in which they are held into the airways of surrounding parenchyma. Haematogenous spread allows for disseminated infection and can involve any organ. TNFα plays an important role in the control of tuberculous disease as macrophages form granulomas where the mycobacteria are contained. Diagnosis of active TB involves radiological and microbiological evidence.

The organism is microbiologically confirmed through specific stains (Ziehl–Nielsen and Auramine) and nucleic acid amplification tests (NAATs). IFNγ release assays and tuberculin skin tests are not useful in the diagnosis of active infection, as a negative result does not rule out the diagnosis.[54]

Treatment for pulmonary TB involves 6 months of antimicrobials and is longer in disseminated (miliary) disease and drug-resistant cases. Latent TB diagnosis and treatment is discussed in the 'Prevention of infection' section.

Non-tuberculous mycobacteria

Atypical or non-tuberculous mycobacteria (NTM) include over 50 species of environmental organisms that can be found in water and soil. In immunocompromised individuals these traditionally non-virulent organisms can cause largely cavitatory pulmonary infections in addition to skin and soft tissue infection, bone and joint infection, and lymphadenitis. Disseminated infection has been reported in individuals on anti-TNF agents.[43,54] Standard mycobacteriological cultures from tissue or pus will facilitate growth of organisms. Treatment and duration of treatment is dependent on the mycobacterium species, the site of infection, and other underlying conditions. Specialist input from infectious disease or respiratory physicians should be sought.

Nocardia

Nocardia, a Gram-positive bacillus, causes granulomatous pulmonary infections mainly in immunocompromised hosts.[55] It is abundant in soil and water and inhaled into the lungs where it can cause a variety of presentations including nodularity, cavitations, or lung abscess. Disseminated disease is more likely in immunodeficient individuals through haematogenous spread leading to granulomas and abscesses in multiple organs.[56] These are slow-growing organisms that can take 4–6 weeks to grow, in specialized media. Nocardia requires treatment over many months (4–12 months) that often includes co-trimoxazole (see Table 107.2). Antibiotic susceptibility varies according to species[57] and in cases of disseminated or severe infections more than one agent should be used according to susceptibility patterns.

Herpesviridae
Herpes simplex

The complete range of clinical syndromes associated with herpes simplex virus (HSV) types 1 and 2 may be seen in rheumatological patients. Antivirals—aciclovir or valaciclovir—are used to treat infection in immunocompromised patients with disseminated infections. With continued immunosuppression after infection or recurrent disabling attacks, secondary prophylactic antivirals may be considered for both HSV-1 and HSV-2.

Varicella zoster

Immunocompromised patients are more prone to reactivation of varicella zoster (VZV), severe disease with a prolonged recovery period, and complications including pneumonitis, hepatitis, encephalitis, and secondary bacterial infection over lesions.[58] Immunocompromised hosts should receive early antiviral treatment (aciclovir and valaciclovir) and intravenous treatment in disseminated disease. In continued states of immunosuppression after infection, secondary prophylaxis may be considered.

Cytomegalovirus

Higher rates of disseminated CMV disease have been reported with azathioprine, cyclophosphamide, and anti-TNF agents.[25] Antivirals such as ganciclovir, foscarnet, and cidofovir can be used to treat disease in immunocompromised patients. In continued states of immunosuppression after infection, secondary prophylactic antivirals may be considered.

Epstein–Barr virus

A close relationship appears to exist between SLE and Epstein–Barr virus (EBV) where disease activity of lupus has been followed by reactivation of EBV; studies suggest that a particular CD8 T-cell defect specific to EBV has been shown in lupus patients.[59] Chronic infection is rare but can cause an ongoing clinical picture of fever, lymphadenopathy, cytopenias, and hepatosplenomegaly; the patient has a persistently high-level viraemia which cannot be controlled into a latent state and can rarely lead to fulminant disease and death. Other complications include cancers such as Hodgkin's lymphoma, Burkitt's lymphoma, and nasopharyngeal carcinoma.

JC virus

JC virus is a dsDNA human polyomavirus mainly described in HIV-positive individuals causing PML. With the recent development of more immunosuppressive treatments for various conditions including autoimmune diseases, case reports have been published of non-HIV patients infected with JCV.[60–62] The virus commonly causes an infection within brain cells that forms white matter demyelinating plaques visible on MRI. Cognitive impairment ensues, with varying degrees of motor dysfunction and in some cases speech and language impairment, visual disturbances, and seizure activity. The disease is ultimately fatal. These cases are rare but clinicians should be aware and include this disease in the differential in the context of neurological changes in autoimmune disease. Virus can be detected in urine and CSF but confirmatory methods use brain tissue samples for histological examination and electron microscopy. In those with autoimmune disease a relationship between rituximab use and PML is documented; isolated cases have occurred in association with infliximab.[48,63] Unfortunately there are no curative therapies and management is largely symptomatic.

Hepatitis B virus

Hepatitis B virus (HBV) reactivation or flares in the disease have also been widely associated with rituximab use and is also documented with other immunosupressants.[64–66] Reactivation of chronic hepatitis B with anti-TNF agents is approximately 40%.[67] It is thought to be related to the profound circulating B-cell suppression which is essential in controlling the virus. Those who are HBsAg positive should be commenced on a nucleoside or nucleotide analogue antiviral prior to immunosuppression.[66–68] This is generally commenced at least 1 week prior to immunosuppressants and continued for 6–12 months from cessation.

Baseline serology should be done before commencing immunosuppressants in individuals with autoimmune disease. Those individuals with positive serology should be reviewed by a viral hepatitis specialist.[9,64,66,69] If a flare of HBV occurs during immunosuppressant therapy, immunosupressants should be stopped and prompt antiviral treatment should be commenced. Sudden flares in hepatitis and fulminant hepatitis have also been reported after stopping methotrexate.[70,71]

Fungal infections
Candida

Candida, a yeast, is often found in the environment and is a normal body commensal of the skin and genitourinary tract. Immunosuppression is a major risk factor for developing invasive candida infection as both the humoral and cell-mediated immune systems fight invasion of the organism.[72] Invasive disease most often occurs from an infected vascular access device (VAD)[72] and can cause bloodstream infection leading to endocarditis, osteomyelitis, and prosthetic joint infections. All cases of candida bloodstream infection should have a formal ophthalmological assessment to search for endophthalmitis and an echocardiogram for endocarditis. Uncontrolled disseminated disease can occur in heavy immunosuppression where multiple microabscesses can occur in multiple organs.

Candida can be cultured using standard microbiological techniques and culture media. A prolonged course of therapy is required and often involves amphotericin B or fluconazole if susceptible.

Aspergillus

Aspergillus, a mould, occurs in patients with chronic lung disease and those with immune deficiencies including active disease states and iatrogenic deficiency.[25,73,74] It may affect many organs, including eyes with keratitis, sinuses with chronic infection, and brain with ring-enhancing lesions found on CT scanning. The diagnosis is confirmed with classical radiological findings and serum galactomannan antigen, an antigen generated by the aspergillus. Parenteral amphotericin B, voriconazole, or caspofungin are the antifungals of choice (see Table 107.2). Some patients with a poor response to antifungals require surgical resection to debulk the disease.

Pneumocystis jiroveci

Pneumocystis jiroveci (formerly known as *Pneumocystis carinii*) has also been reported in those on immunosuppressive medication.[75] It is an environmental fungus that individuals encounter on multiple occasions but does not usually cause disease unless host defences are impaired. It is thought to spread via aerosolized particles and is most likely to result in lower respiratory tract infection

which presents with a dry cough and reduced exercise tolerance. The best diagnostic method is by BAL with cytological examination using silver staining and microscopy. First-line treatment is with high-dose co-trimoxazole although there are alternatives, such as clindamycin and primaquine if co-trimoxazole is not tolerated. Individuals with pneumocystis infection are at risk of spontaneous pneumothorax.[76] Empirical prophylaxis is not considered appropriate but may be considered after treated pneumocystis infection in those remaining on immunosuppressants.

Cryptococci

Cryptococcus neoformans is a ubiquitous, yeast-like organism that causes systemic infections in the immunocompromised host. It can be cultured from trees, soil, or fruit contaminated with bird droppings. It is thought to enter the system via aerosolized particles and eventual haematogenous spread to other organs, mainly the brain, but can cause disseminated and pulmonary disease.[77] Cryptococcal meningitis causes varying symptoms of raised intracranial pressure, although sometimes a persistent headache is the only manifestation. Serum and CSF cryptococcal antigen tests can assist in the diagnosis and serial tests are useful in determining a therapeutic response. Treatment usually involves amphotericin and flucytosine. Secondary prophylactic antifungals are recommended while individuals remain immunosuppressed.

Histoplasma

Histoplasmosis is a granulomatous infection caused by *Histoplasma capsulatum*, a dimorphic fungus, the mycelial form of which is found in soil and in bird or bat droppings. It is endemic in temperate climates such as the mid-west and south-east United States, Africa, Asia, and parts of Australia. Inhalation of particles is the usual method of entry. Severity of disease is dependent on comorbidities, immunodeficiency affecting T cells, increasing age and inoculum size. TNF and IFNγ play a vital role in the immune response to *H. capsulatum* and hence the use of immunosuppressants when individuals are living or visiting endemic regions at risk. It is important that laboratory staff are aware of the differential diagnosis, to ensure that specimens are appropriately examined in specialist conditions. Urine and serum antigen testing are also used. Treatment involves itraconazole or amphotericin B and length of treatment is dependent on the extent of infection.

Other unusual infections

Other unusual infections may occur such as cryptosporidiosis (causing a chronic diarrhoea and sclerosing cholangitis), strongyloides, leishmaniasis, toxoplasmosis, and endemic fungal diseases such as coccidiomycosis and blastomycosis. All of these syndromes require a detailed travel history and specialist diagnostic tests. Infectious disease consultation should be considered in those with travel history to endemic areas for these diseases, and is essential to the management of these conditions.

Prevention of infection

The prevention of infection is an intrinsic part of the ongoing care and management of individuals with autoimmune disease. This is particularly important before starting immunosuppressant treatment, especially with agents that modify particular parts of the immune system and increase the risk to certain infections.

Vascular access devices

Many rheumatology patients require a VAD, often centrally placed and in place for prolonged periods. These devices are associated with a higher risk of catheter-related bloodstream infections (CRBSIs).[78,79] Infection prevention measures using the National Institute for Health and Clinical Excellence (NICE) guidelines, *Saving lives* tools and Centers for Disease Control (CDC) guidelines can dramatically improve rates of CRBSIs and must be implemented for all patients with venous access.[78,80–82] This includes choosing the appropriate VAD, following aseptic protocols for placement and subsequent use, and prompt removal when alternative measures are available. A study by Pronovost et al.[78] implemented 5 steps in 103 intensive care unit patients (hand-washing, full barrier care during insertion, cleaning skin surfaces with chlorhexidine, avoiding femoral VAD, and removing unnecessary VAD) to prevent CRBSI and managed to reduce the overall median rate of infection from 2.7 at baseline to 0 at up to 18 months after. Local guidelines should be in place for VAD insertion and continuing care.

Vaccinations and immunization against infection

Vaccines attempt to provide immunity to a person by using altered organisms or their components to induce an immune response, which is reactivated when the organism is encountered. Live attenuated vaccines use laboratory-grown organisms with weakened virulence. Inactivated vaccines use grown components of an organism that are then 'killed' prior to use and do not induce as long-lasting a response as live vaccines, often requiring booster injections periodically. When using vaccines it is important to consider that the patient may not produce antibodies readily, especially where deficiencies or alterations in the standard cell-mediated response exist. Therefore some cases may require repeat vaccination and all cases require other measures to be taken to prevent infection.

Live vaccines are contraindicated in those who are pregnant or immunosuppressed—which according to United Kingdom, European, and American guidelines include those on DMARDs, biological agents, and high-dose steroids.[83–85] (The United Kingdom Department of Health 'Green Book' defines 'high-dose' steroids as ≥40 mg prednisolone daily use for more than 1 week compared to the CDC guidelines of prednisolone 20 mg or more daily for >14 days.) It is generally accepted that this state of immunosuppression remains for at least 1 month for corticosteroid use and 6 months for DMARD use.[83,84] Low-dose steroid, methotrexate (<0.4 mg/kg per week) and azathioprine (<3 mg/kg per day) may be safe for some live vaccines such as the herpes zoster vaccine.[84,86] Before starting immunosuppressants all patients should be considered for vaccination as appropriate and the course should be completed at least 2 weeks before the immunosuppressants commence.

Active immunization

The recommended vaccinations for patients with chronic disease and immunosuppression are outlined in Table 107.4. The important characteristics of some vaccines are considered here.

The 23-serotype polysaccharide pneumococcal vaccine (PPV) is an inactivated polysaccharide vaccine which covers 23 serotypes of pneumococcus, accounting for 88% of all pneumococcal infection.[86] It is recommended for use in asplenic or hyposplenic patients, those over 65 years of age, and patients with chronic

Table 107.4 Prevention of infection

Infection-associated risk	Method of prevention	Approach
Vascular access device	VAD insertion and care protocols Patient education	Staff education, competency assessment and audits of practice
Influenza	Vaccination Postexposure prophylaxis	Annual vaccine recommended
Pneumococcal disease	Vaccination	23 serotype PPV Vaccine every 5 years recommended
Hyposplenism	Vaccination	Meningococcal ACW135Y, HiB, Pneumococcal vaccine recommended
VZV	Screening and active vaccination Passive vaccination	Consider pre-immunosuppression active vaccine Postexposure VZIg
Hepatitis B	Screening and vaccination	If negative, consider vaccination prior to immunosuppression If positive, pre-treatment or early antiviral treatment; refer to specialist.
CMV	Screening and monitor	If previous symptomatic infection, monitor CMV viral load Consider prophylaxis if previous invasive infection
Fungal	No current recommendations	Consider prophylaxis if previous invasive infection
PCP	No current recommendations	Consider prophylaxis if previous infection
TB	Screening and treatment	IGRA prior to immunosuppressants Treatment if IGRA positive
Tropical diseases	Appropriate vaccination, prophylaxis and education	Refer to travel clinic prior to travel abroad

CMV, cytomegalovirus; IGRA, interferon-gamma releasing assay; PCP, pneumocystis pneumonia; TB, tuberculosis; VAD, vascular access device; VZV, varicella zoster virus.

disease. Individuals on immunosuppressant therapy (methotrexate and anti-TNF) have a reduced response to this vaccine with reduced antibody titres 1 month and 1 year after vaccination.[86,87] Concerns about disease flare after vaccination have also been raised but this has not been demonstrated.[88] It is recommended that this vaccine is administered every 5 years to those with autoimmune disease, with or without immunosuppressant therapy.

Influenza vaccines are inactivated vaccines that are required annually as the composition of these vaccines changes yearly, based on expert group consensus of circulating strains. The vaccine response may be reduced in these patients and some suggest considering repeat vaccination after 3 weeks.[83,89] There is a reduced response to the vaccine with rituximab use, azathioprine, and moderate to high-dose steroids (>10 mg prednisolone daily) but a reasonable response with anti-TNF use has been observed.[86] Household contacts and carers should also be vaccinated to ensure adequate protection, especially in those who show poor seroconversion.[83]

VZV vaccine is a live attenuated vaccine that has been contraindicated for use in patients who are immunosuppressed but may be given to those with autoimmune diseases prior to immunosupressants.[43,90] In those with autoimmune disease it has been shown to reduce infection risk by 51% and postherpetic neuralgia by 66% 3 years after vaccination.[53]

Passive immunization

Intravenous immunoglobulin delivers passive immunity against certain infections. Varicella zoster immunoglobulin (VZIg) should be considered in immunosuppressed patients who are exposed to cases of zoster infection—both chickenpox and shingles—from 48 hours prior to rash developing until crusting of vesicles. VZIg use does not preclude infection and therefore if these patients develop early signs of infection they should be given empirical antivirals. Immunoglobulin use alters the normal immune response to vaccine and therefore use of vaccines should be delayed until 3 months after immunoglobulin administration.[83]

Prophylactic antimicrobials

Medical prophylaxis is generally not recommended in those on immunosuppressive drugs for autoimmune disease unless the patient is asplenic or has a history of invasive infection. Where invasive bacterial, viral, or fungal disease has occurred, the case should be discussed with a microbiologist or infectious diseases physician to consider use of prophylactic antimicrobials, as previously discussed for individual infections. Routine prophylactic antibiotics to prevent infective endocarditis in patients with autoimmune disease and those undergoing immunosuppressive treatment are not recommended.[91,92] Certain individuals

should be given prophylaxis prior to certain procedures only (see Table 107.4).

Latent tuberculosis infection

Up to 10% of patients with latent TB infection (LTBI) develop reactivation of the disease. The use of immunomodulatory drugs in rheumatological or autoimmune diseases allow reactivation of LTBI to occur, through dysregulation of the granulomatous process.

According to published guidelines, prior to starting immuno-suppressive therapy including long-term glucocorticoid therapy (prednisolone >15 mg/day for >2–4 weeks), DMARDs, or bio-logical agents, individuals should be assessed for active and latent TB.[9,34,93–95] An accurate history of previous TB exposure, diagnosis, or treatment should be taken and a clinical examination done to look for signs of active TB, particularly lymphadenopathy. A chest radiograph should be taken to determine whether there are radio-logical appearances of active or old TB. If there are signs of active TB, referral to a TB specialist physician is recommended. If there is a confirmed diagnosis of active TB, treatment with anti-TNF agents should ideally be deferred until at least 2 months of appropriate TB therapy has been taken.[94]

For those with no TB history and no active TB on chest radio-graph, further tests should be performed.[42,94,96]

The current United Kingdom guidelines recommend the use of blood INFγ release assays and IGRA to diagnose LTBI in immu-nocompromised patients, as they are appear to be more sensitive in this population.[42,93,94,97] IGRAs are in-vitro blood tests using antigens that detect a T-cell response to TB antigens by releasing measured INFγ. Positive IGRA tests require prompt treatment for LTBI in those due to undergo immunosuppressive treatment if the risk of treatment (mainly hepatotoxicity) is less than the risk of reactivation. Those deemed at high risk of hepatotoxicity should be monitored 3–4 monthly and warned of TB symptoms. Standard LTBI therapy is 3 months of combination rifampicin and isoniazid or alternatively 6 months of isoniazid monotherapy.[93]

Vaccination against TB uses a live attenuated vaccine derived from *Mycobacterium bovis* that confers up to 70–80% protection depending on individual response.[83] It is generally not recom-mended over the age of 16 years and as it is a live vaccine is also contraindicated in individuals on immunosuppressive therapy.

Conclusion

Rheumatic and autoimmune disease creates a state of immune dys-function and dysregulation that must be taken into account when dealing with infections in these patients. Furthermore, the disease process can lead to end-organ damage that creates an environment for microorganisms to invade or proliferate. The therapies used to treat rheumatic and autoimmune disease target various points in this already altered immune system, making this set of patients more vulnerable to infective agents. Thus those patients diagnosed with these rheumatic diseases should be screened and vaccinated appro-priately for those common infections during their routine medical visits. Before commencing any immunosuppressant therapy they should be screened for underlying chronic infections such as TB. Clinicians must remain highly vigilant in identifying the early signs of infection, being aware of the likely standard and opportunistic infections that may occur.

Rheumatic fever

Andrew Steer

Introduction

Acute rheumatic fever is an autoimmune disease that follows infection with a bacterium, the beta-haemolytic Lancefield group A streptococcus (*Streptococcus pyogenes*). It affects multiple systems including the heart, the joints, the brain, and the skin. Only the effects on the heart can lead to permanent illness; the chronic changes to the valves of the heart are called rheumatic heart disease. Acute rheumatic fever can be primary (a first episode in a patient without a prior episode of rheumatic fever and without evidence of established rheumatic heart disease) or recurrent. Recurrent episodes of rheumatic fever lead to cumulative damage to the cardiac valvular tissues and worsening rheumatic heart disease.

Epidemiology

Acute rheumatic fever was common in industrialized nations including the United Kingdom in the 1800s and early 1900s until its frequency decreased over the course of the first half of the 20th century (Figure 108.1).[1] Much of the reduction in the rate of rheumatic fever occurred before the introduction of antibiotics and therefore this decrease was thought to be mostly due to improvements in living conditions and hygiene with an associated interruption in the transmission of group A streptococci.[1] Cases of rheumatic fever still occur in industrialized countries, however, and outbreaks of rheumatic fever have been reported as recently as the 1980s.[2–4] Overall the incidence of acute rheumatic fever in countries such as the United Kingdom is low (<1 per 100 000), and in the United States acute rheumatic fever is an uncommon hospital admission representing 14.8 cases per 100 000 paediatric hospital admissions.[5]

By contrast, high rates of acute rheumatic fever and rheumatic heart disease are found in developing countries and in populations of indigenous peoples living in industrialized countries.[6,7] There are over 330 000 new cases of acute rheumatic fever each year in children aged 5–14 years worldwide. The highest rates of acute rheumatic fever have been documented in Aboriginal children aged 5–14 in the Northern Territory of Australia (>500 cases per 100 000). More than 2.4 million children aged 5–14 years have rheumatic heart disease worldwide and 94% of these are in developing countries.[6]

Primary episodes of acute rheumatic fever occur mainly in children aged 5–15 years, and are rare in people aged over 30 years. Recurrent episodes remain relatively common in adolescents and young adults up until the age of around 35 years.[8] There is no clear gender predilection for acute rheumatic fever. Most epidemiologic surveys of rheumatic fever and rheumatic heart disease have observed an association with low socio-economic status, most probably related to levels of crowding.[9] There is no definitive evidence for a racial predisposition to rheumatic fever, but there appear to groups at particularly high risk, including Pacific Island populations and Aboriginal Australians.[5,9–11]

Between 3 and 6% of any population may be susceptible to acute rheumatic fever and this susceptibility appears to be inherited.[8,12] Familial clustering of cases of acute rheumatic fever have been found, and there is weak concordance in monozygotic twins.[13,14] Particular HLA class II alleles appear to be associated with rheumatic fever susceptibility including *HLA DRB1*0701* and *DQA1*0201* alleles and *DRB1*0701-DQA1*0201* and *DRB1*13-DQA1*0501-3-DQB1*0301* haplotypes.[15] The D8/17 antigen is expressed on B cells and may act as a binding site for the group A streptococcus on these cells,[16] and there is a strong association in a number of populations between the expression of D8/17 antigen and rheumatic fever

including in the United States, Australia, Israel, Russia, Mexico, and Chile,[17–19] although this association is not universal.[20,21]

Aetiopathogenesis

Acute rheumatic fever is the result of an interaction between a group A streptococcal strain with certain undefined features that confer an ability to cause acute rheumatic fever, and a host with an inherited susceptibility. This interaction leads to an autoimmune response directed against cardiac, synovial, subcutaneous, epidermal, and neuronal tissues. Traditional teaching states that rheumatic fever follows pharyngitis but not pyoderma, although this has been questioned.[22]

The exact nature of the pathogenesis of rheumatic fever is still to be determined, but it is believed that both cross-reactive antibodies and cross-reactive T cells play a role in the disease, and that molecular mimicry between group A streptococcal antigens and human host tissue is the basis of this cross-reactivity (Figure 108.2).[23] With a severe initial attack and with repeated attacks, rheumatic granulomatous inflammation manifests in the myocardium as Aschoff bodies leading to chronic rheumatic heart disease.[24]

Diagnostic criteria

The diagnosis of rheumatic fever is a clinical one. The Jones criteria were established in 1944 to aid clinicians in making the diagnosis of acute rheumatic fever.[25] These criteria divide the clinical features of rheumatic fever into major and minor manifestations. The criteria were modified in 1956,[26] revised in 1965,[27] revised again in 1984,[28] and updated in 1992.[29] The 1992 update is the most widely used

version today (Table 108.1), but the criteria are currently under revision again.

It should be noted that the Jones criteria are intended as guidelines only, designed to aid clinicians in the exercise of their clinical judgment, not replace it. The Jones criteria are often applied in a different manner in high-risk populations as recommended by some international and national health authorities, including the World Health Organization (Table 108.1).[8,30] It may be appropriate, therefore, to consider immigrants from rheumatic fever endemic developing countries as high risk, particularly if they are newly arrived.

Clinical features

The diagnosis of rheumatic fever can be complex and requires attention to all of the manifestations of acute rheumatic fever, while considering other, often more likely, diagnoses for each manifestation. Each clinical manifestation is considered below.

Major manifestations of acute rheumatic fever

Arthritis

Polyarthritis, along with fever, is one of the most common presenting symptoms of rheumatic fever. Joint involvement occurs in more than 75% of first attacks of rheumatic fever, and may be a major manifestation (polyarthritis) or a minor manifestation (polyarthralgia or aseptic monoarthritis). However, because of the broad differential diagnosis of arthritis, including viral and reactive arthropathies, septic arthritis, and systemic lupus erythematosus (SLE), it is the most challenging diagnostic feature of rheumatic fever. The classic history of joint involvement in acute rheumatic fever is one of asymmetrical, large joint (especially knees, ankles,
Fig. 108.2 A proposed model of the pathogenesis of acute rheumatic fever.

Table 108.1 The Jones criteria for the diagnosis of acute rheumatic fever[29]

Major manifestations	Carditis	
	Polyarthritis	
	Chorea	
	Erythema marginatum	
	Subcutaneous nodules	
Minor manifestations	Clinical:	Polyarthralgia or aseptic monoarthritis
		Fever
	Laboratory:	Elevated acute-phase reactants (CRP or ESR)
		Prolonged P-R interval on electrocardiogram
Evidence of antecedent group A streptococcal infection		Elevated or rising streptococcal antibody titres (ASOT, ASD B)
		Positive throat culture or rapid streptococcal antigen test
		Major/minor criteria
Initial episode of rheumatic fever		Two major, or
		One major and two minor manifestations
Recurrent rheumatic fever in a patient with known past rheumatic fever or established rheumatic heart disease		Two major, or
		One major and two minor manifestations

Notes: All of the above clinical manifestations assume that other more likely diagnoses have been excluded. There are a couple of important caveats to remember when applying the Jones criteria:
- In a patient in whom arthritis is considered as a major manifestation, arthralgia cannot be considered as a minor manifestation.
- In a patient in whom carditis is considered as a major manifestation, prolonged P-R interval cannot be considered as a minor manifestation.
- Chorea does not require evidence of a preceding group A streptococcal infection.

In populations at high risk of acute rheumatic fever and rheumatic heart disease (high-risk populations have been defined as a population where the incidence of rheumatic fever is >30 per 100 000 and/or the prevalence of rheumatic heart disease is >2 per 1000),[74] some authorities suggest modifications to the Jones criteria:
- Echocardiographic evidence of valvulitis without clinical findings (so-called subclinical carditis) may be considered as a major manifestation.[30]
- Monoarthritis or polyarthralgia may be considered as a major manifestation.[30]
- A recurrence in a patient with evidence of established rheumatic heart disease may be diagnosed by the presence of at least two minor manifestations plus evidence of a recent group A streptococcal infection provided that other diagnoses have been excluded.[8]

elbows and wrists), migratory (one joint becoming inflamed as another subsides), or additive (multiple joints becoming inflamed at different times without subsiding) polyarthritis. An important clinical pointer is that the arthritis of acute rheumatic fever is often exquisitely painful and is very responsive to non-steroidal anti-inflammatory drug (NSAID) medication; if joint symptoms do not respond within 2–3 days of treatment with NSAIDs, the diagnosis should be reconsidered.

A difficult clinical scenario can be the child presenting with fever and monoarthritis in a high-risk population.[31] The first diagnosis to be excluded is septic arthritis but this diagnosis is usually clear because the child appears unwell and the joint aspirate will show an elevated white cell count that is predominantly neutrophils with subsequent positive bacterial culture. However, a proportion of these cases may be rheumatic fever, particularly if there are there is clinical evidence of carditis and the joint fluid is predominantly lymphocytes and sterile.[32] In this scenario it is prudent to withhold NSAID treatment to observe for the development of polyarthritis, thereby aiding in clinical confirmation of the diagnosis of rheumatic fever.

Carditis

Rheumatic carditis refers to the active inflammation of the myocardium, endocardium, and pericardium that occurs in rheumatic fever. Carditis occurs in 50–80% of first episodes of rheumatic fever, predominantly as a valvulitis.[2,33,34] In many patients with rheumatic fever evidence of carditis can be found at presentation along with fever and arthritis, but in some patients signs of carditis appear after presentation, usually within the first 2–6 weeks, and repeated examination during admission is therefore important.[35]

Valvulitis most commonly affects the mitral valve leading to mitral regurgitation, followed by the aortic valve as aortic regurgitation. Isolated aortic valve disease without mitral valve involvement is uncommon. With a prolonged and severe first attack or with recurrent disease scarring may lead to stenotic lesions, predominantly mitral stenosis. Diagnosis of valvulitis can be made clinically but echocardiography has assumed a central role in diagnosis as well as assessment of severity (see 'Investigations' below).

Patients with severe valvulitis can develop cardiac failure, occurring in up to 10% of first attacks and then more commonly in recurrent episodes.[36,37] The clinical signs of cardiac failure should be augmented by chest radiograph (Figure 108.3) and echocardiography. Patients with carditis rarely present with chest pain, and in these patients pericarditis should be suspected. The main clinical finding of pericarditis is a friction rub. Pericarditis is rarely an isolated finding and the other more common clinical features of carditis (e.g. evidence of mitral regurgitation) should be carefully sought.

Fig. 108.3 Chest radiograph of biventricular failure secondary to rheumatic fever.[78] Steer AC, Kado J, Colquhoun S, Noonan S, Babitu T. Awareness of rheumatic heart disease. Lancet. 2006;367:2118.

Chorea

Sydenham's chorea, also known as St Vitus' dance, was first described in the 1600s.[38] Chorea can present alongside the other manifestations of rheumatic fever (where it occurs in approximately 10% of first episodes), and also as an isolated presentation without fever or other features of rheumatic fever when it is called 'pure chorea'.[39–41]

Chorea consists of purposeless, involuntary, uncoordinated, rapid movements of the body, especially involving the hands, feet, face, and tongue.[38] Chorea particularly affects adolescent females.[38] There history may initially be subtle, with the child becoming fidgety at school and home, with subsequent clumsiness noted before more florid, uncoordinated, and erratic movements appear. There is often an associated history of emotional lability and other personality changes.[42] An extremely useful point on history and examination is that chorea always disappears with sleep, and is made more pronounced by purposeful movements. The head is often involved with erratic movements of the face that resemble grimaces, grins, and frowns. Severe cases may put patients at risk of self-injury or impair their ability to feed themselves. Choreiform movements can affect the whole body, or just half the body (hemichorea). Recurrence of rheumatic chorea can occur, often associated with pregnancy or the oral contraceptive pill.[43]

The diagnosis of rheumatic chorea is a clinical one, but there are a number of useful clinical signs on examination. Examination of the tongue is important; the patient with chorea will be unable to maintain protrusion of the tongue, and the tongue itself can be involved, often described as a 'bag of worms'. When the patient is asked to grasps the examiner's hands, there is a rhythmic, uncontrollable squeezing, so-called 'milkmaid's grip' sign. When the patients hands are extended, there is flexion of the wrists and extension of the fingers, so-called 'spooning' sign. When the hands are held above the head, there is turning outwards of the arms and palms, so-called 'pronator' sign. The differential diagnosis of chorea includes SLE, drug intoxication, Wilson's disease, tic disorders, Huntington's chorea, and intracranial tumours.

Because pure chorea may occur up to 6 months after the inciting group A streptococcal infection, evidence of recent group A streptococcal infection may be absent and is not required for diagnosis.[44] Patients with chorea often have a mildly elevated erythrocyte sedimentation rate (ESR). All patients with chorea should have an echocardiogram because of the high likelihood of cardiac involvement.[45]

Erythema marginatum

Erythema marginatum is a distinctive clinical sign of rheumatic fever; however, it is an uncommon manifestation occurring in less than 5% of cases and is rarely found in the absence of carditis and/or arthritis. The rash is a non-pruritic, non-painful blanching evanescent pink rash with a rounded or serpiginous edge that is well-defined (Figure 108.4). Individual lesions begin as a macule and expand with central clearing. The lesions can vary greatly in size and appear mostly on the trunk and proximal limbs but never on the face. The lesions may appear and then disappear before the examiner's eyes, and have been described as 'smoke rings'.

Subcutaneous nodules

Subcutaneous nodules are an uncommon finding in rheumatic fever, occurring in less than 5% of cases. They are firm, mobile, and painless lumps, 0.5–2 cm in diameter; they may occur in crops and are found mainly over the extensor surfaces or bony protuberances particularly on the hands, feet, occiput, and back. They usually appear after the onset of acute rheumatic fever and last from days to 3 weeks. They are strongly associated with carditis.

Fig. 108.4 Erythema marginatum.

Minor manifestations of acute rheumatic fever

Minor manifestations are used to support the diagnosis of rheumatic fever when only a single major manifestation is present; the diagnosis of a first episode of rheumatic fever should not be made on the basis of minor manifestations alone.

Clinical findings

Fever is a common finding, occurring in nearly all cases at the onset of the illness. Most patients will have fever in excess of 39 °C, but fever in of 38 °C measured orally, rectally, or tympanically is considered significant.

   Arthralgia refers to pain in one or more joints without objective evidence of inflammation. In rheumatic fever arthralgia often has similar features to the polyarthritis described above; that is, it is migratory, asymmetric, and affects large joints.

Laboratory findings

There are two key laboratory findings that are considered minor manifestations of acute rheumatic fever: elevated acute-phase reactants (ESR and C-reactive protein (CRP)) and prolonged P-R interval on electrocardiogram (see 'Investigations').

Investigations

The diagnosis of rheumatic fever requires a series of investigations (Box 108.1).[30] Investigations are required for: (1) confirming/excluding the presence of carditis (chest radiograph and echocardiography); (2) determining the severity of carditis if present (chest radiograph and echocardiography); (3) determining the presence of minor manifestations (elevated acute-phase reactants, prolonged P-R interval on electrocardiogram); (4) establishing evidence of preceding group A streptococcal infection (throat swab, rapid group A streptococcal antigen test, streptococcal serology); and (5) exclusion of differential diagnoses.

Chest radiograph

A chest radiograph should be performed in all cases in whom carditis is suspected.[46] In patients with carditis the radiograph may demonstrate chamber enlargement and frank congestive cardiac failure secondary to valvulitis and valvular dysfunction (Figure 108.3).

Box 108.1 Minimum investigations for the diagnosis of acute rheumatic fever

- ◆ Erythrocyte sedimentation rate (ESR)
- ◆ C-reactive protein (CRP)
- ◆ Electrocardiogram (ECG)
- ◆ Chest radiograph if clinical or echocardiographic evidence of carditis
- ◆ Echocardiogram (consider repeating after 1 month if negative)
- ◆ Throat swab (preferably before giving antibiotics)—culture for group A streptococci and/or rapid antigen test for group A streptococci
- ◆ Anti-streptococcal serology (anti-streptolysin O and anti-DNase B titres, repeat 10–14 days later if first test not confirmatory)

Echocardiography

The 1992 update of the Jones criteria does not allow inclusion of echocardiography findings alone as a criterion for carditis. However, it is clear that echocardiography allows at least accurate confirmation of clinical findings and objective measurement of severity of valvular lesions.[34,47] With increasing experience it appears that echocardiographic evidence alone (so-called subclinical carditis) is sufficient to determine the presence of valvulitis, especially in high-risk populations.[48] Subclinical carditis occurs in approximately 15% of cases of acute rheumatic fever because the first episode of rheumatic carditis is often mild and echocardiographic findings may precede clinical evolution of a murmur.[35,49] Therefore, all patients with suspected acute rheumatic fever, whether they have clinical carditis or not, should have an echocardiogram.

   Echocardiography can be used to determine the presence of characteristic morphologic abnormalities of valvular and subvalvular tissue using two-dimensional imaging, as well as abnormalities of flow across the valve using Doppler imaging. Morphological changes include mitral valve thickening and restricted motion of the mitral valve leaflet that leads to the so-called rheumatic 'dog-leg deformity', and the most commonly observed Doppler finding is that of mitral regurgitation (Figure 108.5).[50] Echocardiography is also very important in determining the severity of valvulitis including assessment of left atrial and ventricular size and left ventricular function, and these findings inform clinical decision-making regarding management.

Electrocardiogram

Conduction abnormalities occur in up to 33% of first episodes of rheumatic fever.[2] Prolonged P-R interval is a non-specific finding, occurring in some healthy people. However, a prolonged P-R interval that resolves over the course of an episode of rheumatic fever is a useful diagnostic feature. Second-degree, and even complete heart block, are less common but can occur (Figure 108.6).[51]

Inflammatory markers

The most reliably elevated acute-phase reactants in rheumatic fever are the ESR ($\geq$30 mm/h) and the CRP ($\geq$30 mg/L). The peripheral

white cell count is less reliably elevated and is not included in the 1992 Jones criteria update.[29]

Supporting evidence of preceding streptococcal infection

Evidence of a preceding group A streptococcal infection should be sought in all cases of suspected rheumatic fever. Absence of a serologic response to streptococcal antigens and/or absence of microbiologic evidence of group A streptococcal pharyngitis makes the diagnosis of rheumatic fever highly unlikely, except in the case of pure chorea.

A throat swab for bacterial culture on blood agar and/or rapid antigen test should be taken, although less than 10% of throat swabs are positive for group A streptococcus,[52] reflecting the postinfectious nature of the disease—i.e. the group A streptococcus is eradicated before onset of the disease. As a result, streptococcal antibody titres are key in confirming the diagnosis of rheumatic fever. The most commonly used tests are the anti-streptolysin O (ASO) titre and the anti-deoxyribonuclease B (ADB) titre. It is generally recommended that paired titres be taken, i.e. an acute titre and a convalescent titre (usually taken 14–28 days after the initial titre). A positive result is defined as a rise in titre of twofold or more.[53] However, a titre greater than

Table 108.2 Recommended upper limits of normal for anti-streptolysin O and anti-DNase B titres[54,75,76]

Age group (years)	Upper limit of normal	
	ASO titre (IU/mL)	Anti-DNase B titre (IU/mL)
2–4	160	240
5–9	240	320–640
10–12	320	480–640
>12	400	200

the upper limit of normal at the initial testing is also considered positive (Table 108.2).[54]

Management

While treatment can shorten the acute inflammation of rheumatic fever, all of the various manifestations will resolve of their own accord, except for carditis. Carditis can lead to chronic rheumatic heart disease, but none of the treatments used in the acute phase of rheumatic fever can alter the course of progression to rheumatic heart disease.[55] However, good compliance with secondary prophylaxis over time can positively alter the progression of rheumatic heart disease. The aims of the management of acute rheumatic fever are summarized in Box 108.2.

Confirmation of the diagnosis of rheumatic fever

All patients with acute rheumatic fever should be admitted so that the diagnosis can be confirmed and so that the clinical features and severity of the attack can be assessed. Some patients in whom the diagnosis has already been confirmed and who have a mild attack may be able to be managed as an outpatient after an initial period of stabilization.

Management of arthritis and arthralgia

The first-line treatment is salicylate therapy, based on extensive experience with aspirin in acute rheumatic fever, although there

---

Box 108.2 Aims of the management of acute rheumatic fever

1 Confirm the diagnosis of acute rheumatic fever

2 Provide symptomatic treatment and to shorten the acute inflammatory phase, particularly for joint involvement which can be very painful

3 Determine the presence and severity of carditis, and manage cardiac failure if present

4 Manage chorea if present

5 Commence secondary prophylaxis in all patients

6 Monitoring in hospital

7 Provide education for the patient and the patient's family about rheumatic fever and rheumatic heart disease, and emphasize the importance of compliance to secondary prophylaxis

8 Ensure that follow-up is arranged

is increasing experience with NSAIDs such as ibuprofen and naproxren.[56–58] Naproxen has been used successfully including in one small randomized controlled trial,[59] and some experts recommend it because of its twice-daily dosing and more favourable side-effect profile. Aspirin can have a dramatic effect on the both arthritis and fever in patients with rheumatic fever, and if there is little or no response after 2–3 days of therapy then the diagnosis should be reconsidered. A particularly important group of patients are those with suspected acute rheumatic fever that have monoarthritis. These patients should be admitted and observed for the appearance of another affected joint and it may be necessary to withhold anti-inflammatory therapy and use paracetamol or codeine to manage the pain of arthritis until the diagnosis can be confirmed.

The duration of anti-inflammatory treatment is dictated by the clinical response and improvement in inflammatory markers (ESR, CRP). Many patients need anti-inflammatory therapy for only 1–2 weeks when there is a good clinical response with resolution of pain and when inflammatory markers normalize. In some patients joint symptoms may recur following cessation of treatment (so-called 'rebound phenomenon')—this does not indicate recurrence, and can be treated with another course of anti-inflammatory therapy.[60] Some patients who still have symptoms or elevated inflammatory markers at 2 weeks may require anti-inflammatory therapy for up to 6 weeks. A very small subset of patients (<5%) require 6 months or more of anti-inflammatory therapy.

Management of carditis

Most patients with mild or moderate carditis without cardiac failure do not require any specific therapy. In general, salicylates, NSAIDs, intravenous immunoglobulin (IVIG), and glucocorticoid therapy are not recommended in the treatment of carditis because their use has not been directly associated with a reduction in residual rheumatic heart disease.[55,61]

All patients with cardiac failure require an urgent echocardiogram and review by a cardiologist. Patients require bed rest with gradual ambulation as tolerated. Diuretic therapy results in improvement in most cases, and the addition of other therapy such as an angiotensin converting enzyme (ACE) inhibitor or digoxin should be undertaken in consultation with a cardiologist. Rarely, more severe cardiac failure is present and it is in this situation that some clinicians prescribe glucocorticoid therapy; anecdotal experience suggests that glucocorticoids can more rapidly improve severe cardiac failure.[61] Acute surgery is rarely attempted unless there is valve leaflet or chordal rupture with associated torrential and life-threatening regurgitation.

Management of chorea

Most patients with chorea do not require treatment as it is benign and self-limiting.[62] Reassurance and a quiet and calm environment often suffice. However, occasionally patients have chorea that is so severe that it may interrupt activities of daily living including eating, may become very distressing to family members, and may even place the patient at risk of serious injury. In these circumstances treatment with valproic acid or carbamazepine is appropriate. Valproic acid may be more effective than carbamazepine,[63] but carbamazepine is preferred as first line because of the potential for liver toxicity with valproic acid.[30] Haloperidol should be avoided, as should combinations of agents. Aspirin has no effect on rheumatic chorea. Anecdotal reports suggest that prednisolone can reduce

symptom severity and shorten the course of Sydenham's chorea, but randomized studies have found conflicting results.[64,65] A few small studies of IVIG have appeared to show a more rapid recovery from chorea, but IVIG should be reserved for treatment of cases that are refractory to first-line treatments.[49,65,66]

Antibiotic treatment and the commencement of secondary prophylaxis

The outcome of rheumatic valvular lesions is not directly affected by the administration of penicillin during an episode of acute rheumatic fever.[67] However, the administration of penicillin is recommended to ensure eradication of group A streptococci in the throat whether there has been a positive throat culture or not. The choice is either oral penicillin for 10 days or a single injection of benzathine penicillin G. Intravenous penicillin is not necessary. In general benzathine penicillin G is preferred as this also serves the purpose as the first dose of secondary prophylaxis. In patients with bona-fide allergy to penicillin, a macrolide such as erythromycin, clarithromycin, or azithromycin should be used. As penicillin is the first-line choice for secondary prophylaxis it is recommended that a patient with reported penicillin allergy be investigated carefully and it may be necessary to consult with an allergist.

Monitoring

Most patients with rheumatic fever can be discharged within 2 weeks of presentation, and anti-inflammatory treatment can be ceased within 6 weeks if not earlier. Progress should be monitored clinically, although inflammatory markers weekly for 4–6 weeks can be helpful, particularly in detecting a rebound episode. It is advisable to repeat the echocardiogram at 4–6 weeks whether carditis was detected or not. Patients with a severe episode complicated by cardiac failure require careful monitoring and frequent echocardiographic assessment.

Education

Education is a key component of the management of all patients with rheumatic fever because of the necessity of ongoing long-term preventive measures. The disease, and its implications, should be explained to the patient and family with the aid of printed educational materials. Patients should be aware that in the long term they are at risk of repeated episodes of acute rheumatic fever and of developing chronic rheumatic heart disease; 30–50% of all patients with rheumatic fever will develop rheumatic heart disease and this risk increases to more than 70% if the initial attack is severe or if there has been at least one recurrence.[68]. Therefore, secondary prophylaxis to prevent recurrent attacks is very important, particularly as 75% of recurrences occur within 2 years of the first attack and more than 90% occur within the first 5 years.[31]

Adequate follow-up and adherence to secondary prophylaxis

The management of a patient with rheumatic fever does not end at discharge because of the implications of the diagnosis for the development of rheumatic heart disease. The main priority of long-term management is to ensure adherence to secondary prophylaxis. Secondary prophylaxis involves regular administration of penicillin (usually intramuscular benzathine penicillin G) to patients with a history of acute rheumatic fever or with established rheumatic heart disease for many years. Intramuscular benzathine penicillin

Table 108.3 Duration of secondary prophylaxis following rheumatic fever

Category	Duration
Rheumatic fever without carditis	5 years or until age 21 years (whichever is longer)
Rheumatic fever with carditis that has resolved	10 years or until age 21 years (whichever is longer)
Rheumatic fever with carditis that has led to residual rheumatic heart disease	10 years or until age 40 years (whichever is longer); Sometimes lifelong if very severe disease

Adapted from the American Heart Association and the American Academy of Pediatrics.[72]

reduces streptococcal pharyngitis by 71–91% and reduces recurrent rheumatic fever by 87–96%.[69] Secondary prophylaxis can also reduce the severity of rheumatic heart disease, can reduce mortality from rheumatic heart disease and can lead to regression of mild rheumatic heart disease in 50–70% of patients who are fully adherent over a decade.[70,71]

Recommendations on the frequency of intramuscular injections and the duration of secondary prophylaxis varies between authorities.[8,30,72] Most patients can be started on 4-weekly injections and if there is a 'breakthrough' episode of rheumatic fever can be switched to a 3-weekly regimen.[73] The duration of secondary prophylaxis is determined by a number of factors including age, time since last episode of rheumatic fever, and severity of disease (Table 108.3).[8]

Conclusion

Rheumatic fever is a multisystem, autoimmune, inflammatory condition that follows infection with group A streptococci. Rheumatic fever is now uncommon in industrialized countries, but remains a major public health concern in many tropical developing countries. Patients typically present with fever and arthritis, but may also present with carditis, chorea, and/or characteristic skin and soft tissue findings. Of greatest long-term concern is the presence of carditis, manifesting as a valvulitis that can progress to chronic rheumatic valvular disease, a condition associated with considerable morbidity and premature mortality. The first priority in management is to make an accurate clinical diagnosis of rheumatic fever as there is a broad differential diagnosis for a number of the clinical features of rheumatic fever. Once the diagnosis is made, the aim of management is to treat the inflammation of rheumatic fever and to can adequately assess and manage any cardiac involvement. Secondary prophylaxis is the mainstay of long-term management and patients require antibiotic prophylaxis for at least 5 years and often much longer.

Rheumatoid arthritis

This page intentionally left blank

CHAPTER 109

Pathogenesis of rheumatoid arthritis

Ranjeny Thomas and Andrew P. Cope

Introduction

Rheumatoid arthritis (RA) is an autoimmune disease in which chronic inflammation predominates. Inflammation is systemic, targeting articular tissues, and predisposing to cardiovascular comorbidity and increased susceptibility to infectious pathogens, combining to reduce life expectancy by up to 10 years in severe cases. The clinically described syndrome we recognize as RA encompasses a spectrum of clinical entities underpinned by distinct genetic, molecular, and cellular signatures. Heterogeneity translates to variable and unpredictable outcomes, in spite of widely adopted treatment programmes focused on early, intensive therapy. Accordingly, defining these phenotypes in the laboratory has become a priority, with the long-term goal of stratification of disease subtypes, and adopting the most appropriate therapy at an individual patient level. Here, we describe genetic associations, immune and inflammatory responses, and the effector pathways characteristic of RA, and how this knowledge has advanced our understanding of disease pathogenesis.

The inflamed rheumatoid synovium

The rheumatoid synovium is a prototypic inflammatory effector site that has taught us much about autoimmune, inflammatory, and destructive mechanisms.[1] From these studies therapeutic targets have been elucidated and used successfully to suppress disease in clinical rheumatology practice. Synovial tissue from normal joints consists of a lining layer of macrophages and fibroblasts from one to three cells thick, associated with a loose, vascularized, connective tissue sublining layer. The lining layer of macrophages and fibroblasts in inflamed RA synovial tissue is hyperplastic, and the sublining is infiltrated by inflammatory cells. In inflammation, vascular endothelial cells are activated, and angiogenesis and high endothelial venule development are evident. Foci of activated dendritic cells (DC), T cells, and inflammatory macrophages are recruited adjacent to vessels. B cells infiltrate RA synovial tissue and, in a subset of patients, form distinct germinal centres associated with follicular DC. Although neutrophils are infrequent in the tissue, they are abundant in inflamed synovial fluid.

RA is driven by autoimmune processes involving antigen presentation by DC to autoreactive T cells and production of autoantibodies by autoreactive B cells. However, the pathological consequences of these processes on joints are not driven directly by T cells or autoantibodies themselves, but by inflammatory products of macrophage and synovial fibroblast effector cells,[2] and by the destructive consequences of proliferative, tissue-invasive pannus derived from 'transformed' synovial fibroblasts,[3] as well as the bone-destructive effects of osteoclasts derived from tissue monocyte precursors.[4] Therapeutic interventions targeting immuno-inflammatory pathways are highly effective. These include inhibition of T-cell costimulation by antigen-presenting cells (APC) through targeting of B7–CD28 interactions (CTLA4-Ig; known as abatacept), inhibition of B-cell function through depletion of B-cell subsets with anti-CD20 monoclonal antibody (rituximab), and inhibition of inflammatory cytokines through tumour necrosis factor (TNF), interleukin (IL)-6 or Janus kinase (JAK) inhibitors. This directly reflects the role of these pathways as critical (and, very likely, multifunctional) control points in disease progression.

Leucocyte migration in response to inflammatory conditions increases the cellularity of the synovial tissue. It is orchestrated by secretion of chemokines and the upregulation of adhesion molecules expressed by endothelial cells which in turn promote cell rolling, adhesion, and transmigration. Increased tissue cellularity provokes hypoxia, stimulating angiogenic and cellular stress pathways and resulting in tissue damage, manifest as necrosis and apoptosis.[1] Post-translational modifications of protein antigens, such as citrullination and carbamylation, occur under conditions of stress and damage. Such modified self-antigens may be presented to the immune system both by DC and other APC such as B cells locally and by migratory DC in joint-draining lymph nodes.

Cell populations recruited to RA synovium through inflamed endothelium are enriched for T and B lymphocytes, monocytes, conventional and plasmacytoid DC, and other innate immune cells such as NK and NKT cells, mast cells, and neutrophils.

T cells in the synovium express a memory phenotype characterized by CD45RO, and activation or differentiation markers such as CD40-ligand, LFA-1, NKG-2D, ICOS, CCR5, and CX3CR1. Synovial fluid and synovial tissue are enriched in terminally

differentiated or ageing CD45RO[neg] memory cells which have re-expressed CD45RA, and which are deficient in the expression of CD27 and CD28.[5] Although poorly proliferative, these T cells produce cytokines (including IFNγ, IL-6, TNF, and IL-10), may be cytotoxic, and may express low levels of T-cell receptor zeta (TCRζ, reducing the capacity for TCR-mediated signalling.[6] RA synovial T cells therefore resemble normal T cells activated by IL-2, IL-6, and TNF more closely than T cells activated through the TCR. These cytokine-activated bystander T cells may chronically stimulate effector responses through cell-to-cell interactions with synovial fibroblasts or macrophages.[7] CD4+IFNγ+IL-17+ T cells are also found in synovial fluid and tissue. as are FoxP3+ regulatory T cells. In RA peripheral blood (PB), enrichment of CD16+ inflammatory monocytes correlates with disease activity.[8]

Subtypes of RA synovium include highly inflammatory tissue containing ectopic lymphoid tissue and germinal centres, tissue containing granulomas, tissue infiltrated by scattered lymphocyte infiltrates, and fibrotic tissue lacking significant infiltrates. These subphenotypes are associated to some extent with clinical features, and with specific gene expression profiles. A gene expression-profiling study of RA synovial tissue demonstrated at least two distinct profiles. One was highly inflammatory, involving genes associated with immunoglobulins (Ig) and innate and adaptive immunity, including STAT-1 and IFNγ-mediated gene activation. Upon immunohistochemical staining, the tissues with this subphenotype contained germinal centres, and organized lymphoid tissue, with expression of CCL19 and CXCR4 and CXCR5. IL-7 was expressed by fibroblast-like synoviocytes, macrophages, and endothelial cells close to T cells, likely supporting ectopic lymphoid development and T-cell survival in the synovium. Patients with this synovial subphenotype on average had higher clinical disease activity.[9] In contrast, the less inflammatory synovial subphenotype showed greater expression of genes associated with tissue remodelling and repair, including members of the Wnt signalling pathway, and matrix metalloproteinase (MMP) activity.

The 'at-risk' subject

The European League Against Rheumatism (EULAR) Study Group for Risk Factors for RA has published guidelines focusing on the preclinical and very earliest clinically apparent stages of disease.[10] Specific phases of RA are proposed, and terminology suggested for describing each stage of disease (Figure 109.1). This provides a framework to define the temporal relationship between genetic, environmental, and immuno-inflammatory factors that confer risk for RA, and will underpin the development of risk stratification and prediction models in the future. Genetic and environmental risk factors are important components of risk stratification.

Genetic factors

Disease concordance rates for twins are 15–30% (monozygotic) and 5% (dizygotic), with heritability estimates of up to 60%.[11] The major histocompatibility complex (MHC), which is highly polymorphic, contributes about one-third of this genetic susceptibility. Specific HLA-DRB gene variants mapping to amino acids 70–74 of DRβ-chains are strongly associated with RA (Figure 109.2).[12] This region encodes a conserved amino acid sequence (the 'shared epitope' or SE) in the HLA-DR antigen-binding groove, common to multiple RA-associated DR alleles. Specific polymorphisms at amino acid positions 11, 71, and 74 of the DRβ chain associate with the highest risk for seropositive RA. Amino acids 71 and 74 form part of the positively charged fourth anchoring pocket (P4), which would preferentially bind non-polar amino acids, such as citrulline, but not arginine. Tightly bound modified peptide antigens are then available for presentation to the T-cell antigenic receptor. Accordingly, RA-specific anti-citrullinated protein autoantibodies (ACPA), which reflect autoimmunity towards a group of citrulline-modified autoantigens, are much more likely to occur in SE+ patients.[13]

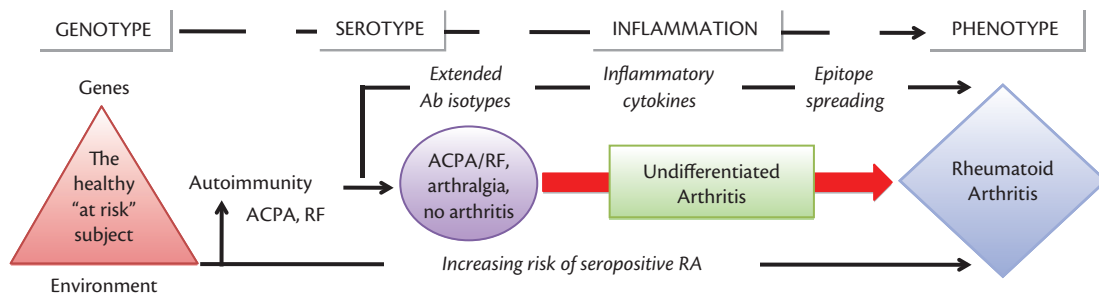
The majority of other susceptibility variants, identified through genome-wide association studies (GWAS), confer low to moderate risk with low penetrance (<50% increased risk per variant).[14] These include PADI4, CD28, CTLA4, CD2-CD58, PTPRC, and CD40 (molecular determinants of lymphocyte activation), CD3Z, PTPN22, PRKCQ, IL2-IL-21, IL2RA, IL2RB, RBPJ, PIP4K2C, and REL (transducer modules of TCR signalling and regulators of IL-2 gene expression and IL-2R signalling), STAT4, and TNFRSF14 (inducers of lineage-specific cytokine gene expression and persistence of memory T cells). Thus, genetic risk for ACPA+ RA is not only linked with genes modifying peptide antigen presentation, but also with variation in genes involved in T-cell activation, differentiation and effector function. Other genetic variants, such as AFF3, TRAF1-C5, TRAF6, TNFAIP3, CCL21, CCR6, IRF5, BLK, TAGAP, FCGR2A, PXK, SPRED2, PRDM1, and IL6ST may perturb cell


Fig. 109.1 The natural history of rheumatoid arthritis—from at-risk subject to expression of disease. An at-risk subject is likely to progress through multiple phases before disease onset. Inheritance of genetic variants associated with disease susceptibility and exposure over time to environmental factors (the 'exposome') initiates autoimmunity. This is manifest through detection of autoantibodies in serum which may be detectable for many years before the onset of symptoms (such as arthralgia). Autoantibody-positive arthralgia subjects may then progress to a phase of undifferentiated arthritis (clinically apparent swollen joints), before fulfilling disease classification criteria for rheumatoid arthritis. Not all at-risk subjects will pass through these phases in the same way; the timing and order of these stages may vary, and some subjects may reach multiple checkpoints over a short period of time.

A

HLA Susceptibility Association	Alleles	Amino Acids				
		70	71	72	73	74
Positive	0401, 0404, 0101, 0408, 0405, 1402, 1001, 09	U	B	B	N	N
Negative or neutral	1501	A	-	-	-	-
	1502	-	N	-	-	-
	03	-	-	-	U	B
	1410	A	A	-	-	-

	07	A	-	-	U	U

B

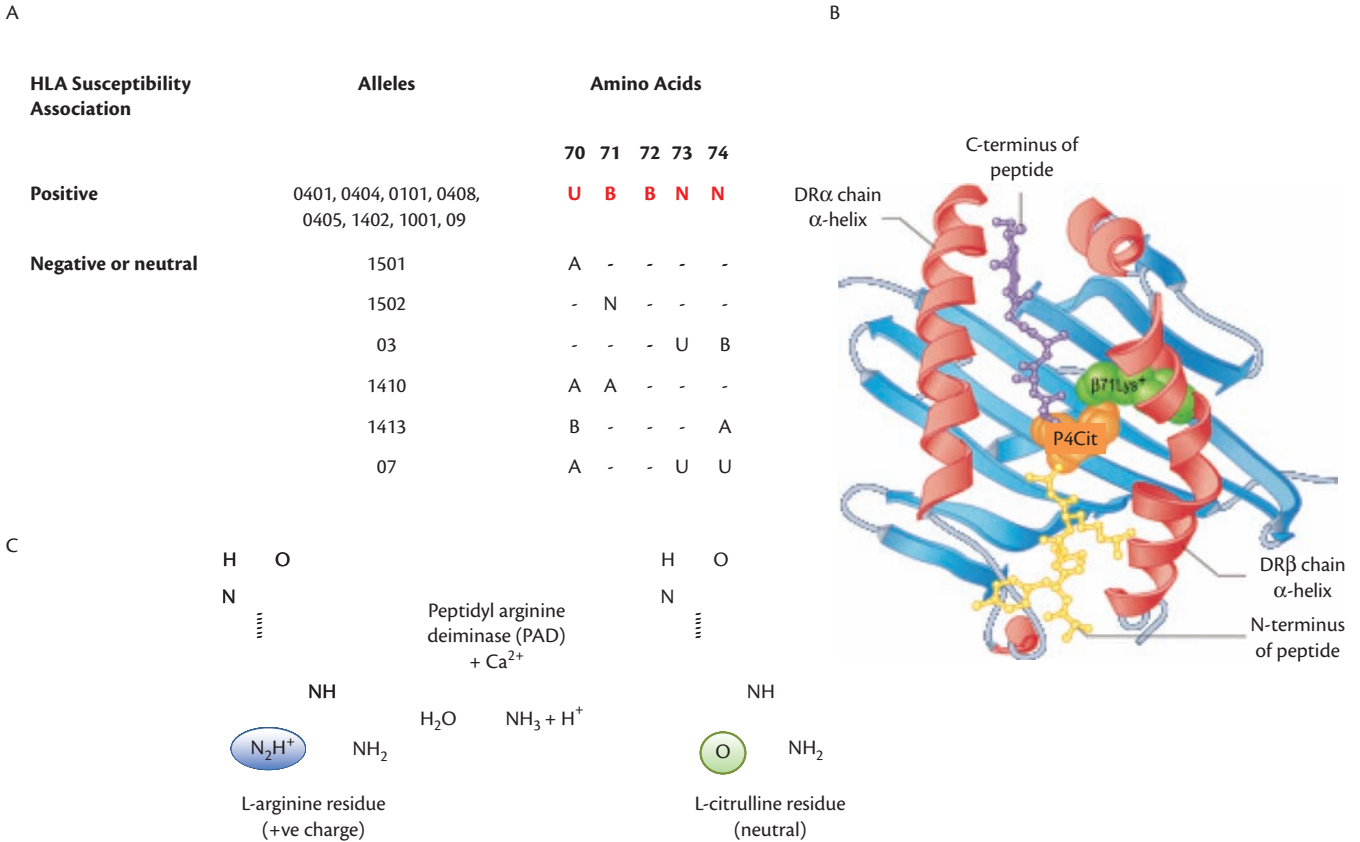
C


Fig. 109.2 Basis for the association between anti-citrullinated protein autoantibodies (ACPA) and HLA susceptibility in rheumatoid arthritis (RA). Specific *HLA-DR* gene variants mapping to amino acids 70–74 of DRβ-chains are strongly associated with RA. (A) This region encodes a conserved amino acid sequence (the 'shared epitope' or SE) in the HLA-DR antigen-binding groove, found in multiple RA-associated DR alleles. Polymorphisms at amino acid positions 11, 71, and 74 of the DRβ chain have highest risk for seropositive RA. A, negatively charged amino acid; B, positively charged amino acid; U, polar uncharged amino acid; N, hydrophobic amino acid. (B) Amino acids 71 (green) and 74 form part of the positively charged fourth anchoring pocket (P4), which preferentially binds non-polar amino acids, such as citrulline (orange), but not the positively charged amino acid arginine. (C) Citrullination occurs in antigen-presenting cells under stress and is associated with conversion of a positive to a neutral charge. Tightly bound modified peptide antigens are then available for presentation to the T-cell antigenic receptor. Thus, RA-specific ACPA, which reflect autoimmunity towards a group of citrulline-modified autoantigens, are much more likely to occur in SE+ patients.

differentiation and innate inflammatory pathways but their functional significance has yet to be determined.

Specific genotypes, including *DRB1*04*, cosegregate with distinct clinical features including ACPA[pos], erosive disease. Genetic associations for ACPA[neg] disease are distinct from ACPA[pos] disease, with major differences in the MHC region, including *HLA-DRB1*03*, as well as *IRF5* and mannose-binding lectin. However, certain *HLA-DRB1* alleles (*DRB1*0103, *0402, *1102, *1103, *1301, *1302,* and *1304*) confer lower disease risk, and reduced radiographic progression in RA even in the presence of one copy of a susceptibility *HLA-DRB1* allele, suggesting that specific subsets of MHC class II genes may confer an independent protective role.[15]

Environmental factors

Low concordance rates for twins with RA point to non-inherited disease risk factors.[16] The 'exposome' is proposed as the total environmental exposures of an individual over his or her lifetime, and is comparable in molecular complexity to the genome and proteome. It includes infectious and non-infectious agents which stimulate host cells or damage mucosal sites. Attention has focused on the gastrointestinal and respiratory tracts as principle

sites of exposure. Smoking contributes approximately 25% of the population-attributable risk of RA. Smoking interacts with all SE alleles to increase RA risk—particularly ACPA+ RA—although this ACPA-specificity is not observed in all populations.[17] Citrullination of proteins is more likely during cellular inflammation, stress, and autophagy. Whereas bronchoalveolar lavage (BAL) cells from healthy smokers contained citrullinated proteins, cells from non-smokers did not.[18] Such proteins are also found in inflamed RA joints. Thus stress-inducing environmental agents, such as smoking, obesity, and exposure to toxins such as silica and mineral oils, may promote expression of post-translationally modified neoantigens. On the other hand, factors such as red wine and statins, which reduce oxidative stress, and pregnancy, which promotes immune tolerance, reduce RA risk.[16]

The symbiont microbial communities that colonize mammals (the 'microbiota') constitute attractive environmental risk factors since they are acquired from around the time of birth and, although modified by diet or physiology, are remarkably stable. Preclinical mouse models have defined links between segmented filamentous bacterial species in small intestine, lamina propria, or large intestine and the rapid emergence of IL-17-expressing effector T cells

in the context of autoimmunity, including inflammatory arthritis.[19] A recent study in patients with RA has highlighted *Prevotella* species, a Gram-negative anaerobe of the *Bacteroides* genus, as being enriched in the gut of patients with early but not established RA.[20]

The similarities between RA and periodontal disease—inflamed tissue, bone erosion, associations with tobacco smoke, and MHC polymorphism—and the finding that *Porphyromonas gingivalis*, which is implicated in severe periodontitis, expresses its own functional deiminating ('citrullinating') enzyme, provide a second link between mucosal 'stress' and citrullinated antigens, which may trigger systemic autoimmunity in the genetically susceptible host.[21]

Initiation of the systemic autoimmune response in rheumatoid arthritis

Autoimmune disease is characterized by the development of chronic inflammation as a result of defective self-tolerance, leading to tissue damage, which eventually becomes severe enough to cause symptoms. A number of spontaneous animal models of autoimmune arthritis demonstrate genetic defects in thymic negative selection, thus permitting the entry of autoreactive T cells into the peripheral repertoire. In the periphery, subsequent genetic or environmental proinflammatory pressure on the innate immune control of antigen presentation may more readily trigger the activation of these T cells and, thus, the development of autoimmune disease.[22] As discussed, the priming of autoantigen-specific responses in patients with genetic predisposition to RA very likely follows an inflammatory or stressful trigger sensed by DC. Bone-marrow-derived professional APC specialize in antigen presentation to T cells. Although multiple subsets of DC with specialized functions have been described in different tissues, they can be simply classified as conventional myeloid-derived DC and plasmacytoid DC. Conventional DC in the resting or steady state are termed 'immature', and in this state they very efficiently take up and process antigen from their local environment.

In response to pathogen- or danger-associated molecular patterns (PAMPs and DAMPs), or to signals derived from T-cell crosstalk, DC undergo phenotypic and functional changes referred to as 'maturation', which influence their antigen-presenting function. Immature DC take up antigen, while receiving and recognizing environmental signals. Ligation of receptors, including Fc receptors, integrins, C-type lectins, Toll-like receptors (TLR), nucleotide-binding oligomerization domain (NOD) proteins, and RIG-I like receptors signal to DC during this process. As a result, maturing DC secrete cytokines, and express chemokine receptors including CCR7, enabling migration to the T-cell rich areas of lymph nodes. Mature DC also express high levels of MHC and T-cell costimulatory molecules, including CD80 and CD86, which enhance their capacity to present captured antigen to T cells in lymphoid organs.[23] DC express CD40 which, when engaged by CD40-ligand expressed by activated CD4+ T cells, promotes NFκB activation. This enhances MHC molecule expression and the production of IL-12p70 among other cytokines, and promotes DC survival.[24] Chemokines secreted by DC, such as CCL5, CCL3, and CXCL-10, recruit T cells, monocytes, NK cells, and other DC into the local environment, further amplifying the inflammatory response.

Autoantigen-specific T cells can be identified in RA patients and at-risk subjects using tetramers—fluorescent reagents that bind TCRs specific for particular HLA-DR–self-peptide complexes[25]—or

by stimulation of T cells with autoantigens in vitro. Synovial and PB DC have been shown to present RA self-antigens, including HC-gp39 and citrullinated peptides, to antigen-specific T cells. Synovial fluid DC stimulate autologous T cells in the absence of exogenous antigen much more effectively than PB DC, suggesting that their MHC molecules are loaded with relevant RA autoantigens.[26] In murine models of inflammatory arthritis, in which autoreactive T cells are enriched in the periphery, inflammatory (usually microbial, including microbiota) triggers of the innate immune system provoke priming of autoreactive T cells and the generation of antigen-specific autoreactive B cells, in association with follicular-helper T cells (Tfh). For example, subclinical pulmonary fungal infection promotes spontaneous Th17-dependent inflammatory arthritis in SKG mice, whose peripheral T-cell repertoire is enriched in autoreactive T cells.[22]

How do these models relate to pathogenesis of human RA? PB gene profiling studies in seropositive at-risk individuals with arthralgia have identified signatures significantly associated with imminent RA development. Overexpressed genes were involved in type I IFN-mediated immunity, haematopoiesis, and chemokine and cytokine-mediated immunity, including IFNγ and IL-7R. In contrast, B-cell-related genes were upregulated in patients who did not go on to develop arthritis.[27] DC are strongly activated by type I IFN, inducing IL-12 production and promoting antigen presentation to CD4+ and CD8+ T cells, and T-cell IFNγ production. IL-7 triggers low-affinity self-reactive T cells into homeostatic proliferation and conversion to memory cells, and promotes priming of efficient T-cell responses by DC.[28] Interestingly, transcriptomic profiling data parallel genetic associations in RA with the pathways of DC activation, NFκB activity, and T-cell activation and effector function predominating.[29] Taken together, the animal and human data suggest that low-affinity autoreactive T cells in at-risk subjects differentiate into effector cells, with the capacity for synovial migration and activation of other innate inflammatory cells, once a signalling threshold for DC activation and IL-7 secretion has been overcome. The development of chronic inflammation also implies that normal mechanisms of effector T-cell regulation are dampened or defective, in part a consequence of exposure to proinflammatory cytokines TNF and IL-1.[30]

A variety of self-antigens is implicated in the development and progression of RA, including joint-derived proteins, such as type II collagen and human cartilage derived glycoprotein HC gp39, and ubiquitous antigens, such as the endoplasmic reticulum stress protein BiP and other stress proteins. Post-translationally modified proteins, including citrullinated and carbamylated self-antigens, and glycosylated IgG Fc, are major RA autoantigens. Autoantigenic citrullinated self-proteins include vimentin, fibrinogen, type II collagen, and α-enolase. Not only do HLA-DR SE alleles provide a receptive peptide binding groove for citrullinated epitopes, but they also disturb T-cell homeostasis. CD4+ T cells in both SE+ RA patients and HLA-DR4+ healthy controls show features consistent with reduced thymic T-cell output to the peripheral repertoire, an increased proliferative drive for naive T cells towards self-antigens, increased immune senescence, and restricted diversity of the TCR repertoire.[31] In such a relatively lymphopenic setting, homeostatic proliferation—associated with IL-7—lowers the threshold for T-cell activation in response to antigen.

What happens in the synovium before and after the disease starts? Recent studies examined immune cell infiltration in synovial

biopsies taken from healthy controls, autoantibody (ACPA or RF) positive non-RA patients, and patients with undifferentiated arthritis. In some subjects, a diagnosis of RA was made within 2 years, and in others, arthritis remitted. Somewhat surprisingly, synovial tissues of autoantibody-positive non-RA subjects and healthy controls appeared similar. In contrast, synovial biopsies from patients with undifferentiated arthritis contained inflammatory cell infiltrates, and these were not significantly different from patients with early RA.[32] These studies suggest that systemic autoimmunity precedes clinical and histological evidence of inflammatory arthritis, and that specific events associated with inflammatory cell migration to synovial tissue associate with clinical onset.

There is evidence of ongoing immuno-inflammatory activity in PB prior to the clinical diagnosis of RA. For example, established RA is associated with an acute phase response, manifested by elevations of hepatic proteins including C-reactive protein (CRP), IL-6, and fibrinogen, and associated with procoagulant activity in the blood. These systemic manifestations provoke high-density cholesterol reductions, fatigue, raised erythrocyte sedimentation rate (ESR), and reduced insulin sensitivity. A study of preclinical sera stored prior to RA onset demonstrated that autoantibodies were associated with elevated cytokines in serum, including IL-1, IL-6, IL-12p70, and CRP, predicting development of seropositive RA (Figure 109.1).[33] Elevated expression of increasing numbers of cytokines were predictive of shorter duration to disease onset. Together these studies suggest that autoreactivity and systemic inflammation precede RA, but that the initiating inflammatory process might derive from tissue(s) other than the synovium, such as sites of microbial colonization.

The synovial stromal response

The synovial stroma—made up of fibroblast-like synoviocytes (FLS) and resident macrophages—expresses a wide range of pattern recognition receptors (PRR) that equip these cells to sense 'danger' in their environment, such as components of bacterial cell wall and viral nucleic acids, fibrinogen fragments, HMGB-1, hyaluronan, and other fragments derived from host tissues following damage or stress. Synovial tissue stromal cells, which are rather heterogeneous at the cellular level and expressing markers similar to bone marrow stroma, respond to such stimuli in a variety of ways. Firstly they undergo semi-autonomous hyperplasia, over time becoming anchorage-independent and expanding in situ as a result of reduced contact inhibition and active attenuation of apoptosis. Cell-to-cell adhesion is regulated by integrins and cadherins; the synovial lining of cadherin-11-deficient mice is hypoplastic, with impaired invasiveness and inflammatory responses.[34] Activated FLS are an abundant source of cytokines, chemoattractants, and enzymes that target the matrix of articular cartilage, such as MMPs and A disintegrin-like and metalloproteinase with thrombospondin (ADAMTS) 4 and 5, which have potent aggrecanase activity.[3] Epigenetic modifications, and microRNA expression profiles, may promote cytokine-independent activation of inflammatory and destructive pathways in FLS.[35] These characteristics equip FLS with invasive properties reminiscent of transformed cells, associated with reduced apoptosis, upregulated proto-oncogenes and defective tumour suppressor genes.[3] RANK ligand+ FLS also support the differentiation of osteoclasts from monocyte-derived precursors. This allows FLS to breach cortical bone and to enter the bone marrow, promoting inflammatory reactions such as osteitis (bone marrow oedema) early in the evolution of the disease.

Synovial stromal cells provide a niche that supports the survival of infiltrating leucocytes, through cell contact and the production of soluble factors such as type I interferons. FLS are also proangiogenic, in response to hypoxic conditions and endoplasmic reticulum stress in inflamed synovium, supporting the formation in some patients of tertiary lymphoid structures. Serial synovial biopsies from RA patients demonstrate dissolution of these lymphoid structures after B-cell depletion (anti-CD20)[36] and, in murine models of arthritis, enhanced lymphatic drainage and egress of resident leucocytes following TNF inhibition.[37]

Cellular mediators of the effector response in situ

Both Th1 cells secreting IFNγ, and Th17 cells secreting IL-17, are found in RA synovium. Th1 cells activate macrophages to produce proinflammatory cytokines, and induce immunoglobulin class switching by B cells, to complement-fixing antibodies. IFNγ also has important regulatory effects through induction of nitric oxide and indoleamine 2,3-dioxygenase (IDO). IL-17 stimulates FLS and osteoclastogenesis, and also provokes cartilage and extracellular matrix destruction in vitro, independent of TNF and IL-1. Synovial DC are involved in antigen presentation, local inflammation, joint destruction, and immune regulation. Their production of IL-12 and IL-23 maintains and promotes differentiation of Th1 and Th17 cells respectively. Differentiation of Th17 requires TGF-β, IL-6, and IL-1β and low signal strength T-cell activation associated with low levels of IL-2 or increased numbers of Treg—all features of RA synovium.[38] TGF-β has both proinflammatory and anti-inflammatory effects, including the promotion of regulatory T-cell differentiation and the maintenance of DC in an immature state. These DC tend to be located close to the synovial lining layer. FoxP3+ Treg cells suppress both effector T cells and innate immune cells, to regulate inflammation.[39] Treg cells are enriched in synovial fluid and tissue of patients with RA, juvenile inflammatory arthritis (JIA), and other inflammatory arthritic conditions, and in some studies also RA PB[39]. In JIA, Treg suppressor function is associated with reduced disease activity, and suppression appears more effective in the joint than in PB.[40] In RA PB, reduced in-vitro suppression of TNF and IFNγ production was demonstrated in active disease, and this improved with TNF inhibitors.[41] In murine models, inflammatory arthritis can be suppressed by induction of functional Treg cells, and more severe disease, or a more extended repertoire of joint involvement, is exacerbated by depletion of Treg or deficiency of Foxp3.[42,43]

Mature conventional, and plasmacytoid DC accumulate perivascularly in inflamed synovium, associated with T- and B-cell follicles.[44] They display evidence of in-vivo activation, with upregulation of MHC molecules, CD86 and RelB, and production of proinflammatory cytokines in response to stimulation with immune complexes or TLR agonists, HMGB-1, or heat shock proteins. Mature conventional DC are associated with synovial cells expressing CCL19 and CCL21.[44,45] CCL19 expression can trigger formation of tertiary lymphoid structures similar to those in RA synovial tissue. In RA synovium, such germinal centre-like structures support autoantibody production, since they express activation-induced

cytidine deaminase (AID) and are surrounded by ACPA-producing plasma cells.[46]

T follicular helper (FH) cells have not been studied in RA in any depth, but murine models demonstrate their importance in the induction of autoantibody-secreting B cells. These CD4+ cells differentiate upon T-cell activation and costimulation in draining lymph nodes; indeed, the higher the affinity of antigen activation, the more T cells are recruited into the Tfh lineage.[47] Tfh express ICOS and CXCR5, secrete large amounts of IL-21, and provide help to B cells for long-lived antibody responses. In a murine model of arthritis, the costimulation blocker abatacept suppressed the development of antigen-specific Tfh and thus B-cell autoreactivity in antigen-induced arthritis.[48] In another model, recipients of cotransferred Tfh and Th17 T-cell subsets developed autoantibodies and inflammatory arthritis.[49] Given that Th17 development is promoted by low-affinity antigen presentation, these data support the contention that optimal development of inflammatory arthritis may be promoted by a mix of T-cell responses to antigens presented by APC with both low and high affinity. These effector mechanisms may require multiple regulatory mechanisms, including Tregs and lytic NK cells.[49]

B cells also play multiple roles in RA—as antibody-producing cells, as APC, and as regulatory cells. B cells have been shown to be activated by immune complexes containing chromatin through the B-cell receptor and TLR9, to produce rheumatoid factor.[50] The pathogenic role of B cells is demonstrated by the lack of development of arthritic models in the absence of B cells, suppression of disease by anti-CD20 mAb, and transfer of disease using anti-collagen II or anti-GPI autoantibodies in mice. In RA patients, it is not clear whether the efficacy of anti-CD20 is due to depletion of pathogenic autoantibodies or the reduction of antigen-presenting B cells. Antibodies may activate Fc receptors expressed by monocytes, DC, neutrophils, mast cells, or platelets and, by activating the alternate pathway of complement, result in the proinflammatory effects of C5a. Nonetheless, B cells represent a large APC compartment, predominantly involved in perpetuation of antigen presentation, after priming by DC has occurred at disease initiation. The regulatory B-cell subset represents an attractive approach for immune modulation in RA. Regulatory B cells secrete IL-10 and this was shown to be induced after CD40 ligation in a murine model[51].

Macrophages and fibroblasts are critical mediators of inflammation and joint destruction in RA. They are the major producers of proinflammatory cytokines, including TNF, GM-CSF, IL-1β, IL-6, IL-10, and chemokines such as IL-8 and MCP-1, as well as MMPs. Blockade of TNF and IL-6 are highly effective therapies in RA. Monocytes and macrophages are APC, and monocytes can differentiate under inflammatory conditions into DC or osteoclasts. They engage in T- and NK-cell cross-talk to promote proinflammatory cytokine production. Monocytes also have beneficial roles in RA, including clearance of apoptotic bodies and immune complexes, secretion of regulatory molecules including tissue inhibitors of MMPs, and wound healing. The balance between inflammatory and healing activities of monocytes and macrophages depends on local stimuli, including TLR ligands, cytokines, and damage-associated molecules. Macrophages and FLS are highly enriched in RA synovial tissue, particularly at the cartilage–pannus junction.[3,52]

Pathways to cartilage destruction

Articular cartilage matrix is composed of a network of type II, IX, and XI collagens responsible for tensile strength.[53] The other major component is the large proteoglycan aggrecan providing compressive resistance; biglycan, decorin, fibromodulin, the matrilins, and cartilage oligomeric matrix protein (COMP) contribute to the extracellular matrix (Figure 109.3). Chondrocytes, whose proliferative capacity is limited, maintain a stable equilibrium between the synthesis and the degradation of these matrix components, with a half-life of more than 100 years for type II collagen and a half-life for aggrecan core protein up to 24 years.[53] They adapt to low oxygen tensions by upregulating hypoxia-inducible factor (HIF)-1α, which can stimulate the expression of glucose transporter proteins (GLUT) and angiogenic factors as well as genes associated with cartilage anabolism and chondrocyte differentiation, including Sox9 and type II collagen. In spite of this, the regenerative potential of cartilage is poor.

In RA, cartilage destruction arises as a consequence of several distinct but temporally and spatially related events. Cartilage integrity is lost early, through exposure to the inflammatory milieu. Synovial IL-1 and TNF (as well as adipokines alone or in synergy with other cytokines), induce nitric oxide (NO) production through inducible nitric oxide synthetase and prostaglandins such as PGE2, in both FLS and chondrocytes. IL-1 also induces the production of proteinases involved in cartilage destruction including MMP-1, MMP-3, MMP-8, and MMP-13. This, together with loss of protective factors such as lubricin, perturbs the protein-binding characteristics of articular cartilage and permits the attachment of FLS to cartilage matrix through syndecan-4 and integrin-dependent pathways. Human chondrocytes also express TLR-1, TLR-2, and TLR-4. Activation of TLR-2 by IL-1, TNF, peptidoglycans, or fibronectin fragments further increases production of MMPs, NO, PGE, and proangiogenic factors such as VEGF. Inflammation also reduces collagen II mRNA synthesis in cartilage. Anti-inflammatory cytokines such as IL-4, IL-10, and IL-13, as well as PPAR-α agonists, may exert anabolic effects, retarding cartilage damage, in part through stimulation of IL-1 receptor antagonist expression.

The MMPs collagenase (MMP-1, MMP-8, and MMP-13), gelatinase (MMP-2 and MMP-9), stromelysin (MMP-3), and membrane type I MMPs (MT1-MMP; MMP-14) target native collagens and proteoglycans, and are expressed by inflamed RA synovium.[54] Indeed, MMP-1 is produced largely by chondrocytes at the cartilage–pannus junction while MMP14 is expressed at the surface of FLS and is important for cartilage invasion. However, ADAMTS-4 and ADAMTS-5 are considered to be the dominant effectors of proteoglycan destruction.[55] Cathepsin K also degrades matrix through its capacity to hydrolyse collagen I and II at multiple sites within the triple helical region. Counter-regulatory networks are evident in articular cartilage and inflamed synovium, including TIMPs, induced by such cartilage protective factors as TGFβ. TIMP-3 is a particularly potent inhibitor of ADAMTS-4 and -5.[56]

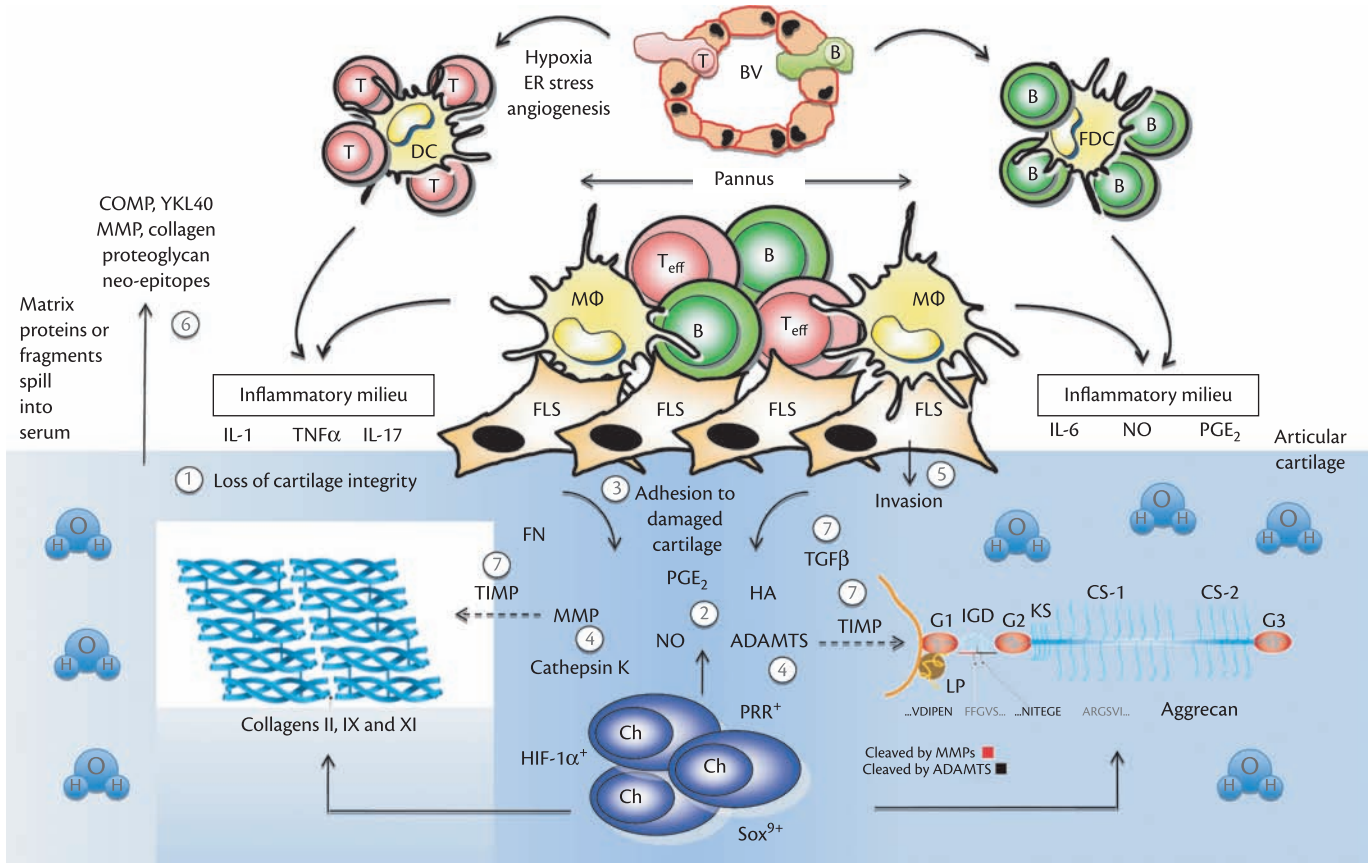
Cartilage degradation to cartilage matrix fragments can be used to monitor disease progression and to predict long-term outcomes; serum levels of COMP, YKL-40/HCgp-39, and MMP correlate with joint destruction. Monoclonal antibodies (mAb) recognizing specific N- or C-terminal sequences of the cleaved protein also detect cartilage degradation. The best-characterized are the C2C


Fig. 109.3 Pathways to destruction of articular cartilage. The major components of articular cartilage are triple helical collagen fibrils (II, IX, and XI), proteoglycans (aggrecan, biglycan, decorin, fibromodullin) and water (H-O-H). (1) An early event in cartilage destruction is loss of cartilage integrity following exposure of cartilage to the inflammatory milieu. (2) Synovial pannus and chondrocytes are a rich local source of inflammatory mediators. (3) Fibroblast-like synoviocytes (FLS) adhere to damaged cartilage. (4) Proteinases of the matrix metalloproteinase (MMP) and A disintegrin-like and metalloproteinase with thrombospondin (ADAMTS) family cleave matrix proteins (see cleavage sites in the IGD for MMP and ADAMTS), further destroying cartilage integrity, (5) promoting invasion of FLS and (6) releasing matrix proteins and their fragments into the synovial joint, spilling over into serum. (7) Counter-regulatory networks exist which serve to inhibit the catabolic process, including anti-inflammatory cytokines such as TGFβ and IL-10, and tissue inhibitors of metalloproteinases (TIMPS). B, B lymphocyte; Ch, chondrocytes; CS, chondroitin sulfate; FN, fibronectin fragments; HA, hyaluronan; IGD, interglobular domain on aggrecan KS, keratan sulfate glycosaminoglycan side chains; Mφ, macrophages; NO, nitric oxide; PRR, pattern recognition receptor; T, T lymphocytesulfsulf.

antibodies, which detect cleavage of triple helical collagen II, and a panel of mAb to neoepitopes of chondroitin and keratan sulfate as well as the specific aggrecanase (VIDIPEN) and MMP (NITEGE) cleaveage sites within the interglobular G1 domain of aggrecan.[56] Once refined and validated, these biomarkers could become valuable surrogates of cartilage destruction, especially when monitoring early responses to therapy. The radiographic outcomes of cartilage damage measure more advanced changes, including joint space narrowing and erosion of cartilage and bone.

Mechanisms of bone resorption

Bone destruction and joint deformity are closely associated with poor joint function. Periarticular bone erosion is initiated at mechanically vulnerable periosteal surfaces adjacent to articular cartilage, such as the second and third metacarpals and fifth metatarsal, and is thought to precede focal articular bone loss.[57] Histological analysis of these erosion-prone sites suggests that microdamage arises adjacent to collateral ligament insertions, especially on the radial side. The resulting 'bare area' is invaded by fibrovascular synovial tissue, evolving into inflammatory synovium in direct contact with bone at what is termed the cartilage–pannus junction. Synovitis exacerbates the damage, breaching cortical bone and allowing access of the synovial pannus into the bone marrow cavity. Lymphocyte aggregates gradually replace marrow fat. This manifests as bone marrow oedema, or osteitis, one of the earliest signs of joint inflammation using MRI (Figure 109.4).

During pathogenic bone erosion, physiological bone remodelling by osteoclasts (the bone-resorbing cell) and ostoblasts (the bone-forming cell) is uncoupled.[4] Osteoclasts are specialized multinucleate, calcitonin-receptor-expressing cells equipped with molecular and enzymatic machinery (cathepsin K and tartrate-resistant acid phosphatase) to attach to bone and cartilage matrix proteins and to digest mineralized tissues. The resulting resorption pits are replaced by inflamed synovial tissue, providing an abundant source of osteoclast precursors and additional proteinases, further exacerbating bone destruction. Osteoclast differentiation is regulated by M-CSF, which amplifies monocyte differentiation to osteoclasts, RANKL, and inflammatory cytokines including TNF which itself promotes M-CSF action, and IL-1, which decreases osteoclast apoptosis.[58]
Fig. 109.4 Pathways to the erosion of bone. Microdamage to cortical bone occurs at vulnerable sites. This allows adhesion and activation of osteoclasts, which carry the machinery to digest mineralized tissues, breaching the bone marrow cavity and allowing access to invading pannus. Osteoclasts are derived from monocyte precursors and require M-CSF, RANKL, and TNFα signals for differentiation. Osteoblasts are derived from mesenchymal stromal cells in which Runx2 and Wnt provide key lineage signals. Levels of RANKL and OPG determine osteoclast differentiation and activation status, while factors such as DKK-1 influence osteoblast differentiation by inhibiting Wnt signalling. DKK-1, Dickkopf-1; FLS, fibroblast-like synoviocytes; mRANKL/sRANKL, membrane/soluble RANK ligand; M-CSF, macrophage colony stimulating factor; MSC, mesenchymal stromal cell; OB, osteoblast; OC, osteoclast; OPG, osteoprotegerin; pOC, precursor osteoclast; RANK, receptor activator of NFκB;T, T cell; TRAP, tartrate-resistant acid phosphatase.

RANKL is normally produced by osteoblasts, and in RA synovium by FLS and activated T cells.

Bone-forming osteoblasts are derived from mesenchymal stromal cells.[4] Lineage differentiation is induced by the Wnt family of glycoproteins. As osteoblasts mature, they produce and mineralize bone matrix, at the same time downregulating expression of RANKL, and upregulating production of osteoproteregin (OPG), a soluble RANKL decoy receptor. In RA, serum RANKL/OPG levels may be a surrogate biomarker of osteoclast activity in vivo.

Proinflammatory cytokines in inflamed joints impair the capacity of osteoblasts to produce bone and to repair bone erosions through reduction of Runx2 (a transcription factor controlling osteoblast differentiation), alkaline phosphatase, and osteocalcin expression. They may induce RANKL and RANK expression, while reducing OPG, and uncouple Wnt signalling, to inhibit the differentiation of osteoblasts and chondroblasts. Agents which suppress osteoclast differentiation and activation, including TNF inhibitors, OPG:Fc, the anti-RANKL monoclonal antibody denosumab, IL-1Ra, or bisphosphonates, fail to adequately repair bone lesions. This demonstrates the impact of factors inhibiting bone formation, and why healing remains a relatively rare event, even in patients in clinical remission.

Persistence vs resolution of inflammation

The capacity to keep innate immune inflammatory responses in check despite exposure of mucosal surfaces to the universe of organisms is in large part due to innate regulatory and anti-inflammatory factors. The devastating pathology arising in mice and humans as a consequence of deficiencies of such elements attests to this.[59]

Pathways that promote immune and tissue homeostasis are overexpressed in inflamed RA joints, in spite of the ongoing inflammatory process. These include the anti-inflammatory cytokines IL-10 and TGFβ and specific cytokine inhibitors including soluble cytokine receptors such as sTNF-R, receptor antagonists like IL-1Ra, receptor 'sheddases' such as ADAM17 and TIMPs, which cleave receptors from the cell surface, and suppressors of cytokine signal transduction (e.g. A20/TNFAIP3—an intracellular inhibitor of NFκB signalling) and SOCS (a family of suppressors of cytokine signalling). Other factors limit the stability of inflammatory cytokine mRNAs (e.g. tristetraprolin), or shorten the activity of signalling intermediates (e.g. IκBα which inhibits NFκB and mitogen-activated protein kinase (MAPK) phosphatases, which inactivates MAPK and annexin 1, all of which are induced by corticosteroids). Indoleamine 2,3-dioxygenase (IDO), expressed by DC, suppresses effector functions by consuming the essential amino

acid tryptophan, producing kynurenine catabolites. Pro-resolving mediators derived from polyunsaturated fatty acids, such as resolvin E2, stimulates host protection throughout the innate inflammatory response, by reducing neutrophil chemotaxis, promoting phagocytosis and anti-inflammatory cytokine production, and downregulating integrin expression. Persistent disease activity implies that intrinsic regulatory or inhibitory mechanisms are insufficient to suppress chronic inflammation; supplementation of endogenous TNF inhibitors with pharmacological neutralization of TNF suggests that homeostasis can be restored.

Immune regulatory cells, besides Tregs, are also enriched in inflamed RA synovium. Mesenchymal stromal cells exert potent anti-proliferative and anti-inflammatory effects and contribute to the tissue repair response as precursors of osteoblasts and chondrocytes. These cells likely contribute to the tissue remodelling and repair signature that predominates in a subgroup of patients.

Conclusion

Research over the last decade has contributed to important advances in our understanding of the factors that put individuals at high risk of developing RA. Pathways of innate immunity and the cells contributing to the earliest events are now better appreciated. The distinctive features and aberrations of adaptive immune responses in RA patients are being uncovered, and many of the end-organ effector pathways that lead to cartilage destruction and bone erosion have now been identified. Major challenges for the future will be to apply targeted therapies that induce rapid and sustained remission without compromising host defence (e.g. through antigen-specific therapy), coupled to well-tolerated regimens for drug tapering and withdrawal. As insights into methods of risk stratification evolve, primary prevention will become the next major goal. This will best be realized through:

◆ an understanding of disease pathogenesis at a molecular and cellular level such that the full spectrum of disease subtypes is appreciated, and can be used more efficiently to predict outcomes and the best therapies for both individual patients and those at highest risk of developing disease

◆ insights into the inherited and acquired perturbations of immunity and inflammation and their impact on the disease over time

◆ detailed knowledge of the clinical and biological remission state (immunological tolerance) and how to measure it.

Rheumatoid arthritis—diagnosis

Daniel Aletaha and Helga Radner

Introduction

Rheumatoid arthritis (RA) affects approximately 1% of the adult population.[1] Currently RA is considered to be a chronic disease for which there is no cure, but remission, as a state where no active disease is present, has become an achievable goal with optimal treatment. At the same time, for the function and quality of life of patients with RA, it is crucial to recognize RA early and treat it effectively from the beginning. Both disability and the enormous costs of the disease are a function of disease activity over time. The ultimate goals are therefore to treat RA early and persistently until remission is present.

The challenge of treatment of early RA is not the lack of effective medicines, but rather ethical and economic considerations related to risk-benefit and cost-benefit. Overtreating patients with potentially self-limiting or non-destructive disease by using disease-modifying anti-rheumatic drugs (DMARDs) is still often feared. The flipside of the coin is the potential undertreatment of patients with true RA, which—particularly in its early phases—can have accelerated structural consequences. This damage cannot be reversed even by optimal delayed treatment.[2,3] At the same time, prolonged use of non-steroidal anti-inflammatory drugs (NSAIDs) in patients with undifferentiated arthritis also carries significant risk of adverse events.[4] In fact, some of the DMARDs could possibly be considered safer than some of the NSAIDs, particularly if the latter are employed over longer periods of time.[5,6] With these thoughts on the table one can draw a hypothetical risk (i.e. over-treatment or undertreatment)/benefit ratio for patients presenting with undifferentiated arthritis or arthritis that is not yet worked up. This leads to a necessary note regarding the terminology and semantics that are used: the term 'early' arthritis is used to indicate the duration of the symptom 'arthritis'; 'undifferentiated' on the other hand, although also early in terms of symptom duration, is used to indicate that no specific diagnosis has yet been made. This is a challenging concept, as the lack of a specific diagnosis is related to the amount of effort that has been put into the work-up. Usually some basic work-up is deemed to be present, if the term 'undifferentiated' is used, e.g. typical lupus arthritis could otherwise be called undifferentiated just because the doctor has not examined the patients and not noted the typical rash, the Raynaud's, and has not ordered the immunological tests that would have shown high antinuclear antibodies and complement activation. In theory, however, there might also be the case of chronic undifferentiated arthritis following the above logic.

Figure 110.1 depicts the scenarios of late, delayed, and early diagnosis of RA in regard to the respective risk/benefit of subsequent treatment or lack of treatment, respectively. Scenarios are split for two principal therapeutic options: immediate DMARD treatment in every patient with early arthritis, or DMARD treatment only upon an established diagnosis of RA. The sequence from panel A to panel C indicates that the risk/benefit ratio for either therapeutic approach improves with an earlier timing of the definite diagnosis. Patients diagnosed earlier (panels B and C of Figure 110.1) would benefit from an earlier 'correction' of the therapeutic approach (DMARDs or symptomatic) preventing overtreatment in patients without RA, and undertreatment in those with RA, and thus improving the overall risk/benefit ratio of the respective therapeutic strategy.

It can be deduced from the above that the question of whether RA should be treated before or only after establishing the definite diagnosis is secondary, but that the timing of the diagnosis in relation to the duration of symptoms is key in both approaches. DMARD institution before diagnosis may, however, be difficult for legal reasons in many countries or settings.

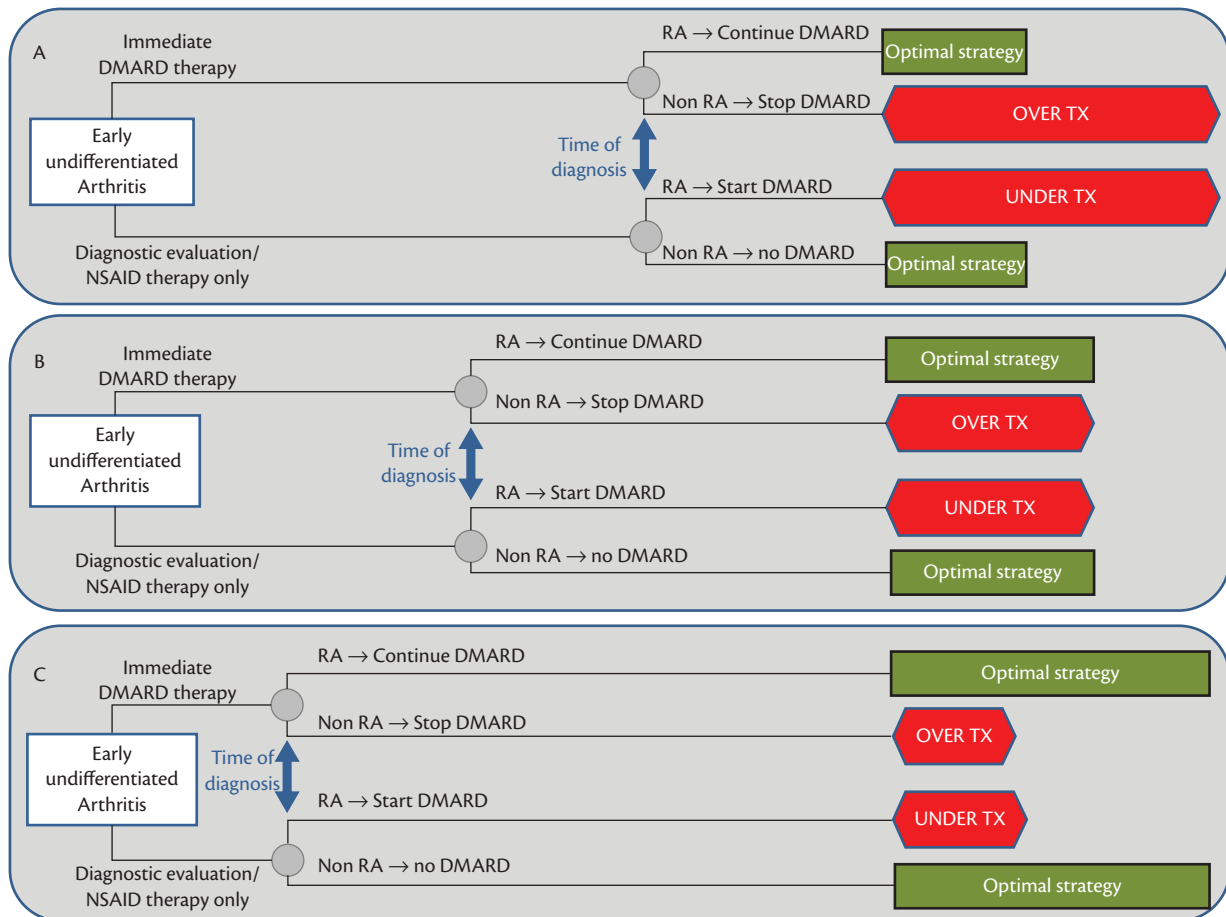
A few thoughts need to be considered in this context: first, the true risk of overtreatment with DMARDs in patients with undifferentiated arthritis is not yet completely clear, particularly when a diagnosis will be established within a reasonable time frame anyway; neither is the risk of prolonged symptomatic treatment, e.g. with NSAIDs, which may also be considerable. Second, early aggressive intervention in undifferentiated arthritis often leads to the challenging situation in which some patients with true RA may be prevented from eventually being diagnosed due to resolution of their symptoms, or, vice versa, some patients with self-limiting arthritis might be misdiagnosed as RA in clinical remission. Only withdrawal of therapy may reveal the underlying chronic condition, which is a diagnostic dilemma in clinical practice. Finally, in Figure 110.1 it is assumed that the diagnostic properties of criteria


Fig. 110.1 Consequences of delayed diagnosis. Three scenarios of risk/benefit are depicted for (A) late, (B) delayed, and (C) early diagnosis of definite rheumatoid arthritis (RA). Physicians face two principal therapeutic options: immediate disease-modifying anti-rheumatic drug (DMARD) treatment in every patient with early arthritis (top option in each panel), or DMARD treatment only upon an established diagnosis of RA (bottom option in each panel). The sequence from panel A to panel C indicates that the risk/benefit ratio for both options improves with an earlier timing of the definite diagnosis of RA.

will be similar at all stages of the disease, while in reality any diagnostic approach will likely be more accurate when more time has elapsed since the onset of symptoms.

All these considerations come into play when one aims to diagnose (and treat) RA early, but in fact currently no diagnostic criteria exist. In the following, we discuss the principal approach to patients presenting with arthritis, looking at the potential differential diagnoses of RA, as well as algorithms and criteria that may be helpful in eventually establishing an accurate diagnosis of RA.

Initial evaluation of patients presenting with new-onset arthritis

The terminology for patients with recent onset of their arthritis is often confusing. While 'early arthritis' may not mean more than a mere description of a temporal notion, many see a difference from 'undifferentiated arthritis'. The term 'undifferentiated' implies that some efforts have already been taken to determine the type of disease underlying the symptom 'arthritis'. This leads to the question of which steps reasonably need to be taken in order to be able to label early arthritis as 'undifferentiated'. For that purpose, an algorithm has recently been proposed to delineate the evaluative steps in the work-up of patients with new-onset inflammatory arthritis

(Figure 110.2), which can either lead to a specific diagnosis or to the classification as 'undifferentiated'.[7] This includes evaluation for a history of trauma, as well as evaluating the clinical presentation of the affected joint. The major initial distinction would be between acutely inflamed ('red hot') arthritis and other forms of arthritis. The former should arouse the suspicion of crystal-induced arthritis or septic arthritis, and although demographic and contextual factors may help to differentiate these two (e.g. age, gender, history, and lifestyle), arthrocentesis is necessary to make the specific diagnosis, as the therapeutic consequences are very different.

Synovial fluid analysis is of greatest use to distinguish between inflammatory and non-inflammatory arthropathy, usually affecting one or a few joints. Among the former are those types of inflammatory arthritis that need immediate care, particularly septic arthritis (see Chapter 98), in which the prognosis rapidly worsens with time to effective diagnosis and treatment. In fact, if the synovial fluid analysis is typical, then a confident diagnosis can be made already at this stage. This includes the presence of a high leucocyte count, positive Gram staining, or the presence of crystals (Figure 110.3). In clinical reality, the synovial fluid analysis will often enough not be diagnostic.

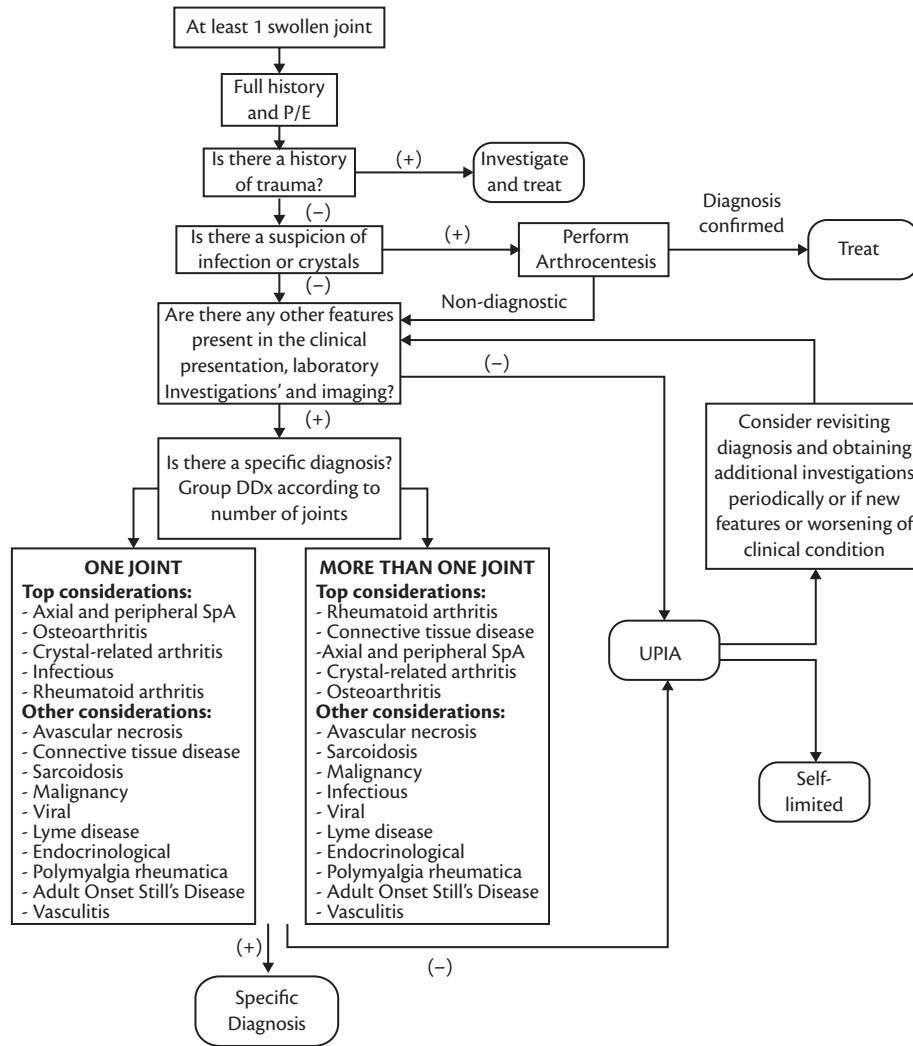
In general, after exclusion of crystal- or infection-related arthritis, a relatively large set of differential diagnoses is to be considered, which is different in patients with mono-, oligo-, and polyarthritis


Fig. 110.2 Flowchart to establishing a specific diagnosis (Dx) in new onset arthritis in at least a single swollen joint. The starting point is a full history and physical examination (P/E). After exclusion of trauma, and acute inflammatory events such as gout and septic arthritis, a specific diagnosis may be established in the presence of suggestive clinical, laboratory, or imaging features, where the differential diagnoses (DDx) differ according to the number of swollen joints involved. If no specific diagnosis can be established, the presentation may be labelled as 'undifferentiated arthritis' (in the algorithm shown as 'UPIA' for undifferentiated peripheral inflammatory arthritis). This status needs to be re-evaluated periodically, as undifferentiated arthritis may evolve into specific diagnosis over time.

(Figure 110.2).[7] The most important of these are discussed in the following section.

If no specific diagnosis can be established, the presentation can be labelled as undifferentiated arthritis. As the state of 'undifferentiated' in fact is a lack of definitive diagnosis, and hence is provisional, this state needs to be revisited periodically, for evolving diagnostic hints, although the presentation may turn out to be self-limiting disease (Figure 110.2).

Important differential diagnoses of rheumatoid arthritis

Viral polyarthritis

Several types of viral infections can mimic RA by leading to the typical polyarthritis of the small joints. This differs from RA in that viral polyarthritis can last from days to weeks, but is less frequently seen over the course of months, although some patients can develop a chronic arthropathy lasting for 6 months or longer.[8] A variety of viruses can lead to arthralgia, fewer even to arthritis, the most important among the latter being the hepatitis viruses (particularly hepatitis B and C virus, HBV and HCV), as well as parvovirus B19 and rubella.

Parvovirus B19 is the cause of erythema infectiosum (also called 'fifth disease'). It is typically a benign self-limiting disease of childhood that goes along with rash, fever, and commonly also arthritis. Less frequently, it may cause aplastic anaemia, which is a life-threatening disease. Joint involvement can impressively mimic RA by a symmetrical involvement of the small finger joints.

Patients with infectious origin of their polyarthritis may not be seronegative for rheumatoid factor, as many viral agents induce transient seropositivity.[8] Therefore determination of anti-cyclic citrullinated peptides (CCP) antibodies may be of more help in these circumstances, as they are less likely to be positive in diseases other than RA.[9,10] Virus-specific serological testing may be helpful to identify patients with recently acquired parvovirus infection, or to identify patients with HBV- or HCV-associated arthritis in the differential diagnosis. The treatment remains symptomatic—NSAIDs in most cases. If arthritis persists after clearance of the infection, then one might not speak of viral arthritis any more, but the viral infection may be considered the trigger of an autoimmune disease, such as RA, in which case DMARDs may be used. Both symptomatic (NSAIDs) and disease-modifying agents are often problematic in the context of viral hepatitis.

Peripheral spondylarthropathy

Several forms of spondylarthropathies (SpA) are known, many of which can cause peripheral arthritis. Recently, classification criteria for peripheral SpA have been put forward,[11] which imply arthritis, enthesitis, or dactylitis ('sausage digit') as an important feature. In combination with other typical SpA features diagnosis of SpA can be established as follows. If one of the three starting symptoms mentioned above is present, then one of the following characteristics is sufficient for a classification: psoriasis, uveitis, inflammatory bowel disease, preceding infection (indicative of reactive arthritis), positive HLA-B27, and evidence of sacroiliitis on MRI. If two of the starting symptoms are present, then a history of inflammatory bowel disease or family history of sacroiliitis is already sufficient. If all three of the symptoms are present, the patient is directly classifiable.

Over and above the classification of peripheral SpA, joint distribution of the different peripheral SpA may help in the diagnostic process, such as the fact that reactive arthritis typically affects the larger joints of the lower extremity in an asymmetric fashion.[12] Although psoriatic arthritis and RA can in most cases be well distinguished based on the criteria of the classification system, the fact that RA often is also seronegative, and that joint manifestations may precede the skin manifestations in psoriatic arthritis by years,[13] may complicate the diagnostic process: a diagnosis of psoriatic arthritis can be made in patients who also have psoriasis and who are seronegative for rheumatoid factor (RF) and antibodies directed to citrullinated peptides (ACPA); on the other hand, a diagnosis of RA may be established in psoriasis patients with a symmetric polyarthritis who are positive for rheumatoid factors or ACPA, since skin psoriasis is very common, and therefore can also simply be a comorbidity to RA. One may occasionally speak of an overlap between RA and psoriatic arthritis, if seropositive disease is present in a patient with psoriasis and radiographic changes are supportive for either diagnosis. In some patients with a symmetric inflammatory polyarthritis, the only clue to the diagnosis of psoriatic arthritis may be a family history of psoriasis.

Lyme arthritis

Lyme arthritis, a late manifestation of Lyme disease (see Chapter 101), occurs primarily in individuals who live in or travel to Lyme disease endemic areas. Lyme arthritis is characterized by intermittent or persistent inflammatory arthritis in a few large joints, especially the knee,[14] shoulder, ankle, elbow, temporomandibular joint, and wrist. Migratory arthralgias without frank arthritis may occur during early localized or early disseminated Lyme disease.

The diagnosis of Lyme arthritis may be supported by serologic testing for borrelia, which should only be done in patients presenting with undiagnosed inflammatory arthritis in endemic areas. In several respects, Lyme arthritis is different from RA as, for example, involvement of the small joints of the hands and feet is uncommon. Aside from serological testing, a positive history of erythema migrans or a tick bite may be suggestive of Lyme disease.

Sarcoid arthritis

Arthritis seen with sarcoidosis most commonly affects the ankles and knees, and less frequently, the wrist, metacarpophalangeal, and proximal interphalangeal joints. It may thus be a relevant differential diagnosis to RA in some cases. In contrast to RA, sarcoidosis can present with a variety of skin and ocular manifestations, such as erythema nodosum or uveitis, with bilateral hilar lymphadenopathy, and elevated serum concentrations of angiotensin converting enzyme (ACE). In some cases sarcoidosis presents with the typical triad of erythema nodosum, hilar lymphadenopathy, and bilateral ankle arthritis (Löfgren's syndrome). Treatment of mild forms of sarcoid arthritis includes NSAIDs whereas more severe cases, particularly those with pulmonary involvement, require the use of glucocorticoids. A high proportion of patient with sarcoidosis have non-progressive, spontaneous remitting disease: only a small proportion require immunosuppressive agents.

Other systemic rheumatic diseases

Early RA may be difficult to distinguish from the arthritis of systemic lupus erythematosus (SLE), Sjögren's syndrome, dermatomyositis, or overlap syndromes, such as mixed connective tissue disease. In

contrast with RA, these disorders are generally characterized by the presence of other systemic features such as rashes, Raynaud's syndrome, dry mouth or dry eyes, myalgia or myositis, renal or haematological abnormalities, and by various autoantibodies not seen in RA. Additionally, in connective tissue disease, particularly SLE, the values and responses of the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) may be less well correlated with each other than in RA. Whereas both are commonly raised in RA, the CRP is often normal or only minimally elevated in patients with active SLE even when the ESR is elevated.

Polymyalgia rheumatica

Polymyalgia rheumatica (PMR) and osteoarthritis (OA, see below) are common differential diagnoses of RA in the elderly population. PMR is an inflammatory rheumatic disease that is typically associated with marked myalgias of the shoulder girdle and the hips, and affects individuals over the age of 50.[15] It can sometimes be mistaken for RA if the presentation includes arthritis of the small joints of the hands.[16] PMR arthritis may be distinguished from RA by the fact that it tends to be milder, more limited, often asymmetric, with rapid response of symptoms to moderate doses of glucocorticoids, the often unduly high ESR, and the seronegativity for RF and ACPA. However, some cases ultimately diagnosed as RA may start with polymyalgia-like symptoms.[16]

Osteoarthritis of the hand

Osteoarthritis (OA) can be confused with RA in the middle-aged or older patient when the small joints of the hands are involved. However, arthritis in OA is different from RA with respect to the distribution of joint involvement, the clinical type of arthritis, and the structural and serological findings.

OA of the fingers typically affects the distal interphalangeal joints causing the so-called Heberden's nodes in this area, as well as the carpometacarpal joint of the thumb—both joint areas are not usually involved in RA, and in fact, are therefore explicitly excluded from the current classification criteria for RA (see further below). Joint swelling is hard and bony in OA, while it is soft in RA. Morning stiffness is typical in both OA and RA, but it is usually transient or lasts no more than a few minutes in OA, while it typically lasts more than 30–60 minutes in RA.

Structural investigations by conventional radiographs in OA are characterized by joint space narrowing that is asymmetric and accompanied by periarticular osteophytes, while the typical erosions of RA are not seen. OA is classically associated with the absence of RFs and ACPAs, and normal levels of acute-phase reactants. However, RFs may be present, usually in low titre, consistent with the generally old age of this patient population.

Critical diagnostic features of rheumatoid arthritis

Joint pattern

Arthritis in RA usually is a polyarthritis of insidious onset,[17] affecting primarily the proximal interphalangeal (PIP), metacarpophalangeal (MCP), and wrist joints, as well as the ankles and the metatarsophalangeal (MTP) joints. All other joints can also be affected by RA, with the exception of the distal interphalangeal (DIP) joints. A monoarthritic onset of RA is less common, affecting larger joints, and usually evolves to typical polyarthritis that includes the small joints over time. Occasionally, RA may start as palindromic rheumatism, characterized by episodes of joint inflammation affecting one to several joint areas for hours to days, with intermittent periods without symptoms that may last from days to months.[18] Palindromic rheumatism may also develop into other systemic disorders, such as SLE, or resolve over time. Particularly in elderly patients, RA may evolve from an initial polymyalgia-like presentation.[16] Typically, arthritis in RA is accompanied by morning stiffness of at least 30–60 minutes until maximum improvement.

Serology

RFs occur in 70–80% of patients with RA. Their diagnostic utility is limited by their relatively poor specificity since they are found in 5–10% of healthy individuals, 20–30% of those with SLE, virtually all patients with mixed cryoglobulinaemia (usually caused by hepatitis C virus infections), and many other inflammatory conditions. Higher titres of RF have greater specificity for RA.[19] The prevalence of RF positivity in healthy individuals rises with age. Antibodies to citrullinated peptides/proteins (ACPA) are usually measured by enzyme-linked immunosorbent assays (ELISA) using CCP as antigen. Anti-CCP antibodies have a similar sensitivity and specificity to (particularly high levels of) RF for RA, although some argue that they may be more specific,[9,10] which is still a matter of debate. The specificity is greater in patients with higher levels of anti-CCP antibodies.

Acute-phase reactants

Elevations of the ESR and/or CRP level are typically seen in inflammatory conditions such as RA. The degree of elevation of these acute-phase reactants correlates with the severity of inflammation and the structural damage that will occur over time.[20] Although increased levels of acute-phase reactants are not specific for RA, they are often useful for distinguishing inflammatory from non-inflammatory musculoskeletal conditions, such as OA. Therefore elevation of acute-phase reactants was also included in the 2010 classification criteria (see below). On the other hand, occasionally normal acute-phase reactants may also occur in untreated patients with RA.

The 2010 classification criteria for rheumatoid arthritis

The major problem for most inflammatory rheumatic diseases is that there are no diagnostic criteria. All criteria available are classification criteria, and the major difference here is that classification criteria are developed to minimize errors at the group level (e.g. for the purpose of including most homogeneous patient populations in clinical trials of a given disease), while they inherently accept the possibility of misclassification in the individual. On the other hand, the goal of diagnostic criteria is to be correct in the individual most of the time, as often the diagnosis is linked with more or less harmful therapies, as also discussed at the beginning of this chapter. The value of a diagnostic test also depends on the a priori suspicion of disease ('pretest probability'). From this, it becomes clear why diagnostic criteria are scarce.

Until 2010, the classification criteria for RA in use were those by the American College of Rheumatology (ACR) dating from 1987.[21] These criteria have been increasingly debated in the recent past, because of their lack of sensitivity in early disease, given that they were derived using mostly patients with long-standing, established RA.[22] The best example is the inclusion of erosions in these criteria

as a feature for diagnosis, which over time contradicted clinical practice, which emphasized the importance of preventing structural damage instead of waiting for irreversible stigmata of RA to occur. Before the introduction of the new criteria, many rheumatologists indicated that their treatment decision was independent of fulfilment of the ACR 1987 classification criteria.[23] Rheumatoid nodules are likewise rarely seen in early disease, and therefore even more weight is put on the remaining six variables, including erosions. In addition, new diagnostic tools, such as testing for ACPA, have emerged in recent years which tends to be at least as sensitive and specific as RF for diagnosis of RA.[10]

A joint working group of the ACR and the European League Against Rheumatism (EULAR) aimed to develop new classification criteria for RA that would replace the 1987 criteria. The work was performed between 2007 and 2010 and included a three-step approach including a data analysis phase using early arthritis cohorts, a consensus science phase, and a refinement phase. These final criteria and the detailed methodology were published in the two journals associated with the ACR and EULAR.[24–27]

As shown in Table 110.1, the 2010 criteria are made up of four domains, including the number and type of the affected joints, serology (RF and ACPA), acute-phase reactants (CRP and ESR), and the duration of symptoms. For evaluation of a patient's classification, the highest category within each domain is taken, and the four scores are added together. The maximum possible score is 10, and a score of 6 or more indicates the presence of definitely classifiable RA. The details of how the various categories and domains are defined are given in the footnotes to Table 110.1. Another way to classify RA, based on the same rules, is by the tree algorithm depicted in Figure 110.4.

Inherent to classification criteria is the fact that they do not work in all individuals who can theoretically be tested. It is very important to understand the target population of the new classification criteria, that is, who they were developed to be applied to. As can be seen in the top part of Table 110.1, the target population for the criteria is well defined: the 2010 criteria may be applied to any patient who presents with at least one clinically swollen joint, for which another disease is not the most likely cause. These limitations were introduced to increase the specificity of the new criteria, and to prevent patients with e.g. gout or obvious SLE being tested with the criteria.

With imaging techniques such as MRI or ultrasonography rapidly developing, it is frequently discussed how these methods can be integrated into the new classification criteria . In this regard, it is important to make two distinctions: for the definition of the target population it is essential to have at least one clinically swollen joint. At this stage, the presence of imaging synovitis without clinical synovitis does not render a patient eligible for application of the criteria. In contrast, once clinical synovitis is confirmed, any imaging method may be used to further explore the extent of arthritis, which may increase the points achieved in the 'joint distribution' category.

The other important issue in imaging is the question about the relevance of erosions, and when to perform standard radiographic investigations. In this respect, a major objective of the new criteria was to not to bias against the diagnosis of RA in individuals who are not yet erosive. Structural joint damage is now a major (bad) outcome of RA but not a feature required for classification. Therefore, the scoring system does not give any weight to erosions,

Table 110.1 2010 ACR/EULAR classification criteria for rheumatoid arthritis

Target population (Who should be tested?)

(1) Patient with *at least one joint* with definite clinical synovitis (swelling)

Exception: patients with erosive disease typical for RA, or those with a history compatible with prior fulfilment of the 2010 criteria, or those who have previously fulfilled the 2010 criteria, should be directly classified as RA. A detailed algorithm for the use of radiographic evidence of erosions is presented in Figure 110.6.

(2) Synovitis is *not better explained* by another disease

In case of any doubt or uncertainty about the presence of an alternative diagnosis, the requirement of this rule is fulfilled.

Classification criteria for RA (Score-based algorithm: add score of categories A–D)

A score of **≥6/10** is needed for a definite classification of a patient with RA. Although patients with a score <6/10 are not classifiable as RA, their status can be reassessed and the criteria might be fulfilled cumulatively over time.

(A) Joint involvement[a]	
1 large[b] joint	0
2–10 large joints	1
1–3 small[c] joints (with or without involvement of large joints)	2
4–10 small joints (with or without involvement of large joints)	3
>10 joints[d] (at least one small joint)	5
(B) Serology[e] **(at least one test result is needed for classification)**	
Negative RF *AND* negative ACPA	0
Low positive RF *OR* low positive ACPA	2
High positive RF *OR* high positive ACPA	3
(C) Acute-phase reactants[f] **(at least one test result is needed for classification)**	
Normal CRP *AND* normal ESR	0
Abnormal CRP *OR* abnormal ESR	1
(D) Duration of symptoms[g]	
<6 weeks	0
≥6 weeks	1

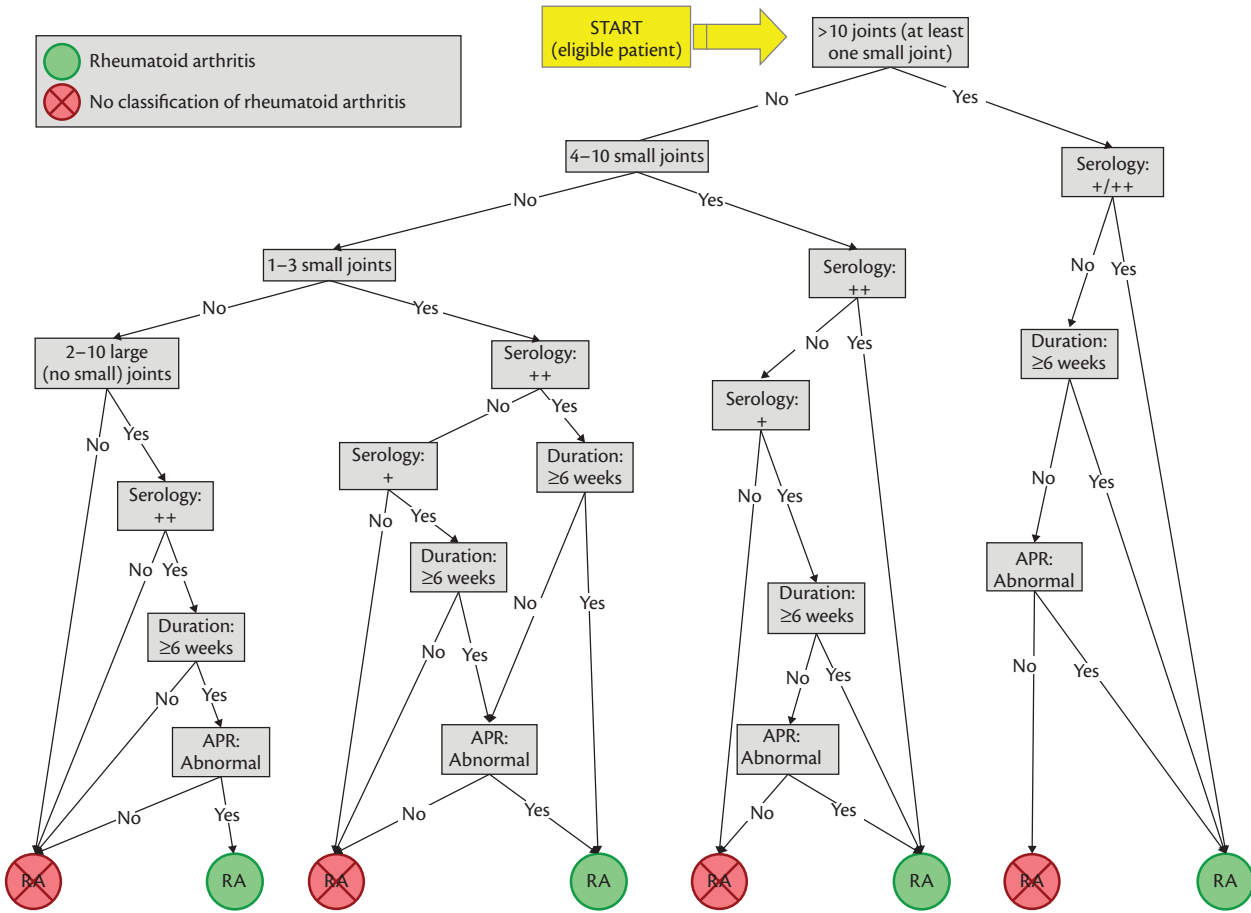
ACPA, anti-citrullinated protein/peptide antibodies; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; RF, rheumatoid factor; ULN, upper limit of normal.
[a]Joint involvement refers to any *swollen* or *tender* joint on examination, which may be confirmed by imaging evidence of synovitis. Distal interphalangeal joints (DIPs), 1st carpometacarpal (CMC) joint, and 1st metatarso-phalangeal (MTP) joint are *excluded from assessment*. Categories of joint distribution are classified according to the location and number of the involved joints, with placement into the highest category possible based on the pattern of joint involvement.
[b]Large joints refer to shoulders, elbows, hips, knees, and ankles.
[c]Small joints refer to the metacarpophalangeal (MCP) joints, proximal interphalangeal (PIP) joints, metatarsophalangeal (MTP) joints 2–5, thumb interphalangeal (IP) joints, and wrists.
[d]In this category, at least one of the involved joints must be a small joint; the other joints can include any combination of large and additional small joints, as well as other joints not specifically listed elsewhere (e.g. temporomandibular, acromioclavicular, sternoclavicular, etc.).
[e]Negative refers to international unit (IU) values that are ≤upper limit of normal (ULN) for the lab and assay; low positive refers to IU values that are >ULN but ≤3× ULN for the lab and assay; high positive refers to IU values that are >3× ULN for the lab and assay. Where RF is only available as positive or negative, a positive result should be scored as 'low positive' for RF.
[f]Normal/abnormal is determined by local laboratory standards.
[g]Duration of symptoms refers to patient self-report of the duration of signs or symptoms of synovitis (e.g. pain, swelling, tenderness) of joints that are clinically involved at the time of assessment, regardless of treatment status.
Adapted from Aletaha et al.[24,25]


Fig. 110.4 Tree algorithm to classify definite rheumatoid arthritis (green circles) or to exclude its current presence (red circles) among those who are eligible to be assessed by the new criteria. For definitions of categories (e.g. serology: +, ++, or joint regions), see footnotes to Table 110.1.

Taken from the original publication: 2010 rheumatoid arthritis classificationcriteria: an American College of Rheumatology/European League Against Rheumatismcollaborative initiative. Aletaha D, Neogi T, Silman AJ, Funovits J, Felson DT, Bingham CO 3rd et al Ann Rheum Dis. 2010 Sep;69(9):1580–8.

and thus does not penalize individuals without structural damage. At the same time there remains the—currently more theoretical—situation of patients with long-standing disease, who have not yet been classified, but may have become less active over time ('burnt-out' disease). For these patients, an option has been introduced, which allows immediate classification by presence of typical radiographic evidence of RA. Typical erosiveness of RA has recently been defined as erosions in more than three joints.[28] This is shown in Figure 110.5.

Therefore, comparing the 2010 classification criteria to those developed in 1987, many aspects have remained while several have changed. The radiographic changes are not weighted into the new scoring system, while patients with long-standing unclassified disease, who do not fit the criteria, can be classified on the basis of their typical joint destruction alone. Rheumatoid nodules have completely disappeared in the new classification system, mainly due to their low prevalence, and thus low diagnostic value, in early disease. The joint distribution remains similar to the 1987 scoring system, as the weight remains on polyarthritis (which at some level inherently includes symmetric disease) and on small joints. Serological changes were expanded from the mere use of RF to also include ACPA, and to a consideration of the antibody level (negative vs low positive vs high positive). Duration was introduced as a separate item in the new system, while it was integrated in the

joint activity items of the 1987 criteria, and elevated acute-phase response was newly introduced.

Classification vs diagnosis of rheumatoid arthritis

The distinction between classification and diagnosis is crucial: classification criteria aim to define a homogenous disease group for clinical and epidemiological studies. To this end, they aim at differentiating a specified rheumatic disease from other diseases (or healthy individuals). Classification criteria thus aim for a good group categorization (usually characterized by sensitivity, specificity, positive and negative predictive values, and likelihood ratios). In contrast, the clinical diagnosis aims at the correct individual categorization, to minimize misdiagnosis at the individual level.

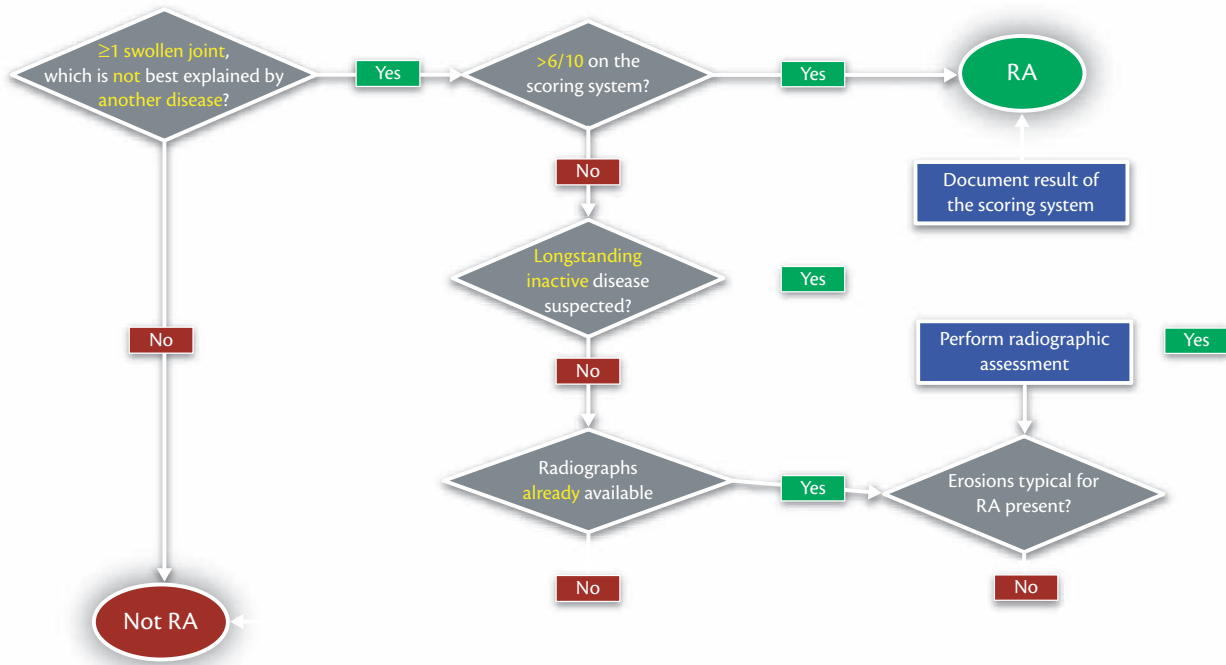
Inherent in these concepts is the fact that classification and diagnostic criteria will not always categorize individuals into the same group (Figure 110.6). This leads to the issue of false-positive and false-negative classification when compared to clinical diagnosis, which is not a deficiency of any classification system, but rather a matter of fact. Since classification criteria will inevitably be applied by clinicians, for diagnostic purposes, it is important to emphasize that a clinician can at any time overrule the classification result using clinical judgement. In other words, clinicians may establish a diagnosis in unclassified patients, as well as decide not to treat classified patients for the lack of a clinical diagnosis (Figure 110.6).


Fig. 110.5 The role of radiographic examination in the 2010 ACR/EULAR classification criteria. The figure depicts an algorithm for patients who are not classifiable by the scoring system, but who are either suspected to have long-standing (unclassified) disease (decision node in the middle of the figure) or already present with radiographic damage, which may then not be ignored (decision node at the bottom). In these two instances, information from radiographs may be used and allow a direct classification of RA in case of presence of typical RA erosions. The definition of 'erosiveness typical for RA' has recently been put forward.[28]
Taken from the Slidekit of EULAR and ACR.
Fig. 110.6 Classification vs diagnosis. The target population for classification is usually smaller and better defined than that for diagnosis, as classification is used for study purposes. Both, classification criteria and diagnostic criteria categorize individuals as diseased or not diseased. The figure implies that there might be considerable overlap between these groups. From a clinical perspective a diagnosis can be established and treatment may be initiated, even if the classification result is negative.
Reproduced from the Slidekit of EULAR and ACR.

A typical scenario for a false-positive classification by the 2010 classification criteria is a patient with osteoarthritis of the hand with one swollen PIP joint. Such a patient would score highly on the joint distribution domain (also tenderness is counted as 'joint activity') and would likely present with a symptom duration of 6 weeks or more, and hence be classified as having RA. Vice versa, patients seronegative for RF and ACPA are prone to false-negative classification: once zero points are achieved in the serology domain, and given the fact that only one point each may be acquired from the acute-phase response and the symptom duration domain, this

means that patients need to show a joint distribution in the top category. In other words, this means that seronegative patients need at least 10 active joints for their disease to be classified as RA. Inherent to the label of a 'diagnosis' is the fact that some sort of therapeutic intervention usually ensues.

It is important to mention in this context that the fulfilment of the new criteria can also be achieved cumulatively, that is, through repeated assessments over time, and in case of adequate previous documentation, also retrospectively.

Conclusion

In summary, the correct diagnosis of RA still remains a challenge, and it remains the task of the rheumatologist. Because of the large number of potential differential diagnoses, and the ability of RA to present in a very heterogeneous way, no criteria can replace the judgement and experience of the rheumatologist in this respect. Nevertheless, classification criteria may help to guide the rheumatologist in this difficult task of establishing a diagnosis, the importance of which still lies in the therapeutic implication for the patient. It is inherent to the concept of classification that it will differ from a clinical diagnosis in a potentially significant portion of individuals. As most current treatment algorithms indicate that treatment should be initiated immediately after the diagnosis of RA,[29] the rheumatologist is charged to lead and accelerate the diagnostic process by using algorithms, criteria, and other tools so as to avoid the most dangerous mistake in treatment of RA: delay.

CHAPTER 111

Rheumatoid arthritis— clinical features

Eugen Feist and Gerd-R. Burmester

Early rheumatoid arthritis

Introduction and epidemiology

Rheumatoid arthritis (RA) is the most frequent chronic systemic autoimmune disease with joint involvement. It affects approximately 0.5% of the adult population of Europe and North America. Females are two- to fourfold more frequently affected and predisposed to develop a more severe disease manifestation. The incidence of disease increases with age and plateaus around 60 years.

Different genetic and environmental factors are involved in the pathogenesis of disease, and have an influence on the risk for developing RA. The incidence rates show a considerable variation even within Europe from south to north, from 16.5 to 29 cases per million people.[1] The risk for first-degree relatives of affected persons to develop RA is increased.[2] In genetically predisposed cohorts, such as some tribes of Native Americans, the prevalence of RA can reach up to 5%, whereas in less prone populations such as in China the prevalence is about 2.8 to 3.5 cases in 10 000 individuals.[1]

Disease onset and diagnosis

The onset of articular symptoms is usually insidious as mono-, oligo- or polyarthritis with pain, soft tissue swelling, and sometimes warmth as a correlate of acute synovitis (Figure 111.1). The predominantly affected joints include small finger joints (the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints), wrists and forefeet, especially the metatarsophalangeal joints (MTP). For unknown reasons, the distal interphalangeal (DIP) joints are not affected. In addition to articular manifestations with pannus formation, joint effusion, bursitis, and risk of cartilage as well as bone destruction, periarticular symptoms can include tendinitis, tenosynovitis, epicondylitis, carpal tunnel syndrome, and myalgias. Involvement of shoulder and hip joints is relatively rare in early RA but common in patients with established and late-onset disease. In relation to the severity of the local and systemic inflammatory response, the disease process can be accompanied by non-specific symptoms such as long-lasting morning stiffness affecting the joints, generalized weakness with loss of energy, fatigue, weight loss, fever, and early functional joint impairment. [3,4] In this context, depression and fatigue in close relation to the inflammatory process of RA can cause psychological stress and a significant reduction of

Fig. 111.1 Patient with early rheumatoid arthritis presenting with swelling and pain of the first and second metacarpophalangeal (MCP) joints of the left hand.

quality of life. High levels of disability have a negative impact on social participation and psychological functioning of patients.

The pattern of joint involvement is of particular importance for the differential diagnosis and separation from e.g. psoriatic arthritis or osteoarthritis, where the DIP joints are typically affected (Table 111.1, see also Chapter 110). If the disease presents with mono- or oligoarthritic symptoms, follow-up examinations are usually required to exclude peripheral spondylarthritides such as reactive arthritis. In patients with systemic onset and presentation with fever, vasculitic skin lesions, and internal organ

Table 111.1 Frequent differential diagnoses for rheumatoid arthritis (see Chapter 110)

Differential diagnosis	Frequent clinical findings for differentiation	Typical laboratory findings	Typical imaging findings
Psoriatic arthritis	Psoriatic skin lesions, different involvement patterns, asymmetric arthritis, irregular deformities, involvement of DIP joints, arthritis mutilans, enthesopathy, fasciitis, dactylitis with 'sausage digit', spinal involvement	Seronegative for RF and ACPA, association with HLA-B27	Ultrasound and MRI with detection of bursitis–tenosynovitis and joint synovitis. Radiographs may show erosive arthritis, missing periarticular osteoporosis, ossifying periostitis, acroosteolysis with resorption of the distal phlangeal tufts, arthritis mutilans with massive periarticular bone resorption, 'pencil in cup' deformity, spinal syndesmophytes and sacroilitis
Polymyalgia rheumatica	Proximal musculoskeletal symptoms with bursitis–tenosynovitis and synovitis	Seronegative for ACPA, strongly elevated ESR	Ultrasound and MRI with detection of bursitis–tenosynovitis of subdeltoid and subacromial bursae, trochanteric bursae and long head of the biceps, interspinous bursae in the neck and back, shoulder and hip joint synovitis
Reactive arthritis	Asymmetric mono- or oligoarthritis, other manifestations (conjunctivitis, urethritis, colitis, enthesitis)	Seronegative for RF and ACPA, positive serology or detection of infectious agent	Ultrasound and MRI with detection of bursitis–tenosynovitis and joint synovitis, non-erosive arthritis
Lyme arthritis	Asymmetric mono- or oligoarthritis, other manifestations (meningitis, encephalitis, carditis, enthesitis)	Seronegative for RF and ACPA, positive serology (IgM and/or IgG) and/or PCR result for *Borrelia burgdorferi*	Ultrasound and MRI with detection of bursitis–tenosynovitis and joint synovitis, non-erosive arthritis
Gout	Attacks of asymmetric mono- or oligoarthritis, gouty tophi	Seronegative for RF and ACPA, elevated serum uric acid (may be normal/low during acute attack), detection of urate crystals by polarized light microscopy	Intra- and para-articular erosions and intraosseous calcifications due to deposits of urate crystals, secondary osteoarthritic changes, dual-energy CT with detection of tophi and urate deposits
Haemochromatosis	Arthropathy with frequent symmetrical involvement of MCP II and III joints, pronounced degenerative changes, accumulation of iron in other organs especially liver with altered function	Seronegative for RF and ACPA, increased serum ferritin and transferrin saturation test, mutations of the *HFE* gene	Prominent degenerative changes with subchondral cyst formation, sclerosis, thinning of cartilage, and osteophytes
Osteoarthritis	Degenerative changes with involvement of DIP and PIP joints (Heberden's and Bouchard's nodes)	Seronegative for RF and ACPA, normal inflammatory markers	Degenerative changes with asymmetric joint space narrowing, subchondral cyst formation, sclerosis, thinning of cartilage, and osteophytes

ACPA, anti-citrullinated peptide antibodies; DIP distal interphalangeal; ESR, erythrocyte sedimentation rate; MCP, metacarpophalangeal; PIP, proximal interphalageal; PCR, polymerase chain reaction; RF, rheumatoid factor.

involvement, e.g. serositis or vasculitis, further differential diagnoses include systemic lupus erythematosus (SLE) or systemic vasculitis. Polymyalgia rheumatic (PMR) is another common inflammatory disorder that has to be considered as a differential diagnosis, especially in elderly patients. In addition to the typical proximal musculoskeletal symptoms of PMR affecting shoulder–neck as well as pelvic regions, an overlap with RA can be frequently seen in patients with peripheral joint involvement (PMR/late-onset RA or LORA overlap). Another distinct arthritic disease is characterized by remitting, seronegative, symmetric synovitis with pitting oedema of hands and forefeet (known as RS3PE syndrome). Further differential diagnoses of arthritic manifestations include acute and chronic sarcoidosis, other connective tissue diseases, Lyme disease, and gouty arthritis. Haemochromatosis with joint involvement is characterized by predominant degenerative changes affecting typically the second and third MCP joints, but can also cause soft tissue swelling and arthritic symptoms. An obscure disorder termed 'palindromic rheumatism' presents with variable episodes of arthritis flares affecting one or more joints. Typically, these attacks resolve without any sequelae after hours or days. However, in approximately one-third of affected patients the disease can progress into classical RA.

Laboratory markers play an important role for diagnosis, follow-up, evaluation and prognosis of patients. At disease onset the presence of rheumatoid factor (RF) and of antibodies against citrullinated protein/peptide antigens (ACPA) are important diagnostic markers and allow differentiation from other distinct forms of arthritides.[5] In approximately one-half of ACPA positive patients

with undifferentiated arthritis, the diagnosis of RA was confirmed within the first year of follow-up.[6] So far the assays for ACPA are not internationally standardized; the most widely used and established antigen is a synthetic peptide (cyclic citrullinated peptide, CCP). Another licensed and commercially available assay with comparable diagnostic performance employs citrullinated and mutated vimentin (MCV) as antigen.[7] In Table 111.2, typical laboratory findings in patients with RA are summarized. Interestingly, as the first preclinical sign of disturbances in the immune system with formation of an auto-inflammatory response, RF, and ACPA as well as slowly rising levels of C-reactive protein (CRP) can be detected even years before the onset of articular disease manifestation in some patients.[8,9]

Conventional radiographic examinations (including wrists, hands, and forefeet as well as other affected joints) are still the gold standard for the documentation of the erosive nature and progress of RA, but provide relatively low sensitivity for detection of early soft tissue and erosive bone changes. Therefore, as useful imaging techniques for documentation of the inflammatory soft tissue process in early RA, ultrasound including power Doppler examination (US with PD: visualization of effusion, synovitis, hyperaemia, bursitis, tenosynovitis, and eventually erosions) and MRI (more sensitive than US for early detection of erosions, and additional visualization of bone oedema) should be used.[10] Bone scintigraphy can differentiate inflammatory from degenerative joint processes, but—besides irradiation exposure—provides a rather low diagnostic specificity and also low image resolution. In case of active disease, radiographic examinations can be recommended every 6–12 months to assess joint damage and adapt therapy appropriately. In contrast, MRI and especially US can be useful tools to frequently assess disease activity.

Classification criteria

Novel classification criteria for RA were recently introduced by an American College of Rheumatology/European League Against Rheumatism (ACR/EULAR) initiative.[11,12] The goal of these classification criteria was to improve early differentiation of patients with RA from other causes of arthritis. The main purpose was to facilitate the early initiation of disease modifying anti-rheumatic drug (DMARD) therapy and to support the performance of clinical studies in the field of early RA (see Chapter 110). Patients with a score of at least 6 points are classified as having RA. Scoring should only be done if information from at least one serological test (RF or ACPA) is available. In this context, high-level positive autoantibodies were defined as a result of at least three times the upper limit of normal. In fact, the introduction and weighting of ACPA and inflammatory markers would allow classification as RA of a patient with involvement of only one small joint or two large joints in case of symptom duration of at least 6 weeks. However, it should be pointed out that these criteria are not meant for the *diagnosis* of early RA and that before applying them other inflammatory joint disorders have to be excluded. In addition, patients with typical radiologic changes would per se classify as RA in the absence of other explanations.

Table 111.2 Laboratory findings in patients with rheumatoid arthritis with relevance for disease activity, diagnosis and prognosis

Laboratory parameter	Finding	Relevance
CRP	Slight to moderate increase	Inflammatory marker (acute-phase reaction) Prognostic marker for erosive disease
ESR	Slight to moderate increase	Inflammatory marker (chronic process)
Erythrocytes and haemoglobin levels	Reduced, slight to moderate anaemia	Active inflammatory disease, anaemia due to overexpression of IL-6 with induction of hepcidin causing disturbances in iron metabolism
Thrombocytes	Increased, slight to moderate thrombocytosis	Active inflammatory disease
Leucocytes	Increased, slight to moderate leucocytosis	Inflammatory process
Immunoglobulin levels	Slight to moderate increase	Inflammatory marker (chronic process)
Iron metabolism	Iron levels reduced and ferritin increased	Disturbances in iron metabolism due to induction of hepcidin and increase of ferritin as inflammatory marker (acute-phase reaction)
Lipid levels	Decrease of total cholesterol and LDL	Inflammatory marker (chronic process)
Rheumatoid factor (RF, measurement of IgM and IgA subtypes)	Positive titres in international units (>20 IU)	Diagnostic marker with moderate sensitivity, specificity and positive predictive value. Prognostic marker for erosive and systemic disease, Autoantibodies against Fc part of human IgG
ACPA, measurement of IgG subtypes)	Positive titres (no international standardization)	Diagnostic marker with moderate sensitivity, but high specificity and positive predictive value. Prognostic marker for erosive and systemic disease. Autoantibodies against citrullinated epitopes of different antigens (such as fibrinogen, vimentin, α-enolase, collagen type II and as artificial antigen, CCP)

ACPA, anti-citrullinated peptide antibodies; CCP, cyclic citrullinated peptide; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; RF, rheumatoid factor.

The earlier revised ACR classification criteria dating from 1987 provided good specificity for established RA.[13] The main limitations of these criteria are reflected by the incorporation of signs and symptoms that are more present in advanced disease such as symmetric polyarthritis, rheumatoid nodules, and radiological changes. Furthermore, ACPAs, as the most specific biomarkers for diagnosis of RA nowadays, were not routinely available when these criteria were introduced. Therefore, these criteria are not very useful for differentiation of patients with early arthritis.

Established and advanced rheumatoid arthritis

Symptoms and diagnosis

Involvement of musculoskeletal apparatus
Small joints

The inflammatory process of RA predominantly affects small joints, leading to synovitis with pannus formation and clinically evident signs and symptoms of arthritis. In the joint region, the influence on bone metabolism and the destructive nature of disease manifest as periarticular bone demineralization, and irreversible destruction of cartilage as well as articular bone. First erosions are frequently found at the insertion region of the joint capsule, where pannus tissue starts to invade into the naked bone structures not covered by cartilage.

As signs of advanced disease in the upper limb, the involvement of carpal bones and MCP joints causes ulnar drift, often in combination with radial deviation of the wrist and flexion deformities (Figure 111.2). Typical wrist deformities include volar subluxation of the hand with a visible sliding at the radiocarpal joint and radial deviation of the carpal bones (Figure 111.3). Involvement of the radioulnar joint can lead to instability and dorsal subluxation of the ulnar head with a 'piano key' phenomenon on downward pressure. The resulting instability and mechanical tension of the ulnar head can eventually cause rupture of carpal extensor tendons.

Fig. 111.3 Patient with rheumatoid arthritis presenting with volar subluxation of the right hand with a visible sliding at the radiocarpal joint and Z-deformity (or 90–90 thumb) with flexion of the first metacarpophalangeal joint and hyperextension of the interphalangeal joint.

Fig. 111.4 Typical forefoot deformities in a patient with rheumatoid arthritis with clawing of the toes and dislocation of the metatarsophalangeal (MTP) joints.

Involvement of MCP and PIP joints is typically symmetric and can lead to articular destruction, subluxation, or dislocation and finally, as an endstage change, to an ankylosis of joints. Tenosynovitis of tendon sheaths can cause typical finger deformities such as Z-deformity of the thumb, swan-neck deformity, and boutonnière deformity (Figures 111.2 and 111.3). Furthermore, tenosynovitis of the carpal flexor tendons can lead to compression of the median nerve causing carpal tunnel syndrome with altered/lost sensation of the thumb, index, and middle fingers predominantly, in association with a characteristic pattern of weakness. Another typical sign of established RA is atrophy of interosseous muscles of the hand mainly due to reduced use as a consequence of joint pain and stiffness. As in early RA, the DIP joints are typically not involved even in advanced stages of disease.

As signs of advanced disease in the lower limbs, involvement of the metatarsophalangeal (MTP) joint is very common, frequently leading to forefoot deformities (Figure 111.4). Synovitis with erosive bone changes as well as tenosynovitis especially of the flexor tendons can cause clawing of the toes and dorsal dislocation of the MTP joints.

Fig. 111.2 Patient with rheumatoid arthritis presenting with a radial deviation (right wrist), swan-neck deformity with hyperextension of the proximal interphalangeal (PIP) and flexion of distal interphalangeal (DIP) joints (digits 3 right and 5 on both sides) and boutonnière deformity with flexion of the PIP and hyperextension of DIP joints (digits 2–4 left).

Another occasional but relevant manifestation of RA can affect the temporomandibular joints, with resulting painful limitation of mouth opening.

Large and medium-sized joints

At the upper limbs, involvement of the elbow is often accompanied by considerable synovitis with effusion in the olecranon fossa and bursitis, leading to a reduction of extension, flexion, and supination (Figure 111.5). Shoulder involvement often starts with bursitis and tenosynovitis of the biceps tendon. In patients with advanced disease, synovitis can cause erosions and destruction of the glenohumeral joint. Furthermore, rupture of tendons including parts of the rotator cuff are frequently observed in patients with shoulder involvement. Taken together, all these manifestations can cause significant functional loss in such basic daily activities as eating, washing, and dressing.

At the lower limbs, knee involvement is very common and presents with synovitis, bursitis with effusion especially in the supra patellar recess, and erosive lesions. Popliteal bursitis (Baker's cyst) is associated with risk of popliteal vein compression, which can lead to thrombosis and subsequently, life-threatening pulmonary embolism. Rupture of a Baker's cyst can cause acute pain and inflammatory swelling of the soft tissue compartment of the lower leg and also thrombotic complications. At the knee joint, functional loss is associated with a reduction of extension and instability as a result of laxity in the collateral and cruciate ligaments. Subsequently, progressive valgus deformity can occur, especially in women with a physiological valgus position. Due to involvement of the tibiotalar and subtalar joints, a progressive flattening of the longitudinal foot arch can further increase valgus deformity of the legs (Figure 111.4). Furthermore, involvement of the ankle joints can cause considerable functional deficits interfering with walking ability. In long-standing and poorly controlled RA, prosthetic joint replacement is frequently required for knee and hip joints.

Axial joints

The most critical involvement of the axial joints in RA affects the cervical spine. Particularly, inflammatory changes of the atlantoaxial joint (C1–C2) with destabilization and atlantoaxial dislocation represents a potentially life-threatening complication. This process is typically driven by synovitis, most commonly in the space between the transverse ligament of the atlas and the posterior part of the dens. Ventral atlantal dislocation has to be considered if the space between the anterior dens border and atlas arch increases to 5 mm or more. Vertical dislocation of the dens can occur in conjunction with a ventral atlantal dislocation but also in isolation, leading to a rising of the dens position sometimes even passing the foramen magnum line. Erosive changes of the dens are particularly associated with the risk of dens fracture causing compression of the cervical cord and basilar invagination. This severe complication can lead to paraplegia potentially accompanied by fatal respiratory paralysis. Therefore, functional cervical radiographs and/or MRI are strongly recommended in patients with suspected cervical involvement (pain in the neck, headache, pain with projection to shoulder and upper extremities, paraesthesiae or numbness of upper extremities). Instability in the atlantoaxial joint must be excluded especially before procedures leading to hyperflexion of the cervical spine such as during physiotherapy, dental care, and intubation. In case of proven instability, wearing a stiff collar and surgical stabilization are appropriate measures.

Disease assessment in daily practice

Several composite scores are useful and established in daily practice for assessment of disease activity in patients with RA (Table 111.3).[13,14] These scores include the number of tender and swollen joints (usually out of 28 defined joints), patient's and physician's global assessment of disease activity on a visual analogue scale (VAS) as well as levels of acute-phase reactants (erythrocyte sedimentation rate (ESR) or CRP). The Disease Activity Score using 28 joint counts (DAS28) is a frequently used measure for disease activity in RA.[15] The score is calculated by a complex mathematical formula providing a good sensitivity to change of disease activity. However, it is important to note that a limitation of the DAS28 includes a rather high false-positive rate for remission. The main advantage of the Simplified Disease Activity Index (SDAI) and Clinical Disease Activity Index (CDAI) is the ability to evaluate disease activity without using a calculator.[16] The CDAI even allows immediate scoring without the need for a laboratory marker. These scores can be used as useful tools for monitoring disease activity and tight disease control and can guide treatment decisions. For assessment of joint damage and disease progression in stable RA, conventional radiographic examinations can be recommended once a year. In active, early or resistant disease, radiologic re-evaluation at shorter intervals (e.g. 6 months) can be recommended.

The Stanford or Modified Health Assessment Questionnaires (HAQ) are frequently used to assess functional disability in daily practice.[17,18] Functional disability as such is influenced by age, female sex, disease duration, disease activity reflected by the number of affected joints (particularly in early disease), and radiological joint damage (particularly in established disease).

Prognostic markers, course of disease, and outcome

RA is a severe systemic autoimmune disease with increased morbidity and mortality compared to the general population of the same age and gender. Furthermore, the disease is characterized by disability, reduced quality of life, and high levels of work instability. Pain, joint destruction, progressive loss of mobility, and reduced ability to care for oneself are closely related features of RA.

Fig. 111.5 Patient with rheumatoid arthritis presenting with involvement of the elbow accompanied by effusion in the olecranon fossa and bursitis, plus a rheumatoid nodule distal to olecranon bursitis.

Table 111.3 Composite scores for disease activity in rheumatoid arthritis[13,14,16]

Tool	Calculation	Cut-off for remission
DAS28 (ESR)	$(0.56 \times TJC1/2) + (0.28 \times SJC1/2) + (0.7 \ln [ESR]) + (0.014 \times PtGA)$	<2.6
CDAI	SJC + TJC + PhGA + PtGA	≤2.8
SDAI	SJC+ TJC + PhGA + PtGA + CRP (mg/dl)	≤3.3
New ACR/EULAR remission criteria 2011		
For clinical trials		
Boolean criteria or	SJC, TJC, PtGA, CRP	all ≤1
Index-based criteria	SDAI SJC+ TJC + PhGA + PtGA + CRP (mg/dl)	≤3.3
For clinical practice		
Boolean criteria or	SJC, TJC, PtGA	all ≤1
Index-based criteria	CDAI SJC + TJC + PhGA + PtGA	≤2.8

APR, acute-phase reactant; CDAI, Clinical Disease Activity Index; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; PhGA, physician global activity; PtGA, patient global activity; SDAI, Simplified Disease Activity Index; SJC, swollen joint count; TJC, tender joint count.

Since RA is a heterogeneous disease with a highly variable course and outcome, it is important to predict the course of disease and adjust treatment options individually. The spectrum includes patients with remitting flares, patients with mild disease manifestations without erosive arthritis, and also severe, progressively destructive disease and even refractory cases. The differentiation of clinically distinct subgroups is also reflected by distinct serological and genetic characteristics (see Chapter 109). In this context, the prognosis and outcome of joint involvement is influenced by several independent factors. The following predictors for severe and erosive disease have been identified so far: female gender, early detection of erosive changes, elevated acute-phase reactants (ESR and/or CRP) as well as seropositivity for RF and/or ACPA.[19] High autoantibody titres for RF and ACPA are also indicative for more severe and systemic disease.

The outcome of patients with RA with respect to joint involvement has been significantly improved over recent decades due to major advances in diagnostics, treatment strategies, and the development of novel drugs. Under optimal treatment conditions, even patients with long-standing disease can present without joint damage or disability. In this context, it is particularly important to start effective treatment within the so-called 'window of opportunity' before such changes occur. It remains to be determined whether the outcome with respect to extra-articular disease manifestations (e.g. systemic manifestations and amyloidosis) as well as comorbidities (e.g. cardiovascular events and lymphoma) will also be influenced by more recent treatment approaches.

Extra-articular manifestations in rheumatoid arthritis

Extra-articular disease manifestations reflect the systemic nature of RA and play a significant role in prognosis and treatment decisions.[20] Since involvement of internal organs is frequent, detailed organ examination and, if required, interdisciplinary management of complications is necessary.

Rheumatoid nodules

Subcutaneous rheumatoid nodules belong to the frequent extra-articular disease manifestations primarily in seropositive patients with severe and active disease. However, with increasingly effective use of conventional and biological DMARDs the occurrence of subcutaneous nodules has decreased and is now rare. They present predominantly at the extensor surfaces of the upper limb, along the forearm (Figure 111.5) and fingers, but can occasionally be found at other periarticular regions such as the Achilles tendon and in internal organs, e.g. in the lung parenchyma and myocardium.[21] In some patients, the occurrence of subcutaneous nodules is paradoxically pronounced during treatment with methotrexate (MTX). Since the clinical manifestation of rheumatoid nodules is very typical, histological examination is usually not necessary. However, with atypical presentations or in cases of symptomatic nodules (e.g. due to pressure effects), biopsy or removal of the tissue reveals a granulomatous lesion with focal central fibrinoid necrosis surrounded by fibroblasts.

Eye involvement

Eye involvement includes the frequent occurrence of secondary Sjögren's syndrome as well as the rarer and mild complication of episcleritis and the potentially severe manifestation of scleritis and keratitis.[22] Secondary Sjögren's syndrome occurs in about one-quarter of patients and is characterized by typical sicca symptoms of eyes and mouth. Treatment should be symptomatic with substitution of saliva and tears. The incidence of episcleritis in patients with RA is less than 1%. The clinical manifestations are usually mild to asymptomatic with separation of diffuse and nodular episcleral types of inflammation. The prevalence of scleritis is lower with clinical symptoms of pain, vascular injection, photophobia and visual disturbance (Figure 111.6). Clinically, scleritis can be classified as anterior (approximately 90% of cases) vs posterior localization, and by the inflammatory process in non-necrotizing (diffuse or nodular) and necrotizing (often painless, affecting approximately 10% of cases) forms. Importantly, scleritis has to be considered as an emergency situation, since it can progress to eye perforation with resulting blindness. Often in conjunction with scleritis, the most severe eye involvement includes peripheral ulcerative keratitis (PUK, corneal 'melt'). This typically painless manifestation occurs primarily in patients with long-lasting RA, which may be clinically inactive, and is associated with a high risk of ocular perforation and subsequent blindness. Therapy of inflammatory and severe eye
Fig. 111.6 Patient with rheumatoid arthritis presenting with acute scleritis with pain, vascular injection, photophobia, and visual disturbance.

involvement in RA includes topical and systemic administration of anti-inflammatory and potentially highly potent immunosuppressive drugs in close interdisciplinary cooperation.

Haematological and systemic manifestations

Blood cell count disturbances in association with disease activity in RA are presented in Table 111.2. Benign lymphadenopathy is another common finding in active and chronic RA and must be differentiated from non-Hodgkin's lymphoma in suspicious cases. As a systemic form of RA, Felty's syndrome is characterized by chronic neutropenia, splenomegaly, destructive joint involvement, high positive results for autoantibodies (RF and ACPA), and rheumatoid nodules. Felty's syndrome affects about 1% of cases and usually requires an intensive immunosuppressive treatment strategy.

Vasculitis

Vasculitis is now rare and associated with disease severity and activity in RA. The most frequent manifestation is cutaneous vasculitis of small to medium-sized vessels leading to necrosis and ulceration, predominantly of the lower legs. Furthermore, vasculitis may cause peripheral neuropathy either symmetrical 'glove and stocking' or mononeuritis multiplex with loss of sensory and motor conduction. Organ-specific vasculitis may lead to infarction including myocardial infarction or stroke, or damage of other internal organs by affecting e.g. mesenteric arteries with abdominal pain, digestive symptoms, and bowel ischaemia. Laboratory results usually reveal a strong inflammatory response (elevated CRP and ESR levels) as well as signs of an immune-complex-mediated vasculitis (e.g. high titres of RF, positive results for cryoglobulins, and low levels of complement). Treatment of vasculitic manifestations includes optimal anti-rheumatic treatment with immunosuppressive drugs, including glucocorticoids, but also optimal management of traditional cardiovascular risk factors.

Lung and cardiac involvement

Lung involvement in RA is frequent and under-recognized.[20,23] Pleuritis might occur at onset of disease and can cause progressive respiratory distress due to accumulating pleural fluid. However, in some asymptomatic patients with minor effusion, pleuritis is detected only incidentally by routine imaging. Furthermore,

interstitial lung disease usually of mild to moderate severity is quite common. Approximately 6% of patients will develop clinical symptoms due to pulmonary fibrosis and pulmonary hypertension, especially in long-standing disease. It is important to keep in mind that interstitial lung disease is also a rare but important adverse effect of MTX therapy. However, this toxicity often occurs within weeks of MTX initiation and has a subacute to acute onset with rapidly progressive respiratory symptoms. Interstitial lung disease can also present as nodular lung disease in association with rheumatoid nodules.

In the context of serositis, pleuritis may be associated with exudative pericarditis. Pericarditis with acute chest pain, dyspnoea, and pericardial effusion represents the most frequent heart manifestation in RA. Since this condition can lead to pericardial tamponade, close monitoring by echocardiographic examination is required. Chronic constrictive pericarditis can lead to right-sided heart failure. Involvement of the myocardium and endocardium can also occur as well as conduction defects and coronary arteritis due to vasculitis. In cases of active inflammatory heart or lung involvement, especially in patients with acute serositis, immunosuppressive treatment is indicated and usually includes glucocorticoids.

Amyloidosis

Secondary amyloidosis due to chronic persistent inflammation is a severe and potentially underdiagnosed condition. Deposition of amyloid A interferes especially with renal function and may lead to terminal renal failure requiring dialysis. Mortality in affected patients is strongly increased and, therefore, early recognition and effective anti-inflammatory regimes with suppression of the inflammatory cascade are the treatment goals. With the introduction of effective therapeutic approaches, amyloidosis is increasingly rare in daily practice.

Comorbidity in rheumatoid arthritis

Mortality and disability in RA is significantly influenced by comorbidities such as cardiovascular disease (myocardial infarction and stroke), infections, osteoporosis, overlapping autoimmune diseases, and lymphoma. Therefore, management of comorbidities is of major relevance for treatment decisions and individual prognosis.

Infection

The incidence of infections including severe infections is significantly increased in patients with RA, due to effects on the immune system of the autoimmune disease itself as well as the prescription of immunosuppressive drugs. The risk profile includes infections of soft tissue and skin, respiratory and urinary tracts, as well as joints and bones. Early diagnosis and treatment are essential. For example, in every suspected case of septic arthritis, an immediate aspiration of synovial fluid must be performed for microscopic and cultural diagnostics.

It is important to note that concomitant medication, especially the use of glucocorticoids, is a well-known risk factor for recurrent infections. Furthermore, increased risk for infections is also a relevant safety issue for all biologics.[24] However, there are certain differences between the compounds. It has been shown in clinical trials and registries that blocking of the cytokine tumour necrosis factor alpha (TNFα) is associated with an increased risk of opportunistic infections, including reactivation of latent tuberculosis. In contrast, up to now there is no evidence for the same risk under

the B- and T-cell directed drugs rituximab and abatacept.[25,26] For all biologics except rituximab, screening for latent tuberculosis is a standard procedure before starting therapy. Furthermore, prophylactic vaccination using killed or inactivated vaccines is nowadays strongly recommended for patients with RA prior to initiation of immunosuppressive therapy especially biologics (including but not limited to vaccinations against tetanus, hepatitis B, influenza, and pneumococcal vaccines; see Chapter 94).[27] In contrast, immunization with live or attenuated vaccines is not recommended in immunocompromised patients with RA. In some patients, especially those undergoing treatment with immunosuppressive drugs, signs and symptoms of infections can be hidden or atypical. For example, under treatment with biologics such as tocilizumab, the inflammatory response against infectious agents might be suppressed with lack of increase in CRP levels.

Cardiovascular risk

The risk for cardiovascular events is strongly increased in RA from the beginning of the disease process and is comparable to that for patients with diabetes mellitus.[28] RA should therefore be considered as an independent risk factor for cardiovascular disease, with myocardial infarction, congestive heart failure and stroke representing the main complications for mortality.[29] The vascular changes can be best described by a premature atherosclerosis, which is associated with prolonged increased inflammatory parameters such as ESR and CRP, extra-articular features of RA, and the use of glucocorticoids. In addition, increasing evidence suggests that particularly seropositive patients and patients with extra-articular disease manifestations have the highest risk of developing cardiovascular complications.[30] Since the process of premature atherosclerosis appears to associate with disease activity, effective anti-inflammatory treatment is the appropriate preventive approach. In this context, a reduced risk for cardiovascular events is emerging from registries, due to use of traditional DMARDs as well as biologics such as TNF blockers. In the prevention and management of cardiovascular disease, traditional risk factors such as smoking, hypertension, diabetes, and hypercholesterolaemia must be considered appropriately. It should be noted that in active RA the measurable lipid levels are suppressed due to the inflammatory response. Therefore, higher levels of cholesterol appear frequently after the initiation of an effective therapy. Under such circumstances, the use of statins should be considered, especially since they may beneficially influence both vascular risk as well as disease activity.

Osteoporosis

The association of RA with an increased risk of generalized bone loss and osteoporosis is well documented. It has been shown that the risk of osteoporosis in patients with RA is increased approximately twofold in males and females. As a consequence, the risk for vertebral as well as non-vertebral fractures (especially hip, pelvis, humerus, tibia, and fibula) is also increased. Development of osteoporosis is driven by several factors including release of proinflammatory cytokines such as IL6 with impact on bone metabolism but also simply immobilization due to pain and functional impairment. Long-standing, particularly active, disease and low body mass index (BMI), which may be a manifestation of disease activity, are predictive factors. Therefore, osteoporosis can also be addressed as an extra-articular manifestation of RA. In addition, prolonged

exposure to glucocorticoids is a risk factor for the development of secondary osteoporosis. Therefore, early initiation of preventive measures (e.g. calcium, if not sufficient in the diet, vitamin D supplementation, bisphosphonates) and consequent treatment of manifest osteoporosis are part of the standard care of RA.

Malignancies

The risk for development of certain malignancies is slightly increased in patients with RA. Amongst them, the incidence of non-Hodgkin's lymphoma (most frequent subtype large-cell B-cell lymphoma) is increased approximately two- to fourfold compared to the healthy population.[31] With a clear association to active and severe disease, development of non-Hodgkin's lymphoma can be considered as a long-term risk in uncontrolled and refractory patients.[32] Furthermore, data from meta-analyses showed an increased risk for lung cancer and potentially decreased risk for colorectal and breast cancer compared with the general population.[33] So far the available data for patients under biologics, especially TNF blockers, showed an overall unchanged risk for the development of non-Hodgkin's lymphoma.[24] On the other hand, the anti-CD20 antibody rituximab represents a preferable biological option for patients with coexistent or previous B-cell lymphoma.

Overlapping autoimmune diseases

RA is frequently accompanied by or overlaps with other systemic and non-systemic autoimmune diseases. Under certain circumstances the manifestations are inseparable, such as in patients with polymyalgia rheumatica in association with late-onset RA as well as in patients with mixed connective tissue diseases, secondary Sjögren's syndrome or SLE; in the latter, seropositive patients can present with an erosive arthritis ('rhupus'). Furthermore, potentially due to a common genetic predisposition, the incidence of multiple sclerosis, myasthenia gravis, and autoimmune thyroiditis as well as autoimmune liver diseases are increased in patients with RA. If repeatedly positive anti-phospholipid antibodies are detectable in patients with RA and vascular thrombosis or characteristic pregnancy morbidity, secondary anti-phospholipid syndrome must be considered.

Conclusion

RA is a heterogeneous disease with involvement of the musculoskeletal system but potentially also other organs. Risk factors for aggressive disease include the inflammatory response, the formation of autoantibodies, and internal organ involvement. RA is closely associated with different comorbidities including cardiovascular disease and malignancies. Active and uncontrolled disease leads to loss of function, early invalidity and an overall increased mortality rate. Therefore, early diagnosis, application of novel classification criteria, stratification of patients according to prognostic markers, and appropriate treatment are crucial for the best outcome.

CHAPTER 112

Rheumatoid arthritis—management

Chris Deighton

Introduction

Rheumatoid arthritis (RA) management has been revolutionized in the past 20 years.[1,2] Where remission was once an aspiration, it is now common to see patients with no or minimal disease activity, no progressive damage on joint imaging, and consequently no disability.[1–3] This has resulted in improved mortality, ability to work, and reductions in joint replacements.[4–6]

Influential international and national RA management guidelines have been published (see Box 112.1).[1,7–11] Guidelines are helpful for several reasons:

- RA is common, affecting up to 1% of the population.

- Low incidence means that primary care physicians (PCPs) may see only new RA patients less than once per year.[12,13] Guidelines promote awareness of symptoms and signs of new disease, and clues that synovitis will persist.

- RA is very expensive for national economies. In the United Kingdom direct care costs to the National Health Service are £560 million per year, with additional costs to the economy of sick leave and work-related disability at £1.8 billion a year.[13] Implementation of national guidelines, particularly in treating early and intensively, would save money in the national economy,[13] with similar conclusions in international studies [14]

- The provision and quality of care for RA shows marked variation which guidelines can decrease, and set benchmarks for high-quality care.[13]

- The advent of biological therapies has given rheumatology the ability to consume large amounts of healthcare resources, but the responsibility to spend this appropriately. Treating disease early and intensively may decrease, or at least delay, the need for biologics.[15,16]

Some examples of key international and national guidelines are listed in Box 112.1. The following is a summary of key recommendations that are common to these guidelines:

- There is a need for early diagnosis and rapid referral to specialist care (see Chapter 110). Any persistent joint inflammation, irrespective of the distribution of joints affected, should be referred

---

Box 112.1 Key national and international rheumatoid arthritis management guidelines

- EULAR recommendations for the management of rheumatoid arthritis with synthetic and biological disease-modifying anti-rheumatic drugs[1]

- American College of Rheumatology 2008 recommendations for the use of nonbiologic and biologic disease-modifying anti-rheumatic drugs in rheumatoid arthritis[8]

- British Society for Rheumatology and British Health Professionals in Rheumatology guideline for the management of rheumatoid arthritis (the first 2 years)[10]

- British Society for Rheumatology and British Health Professionals in Rheumatology guideline for the management of rheumatoid arthritis (after the first 2 years)[11]

---

for a specialist opinion. Inflammatory arthritis is a clinical diagnosis, based on signs and symptoms of inflammation in joints. Although PCPs may perform blood tests, waiting for the results should not lead to a delay in specialist referral. Even more importantly, if test results are available, normal inflammatory markers and negative serology should not put PCPs off referring promptly. This is particularly the case if poor prognostic clinical signs are evident, such as small-joint disease of the hands and feet. The more joints that are affected, the worse the outcome. In most countries the main component of the delay between patients developing initial symptoms and starting disease-modifying anti-rheumatic drugs (DMARDs) is the delay in seeing PCPs in the first place.[12] Public health campaigns need to emphasize the signs and symptoms of inflammatory arthritis, so that patients do not delay seeing their PCPs (see Figure 112.1).
Fig. 112.1 The S Factor Campaign in the United Kingdom to highlight awareness of early inflammatory arthritis.
Reproduced with permission of Arthritis Research UK.

◆ Early intensive treatment of active RA is needed. If treatment is not initiated within the 'window of opportunity', the chances of influencing long-term outcomes is profoundly diminished.[17]

◆ Early disease should be followed up closely and documented objectively, to ensure adequate disease activity suppression.

◆ For early and established disease there should be availability of education on self-management and the need for medication, and ongoing access to the MDT. Prompt access should be available for any flare-ups of the disease, with flexible follow-up based more on the need of the patient rather than the convenience of the clinic.

◆ For established and stable disease, annual review should be available (see below).

There are controversies in the management of RA due to either different interpretations of or lack of evidence, or because the label of RA covers a broad diversity of disease expression. These include:

◆ the need for the same intensive interventions in all patients, irrespective of disease activity or prognostic markers, and whether DMARD monotherapy or combination therapy is appropriate

◆ the role of steroids

◆ the appropriate introduction of biological therapies.

The next section expands on these issues.

Early intervention

Remission is easier to achieve and maintain by prompt treatment.[1,2] Immunopathological changes in the first 3 months of RA lead to self-perpetuation of the disease, and become increasingly difficult to influence.[17] Sustained remission translates into less radiological damage and less disability. In the early stages of disease the disability index Health Assessment Questionnaire (HAQ) is determined largely by inflammation which is amenable to intervention, but as time goes by the HAQ is more governed by increasing joint damage which is less responsive to medical therapy. Aletaha and colleagues pooled six trials looking at remission, and demonstrated that the ability to influence HAQ decreased progressively with delays in treatment.[18] The Finnish RA Combination Therapy (FIN-RACo) study showed that early suppression of disease activity resulted in a greater likelihood of maintaining work capacity at 5 years, and was maintained for up to 11 years.[19] The Norfolk Arthritis Register demonstrates that sustained remission is less likely to show deterioration of function over 5 years.[20]

However there are still frustrating delays in patients initiating DMARDs. In the United Kingdom the Early Rheumatoid Arthritis Network demonstrated median delays of 8 months.[21] The National Audit Office Report found that people with RA visit a GP on average four times before being referred to a specialist for diagnosis.[13]

In early intervention a balance should be struck between overtreating self-limiting inflammatory arthritis, and undertreating poor-prognosis aggressive RA. Trials have attempted to address this with interventions in early undifferentiated synovitis. In the PROMPT trial treatment with weekly methotrexate reduced and delayed the number of patients transforming from undifferentiated arthritis to RA at 1 year (mainly anti-citrullinated protein antibodies (ACPA) positive patients), with radiological progression diminished also, but no improvement in remission rates.[22] The STIVEA trial gave three intramuscular injections of 80 mg of methylprednisolone or placebo at weekly intervals to patients with early inflammatory polyarthritis (4–10 weeks' duration); methylprednisolone resulted in a modest but significant decrease in the percentage of patients who needed DMARDs at 6 months (61% vs 76%, p = 0.015) and an increase in resolution of arthritis at 1 year (19.8% vs 9.9%, p = 0.05).[23] By contrast, a single dose of methylprednisolone in the SAVE trial did not change disease progression.[24] In arthralgia patients positive for rheumatoid factor (RF) or ACPA two injections of 100 mg of dexamethasone reduced antibody titres at 6 months compared with placebo, but did not prevent progression to arthritis.[25] The ADJUST trial compared 6 months of abatacept (a T-cell costimulation inhibitor biological drug) against placebo in undifferentiated arthritis.[26] At a year there was a decrease in the proportion of patients who developed RA in the abatacept group, though this did not reach significance (46% vs 67%). In a small study infliximab (10 patients) was used against placebo (7 patients) in undifferentiated arthritis of less than 1 year's duration which had relapsed after a steroid injection.[27] The use of infliximab showed modest short-term relief but did not prevent the development of RA.

Biomarkers to predict who will transform from arthralgias or undifferentiated arthritis into RA do not currently exist to warrant widespread use of steroids, DMARDs, or biologics. Methotrexate, and steroid injections, could be considered in patients with early persistent synovitis who are ACPA positive. ACPA and/or RF status

should be assessed in all early persistent synovitis patients because of the diagnostic specificity,[28–30] prognostic assistance,[28,30] and potential to influence therapy decisions.[22] However, in any patient in whom RA is suspected irrespective of serology, a low threshold for starting DMARDs should operate, because the diagnosis is not always easy, and the consequences of delaying DMARDs can be serious.[1]

The current label of RA covers a heterogeneous spectrum of disease. It would be useful to be able to stratify patients according to risk of progression, with patients with poor prognoses being treated very aggressively from the start with combinations of DMARDs and steroids, whereas patients with good prognoses might receive more cautious DMARD monotherapy. A validated prediction rule has been developed using information regularly collected in clinic: patient age and gender, number and types of joints involved, duration of morning stiffness, C-reactive protein (CRP) level, RF and ACPA levels.[31] Such indices can help management decisions, as advocated by guidelines.[1,8]

Multidisciplinary support for patients from the start, and throughout the course of the disease, is vital.[7,9,10] All patients must be informed about our understanding of the disease and the need for interventions, and receive the opportunity for early education on how to best manage their own disease.[7] Specialist nurses often provide follow-up monitoring of DMARDs and disease activity. Access to physiotherapy and occupational therapy is also important from disease onset. The impact of RA on patients, particularly their social roles, can be devastating, as well as affecting carers.

Treating to target

The concept

Treatment should aim for remission preferably, or low disease activity where this cannot be achieved, and this should be sustained to avoid disease progression and disability. The American College of Rheumatology (ACR) and the European League Against Rheumatism (EULAR) have agreed criteria on remission which are a tender joint count, swollen joint count, CRP (in mg/dL), and patient global assessment (0–10 scale) all being less than or equal to 1, or when the Simplified Disease Activity Index (SDAI) is 3.3 or less.[32] Although designed for clinical trials, this is bound to influence clinical practice. Four key approaches are needed for early RA:

◆ Patients should be seen regularly to ensure that inflammation is suppressed quickly and permanently. The National Institute for Health and Clinical Excellence (NICE) guidelines advocate monthly clinic visits for early active RA, based on studies such as TICORA,[7,33], where frequent visits with action taken for active disease were associated with excellent outcomes. EULAR guidelines suggest every 1–3 months [1]

◆ Patients should have a formal assessment of their disease activity. Validated measures include the Disease Activity Score (DAS), the 28 joint Disease Activity Score (DAS28—see Figure 112.2), the SDAI, and the Clinical Disease Activity Index (CDAI).[34] Although there are criticisms of scores such as the DAS28,[2,16] they are better than a 'physician's global assessment', and record a figure in the patient record, without which there is no target to aim for.[2]

◆ Inflammation must be suppressed quickly. Disease activity at 3 months is a good predictor of long-term outcomes.[2] Combinations of DMARDs may extend the window of opportunity for influencing long-term outcomes,[35] but there is no room for complacency.

◆ Each follow-up occasion on which the target DAS is not achieved needs treatment intervention.[1,2,7] Individual inflamed joints can be injected with steroids, or for more widespread disease activity, an intramuscular injection or course of oral steroids might be used. Steroids alone should not be relied upon in the long term, and DMARDs also need to be adjusted or changed to aim for prolonged disease suppression. This may mean increasing the dosage of established DMARDs, adding others in, or using alternative drugs if they are not working or causing side effects.[1,7]

Methotrexate as the anchor drug

For patients with early active RA methotrexate should be included in the DMARD regimen, because:

◆ It is as good as any other conventional DMARD, and in head-to-head studies in early RA compares favourably with anti-TNF. In the BeSt trial monotherapy arm, 44% of methotrexate patients were in remission at 6 months, and 32% at 2 years follow-up.[36] An observational cohort comparing methotrexate with sulfasalazine found similar outcomes, but greater erosion suppression with methotrexate.[37]

◆ There is considerable experience of methotrexate in combination regimens with other DMARDs and biological therapies.[1,7]

◆ The dose is highly adjustable, with higher doses (20–30 mg once weekly) more efficacious than lower (7.5–15 mg).[1]

◆ Patients are more likely to stay on methotrexate longer, due to sustained efficacy, and good long-term tolerability.[38]

◆ It is available orally and subcutaneously. With intolerance of tablets, or limited efficacy, switching to subcutaneous injections improves bioavailability, increases efficacy, and decreases toxicity.[39]

◆ Methotrexate is cheaper than most other DMARDs, and considerably cheaper than biologics.

Not all new patients need to go onto methotrexate. In some there may be an absolute contraindication. The evidence for using methotrexate either alone or in combination has largely been generated in trials on 'active' RA (defined in different trials in different ways). Evidence is lacking in patients with milder or palindromic RA, where other monotherapies may be just as appropriate.[1,9]

Monotherapy or combination therapy?

There are disagreements between guidelines on whether methotrexate should be used as mono- or combination therapy in early RA. EULAR guidelines argue for initial monotherapy usually,[1] and NICE for combination therapy in early active disease[7] The arguments against combination therapies are:

◆ Methotrexate can work very effectively as a monotherapy.[1]

◆ Combination therapies have a higher rate of toxicity.[40] If drugs with similar side-effect profiles are administered concomitantly it is difficult to judge which drug might be responsible for a certain side effect (e.g. elevated alanine transaminase in a patient

Fig. 112.2 The joints included in the DAS28 and the form used for recording disease activity at the Royal Derby Hospital (United Kingdom). This consists of a tender joint count, swollen joint count, measure of inflammation (usually ESR, though a CRP version is available) and a visual analogue score of global health (1–100). The calculation is complex, but calculators are readily available (e.g. www.4s-dawn.com/DAS28/DAS28.html)

recently starting methotrexate and sulfasalazine). If combination therapy is effective it is difficult to know whether this is due to just one or more of the agents.

♦ Combination therapies are more expensive than monotherapies and may require more monitoring tests.

♦ A recent trial of step-up therapy starting with sulfasalazine compared with combination therapy from the start showed no significant differences in outcomes.[33]

Arguments for combination therapies include:

♦ They are more efficacious than monotherapies. A meta-analysis supported this.[40] The combination of methotrexate with biological therapies is more efficacious than the single drugs.[41] However, in many trials, steroids were included in the combination arm which might account for improved and more rapid outcomes.[1] Comparisons of combination therapies with monotherapies without steroids have sometimes not shown significant differences in efficacy.[1]

♦ They may extend the window of opportunity for influencing long-term outcomes, and should be used when there have been DMARD delays.[35]

♦ Combination therapies are more cost-effective than monotherapies, due to a greater ability to postpone the need for expensive biological therapies.[42] Four-year follow-up data from the BeSt study showed that 39% of sequential monotherapy patients needed to start infliximab and methotrexate at some stage during the follow-up period. However, in the sequential step-up combination therapy, only 11% went on to anti-TNF, and 20% of the combination therapy with tapered steroids,[43] suggesting that combination therapies are superior to monotherapies in decreasing the need for biologics.

♦ Some trials suggest sustained benefits for patients on combination therapy compared with monotherapies,[44,45] whereas others have shown a convergence of long-term outcomes irrespective of the initial treatment strategy.[46]

In deciding for each individual patient which is the appropriate treatment strategy, the most important principle is to suppress inflammation quickly and sustain this. All is well if this can be achieved with monotherapy.

Alternatives to methotrexate include sulfasalazine, leflunomide, and intramuscular gold injections.[1] In the EULAR guidelines these drugs were given priority over other DMARDs because systematic

reviews found no evidence that these drugs are inferior to methotrexate.[1] Hydroxychloroquine was deemed to be a weaker DMARD in isolation, and having a place in milder disease, or in combination therapy regimens, but showing inferiority to sulfasazine in inhibiting structural damage.[1] The ACR guidelines on DMARD therapy give a useful overview on DMARD combinations.[8] The best evidence is for methotrexate with hydroxychloroquine, leflunomide, or sulfasalazine, and triple therapy combining methotrexate with sulfasalazine and hydroxychloquine.[8]

The role of steroids

Steroids are the best way of getting active RA under rapid control, with greater potency than non-steroidal anti-inflammatory drugs (NSAIDs), because they act on numerous inflammatory pathways, not just antagonizing cyclooxygenase.[47] A meta-analysis has shown they are disease modifying, unlike NSAIDs.[48] They are often safe where there are contra-indications to NSAIDs (e.g. ischaemic heart disease, asthma, renal disease).

There are several ways of employing steroids.

- Inject inflamed joints as and when they occur, though the role of this approach is limited in active polyarthritis.

- Give regular intramuscular injections in the early phases of the disease, e.g. TICORA where active disease was treated with monthly injections up to a total of 120 mg of methylprednisolone either into inflamed joints or intramuscularly.[33]

- Give a tapered oral regimen, starting on a high dose and tailing this down as the disease is controlled, e.g. COBRA where patients start on 60 mg of prednisolone with methotrexate and sulfasalazine, and the steroids are gradually tapered subsequently.[45]

- Use longer-term low-dose steroids. There are no trials comparing high-dose tapered steroids against longer-term low-dose regimens.[1] Although steroids are invaluable in rapidly dampening active inflammation while waiting for other DMARDs to become effective, their long-term use should be avoided wherever possible. They are also useful in managing disease flare-ups, either in the early stages of attempting to induce remission, or in established disease. However, difficulties in weaning patients off steroids, or the need to use recurrent steroids for repeated flares of disease, should result in adjustments to other DMARDs.[7] The safety of glucocorticoids is an important aspect of the EULAR guidelines on the management of steroid treatment.[49]

In treating to target, all aspects of the patients and their disease need to be taken into account. Some patients may get a useful drop in DAS, yet still have ongoing grumbling synovitis that can damage joints. MRI evidence shows that patients 'in remission' can still erode joints due to clinically silent synovitis.[50] Early inflammatory arthritis EULAR guidelines advocate radiography of affected joints every 6–12 months to assess progression of joint damage.[51] DMARDs should be adjusted accordingly when there is ongoing structural damage, even if the disease activity appears to be well controlled. Likewise, in patients appearing to be in remission, any DMARD decreases should be performed slowly and cautiously, with ongoing documentation of both disease activity and structural damage on imaging.[52]

Biological agents

The introduction of biologics to RA and other inflammatory arthropathies has had a huge impact on improving the control of poor-prognosis and refractory disease. In RA, biologics have the following advantages over DMARDs:

- Most conventional DMARDs were discovered by serendipity, and there is ongoing debate on how they specifically work. Biologics were designed with an increasing understanding of the pathogenesis of RA to specifically block cytokines, cells, or interactions between cells that are critical in RA pathogenesis.

- Unlike conventional DMARDs where benefits are delayed, anti-TNF and other biologics can work quickly with symptom-relieving benefits, as well as profound disease-modifying capabilities in preventing disease progression.

- They can have dramatic benefits where conventional therapies have failed.

The disadvantages of biological therapies are:

- They are very expensive compared with conventional DMARDs.

- As monotherapies in early RA, they are no more efficacious than methotrexate, which makes it challenging to suggest that they are cost-effective.[53] They are better at slowing radiological progression than single conventional DMARDs, though a meta-analysis of anti-TNF vs conventional combination therapies suggests no significant differences.[54]

- They cannot be administered orally, which adds to costs for intravenous therapies, and inconvenience for subcutaneous drugs compared with tablets.

- They increase the risk of infections. For anti-TNF therapies this is particularly in the first 6 months of treatment,[55] but vigilance is required for emerging infections while patients continue on biologics. Specific infections such as tuberculosis (TB) need to be screened for at baseline as this decreases the risk.[56]

- There is concern over long-term administration of cytokine and cell blockers, particularly with regard to malignancies, and immunosuppression-associated rare infections (e.g. progressive multifocal leucoencephalopathy reports with rituximab[57]). Because anti-TNF therapies have the longest track record, considerable data have accumulated from national registers that are largely reassuring for the predisposition to solid malignancies and lymphomas, though concerns around increased risks of skin cancers remain, and patients need to be counselled about this.[58,59]

Anti-TNF therapies currently take precedence as they were the first RA biologics, and unlike some other biologics, are licensed for patients who fail on DMARDs. The best time to introduce anti-TNFs.is debatable. EULAR and ACR guidelines suggest a place for first-line use in patients with poor-prognosis RA.[1,8] However, there is a lack of biomarkers to accurately predict the course of RA, and some of these patients can do very well on standard DMARDs. Health economic modelling has largely failed to demonstrate that widespread use of first-line anti-TNF therapy is good use of limited healthcare resources.[53] Most health economies restrict anti-TNF use to patients who fail on conventional DMARDs (usually at least methotrexate), and have ongoing active disease (set differently across nations).[60] Other biologics are currently largely used in patients who have failed anti-TNF, because of licensing restrictions, or national guidelines. Health economic models could potentially lead to advocating first-line anti-TNF

use with accurate predictions of which patients would do badly on conventional therapies (with poor efficacy or high toxicity), and who would do well on anti-TNF. This would be even more cost-effective if anti-TNFs could induce remission and then be withdrawn and replaced by cheaper drugs. Infliximab could be used in this way, such as in the BeSt study, where 50% of patients were able to stop anti-TNF and be maintained on conventional DMARDs,[46] and sustained benefits over 8 years from a smaller study using 1 year of initial infliximab with methotrexate maintenance thereafter.[61] More research on biomarkers to predict disease course and response to therapies, and on the health economics of targeted early anti-TNF therapy, is needed, before health economies would advocate widespread use of early biologics. Alternatively, the price of biologics needs to drop considerably, with maintained evidence of long-term safety.

If widespread first-line anti-TNF therapy is currently unlikely, then should anti-TNF be introduced after the failure of one, or several DMARDs? The SWEFOT trial is informative. The addition of infliximab for patients who failed to reach low levels of disease activity after 3 months of methotrexate monotherapy resulted in better outcomes than the addition of sulfasalazine and hydroxychloroquine.[62] Furthermore, in the BeSt trial, patients in any arm who failed on methotrexate had only approximately a 12% chance of responding to other conventional therapies.[43] Consequently, patients failing on early DMARDs, particularly methotrexate, should have access to anti-TNF, instead of inappropriate faith in trials of more conventional DMARDs.

There are discrepancies in national guidelines on eligibility criteria for anti-TNF.[60] Most nations define active disease worthy of biologics as a DAS28 score greater than 3.2, whereas others, including the United Kingdom, pitch this cut-off at 5.1.[16,60] The latter level is inappropriately high, and should be reduced because:

◆ A sustained DAS28 between 3.2 and 5.1 is not benign disease, with radiological progression, functional decline, and loss of work not much less than patients with higher disease activity. If a patient on combination conventional therapy has a DAS28 greater than 3.2, they are not being controlled satisfactorily.[16,21,63]

◆ Patients with a DAS28 of less than 5.1 starting anti-TNF therapy do just as well as, if not better than, patients with higher DAS28, with decreased disease activity, and improved functional ability.[16,64,65]

If a patient fails on their first anti-TNF, either through toxicity, or no response (primary non-responders), or because of gradual loss of response (secondary non-responders), there is emerging evidence on the next-best strategy. For secondary non-responders, there may be a greater chance of responding to a second anti-TNF than for primary non-responders.[66] If patients have had adverse reactions to a first anti-TNF, there is a greater chance that they will have toxicity with a second.[67] Irrespective of why the first anti-TNF was stopped, patients may do better on rituximab as the second biologic compared to a second anti-TNF.[68] This appeals to healthcare funders because rituximab is significantly cheaper than anti-TNF if administered less frequently than 6 monthly.[69] Patients who are seropositive for RF and/or ACPA respond better to rituximab, though a health economic model from NICE still suggested it was more cost-effective to use rituximab in seronegative disease than a second anti-TNF.[69,70] For other biologics, rheumatologists are spoilt for choice. There are now five anti-TNFs (etanercept, infliximab,

adalimumab, golimimumab, certolizumab), a B cell depleter (rituximab), an IL-6 inhibitor (tocilizumab), a T-cell costimulatory molecule inhibitor (abatacept), and an IL-1 inhibitor (anakinra—though this is of lesser efficacy than other biologics, and consequently restricted access in some health economies). There are extremely limited head-to-head comparisons between these drugs, but indirect comparisons suggest similar efficacy in biologic-naive patients, and in patients failing on a first anti-TNF.[1,71] There are some differences in toxicity profiles that might lead a clinician to choose one drug over another,[72] but there is a need for further research to elucidate biomarkers that might guide clinicians on the best biologic for each patient, perhaps based on cytokine profiles, or cellular infiltrates in synovial biopsies,[73] or pharmacogenetics.[74] Currently the choice of biologics is governed by national guidelines and intuitive guess work.

Established disease: annual review

The NICE and British Society for Rheumatology (BSR) guidelines recommend that all patients with established disease have at least an annual review with the MDT in order to check for progression of articular disease, manifestations of extra-articular disease, emergence of comorbidities (particularly the increased risk of cardiovascular morbidity[75]), and the need for referrals to members of the MDT, such as physiotherapy, occupational therapy, podiatry, and orthopaedic surgery.[7,11] An overview of what this might include is in Table 112.1. Annual review also gives an opportunity to review medication to ensure ongoing efficacy with preferably remission, or at least a level of disease control that the patient finds satisfactory with minimal interference with their lives. For patients in remission, it should be considered whether they could be as well controlled with less DMARDs, either by stopping drugs if they are on combination therapy, or decreasing doses. The first priority should be to decrease steroids, or at least reduce the dose, in the minority of patients who have to stay on them long term. Any reduction should be performed cautiously and slowly. There may be opportunities to decrease biological agents also, tapering them down whenever possible, but with close monitoring to ensure ongoing excellent control, and restoring previous drug regimens if synovitis is returning.[1]

Complications of articular disease in which inflammation has been inadequately controlled include deformity of joints, pain due to mechanical damage, rupture of tendons (particularly finger extensors), and compression of nerves through synovial hypertrophy and deformity (e.g. carpal tunnel syndrome). Where pain and nerve compression cannot be controlled by conservative approaches, orthopaedic surgeons should be involved quickly to optimize surgical management plans. Where joint function is compromised by deformity or tendon rupture, the opinions of orthopaedic surgeons, physiotherapists, and occupational therapists, should be sought promptly.[7]

Conclusion

Influential guidelines on RA management agree on most key recommendations. Early diagnosis of persistent synovitis, and identification of poor prognostic markers, is essential. Rapid intervention is vital with drugs that suppress inflammation, slow down damaging disease components, and prevent disability.

Table 112.1 The components of an annual review

Assessment	Methods of assessment and references
Disease activity and drug assessment for efficacy and toxicity ◆ If in remission or low levels of disease activity, consider cautious reduction of DMARDs or biologics (including steroids if appropriate) ◆ If ongoing active disease, adjust or change DMARDs or biologics	DAS28 or similar validated measure of disease activity (see Figure 112.2[34])
Functional ability and damage to joints and soft tissues. Consider involving the MDT and Orthopaedics where appropriate. Cervical spine disease needs assessment[76]	Examination, radiographs, ultrasound, HAQ-DI[77]
Comorbidities such as hypertension, ischaemic heart disease, osteoporosis, depression	EULAR cardiovascular risk management guidelines[75] Osteoporosis guidelines (e.g [78,79]) Depression screening (e.g. Beck Depression Inventory)[80]
Check for extra-articular complications,[81] particularly: ◆ Anaemia of chronic disease, Felty's syndrome, drug-induced abnormalities, non-Hodgkin's lymphoma ◆ Pulmonary involvement; pleural disease, interstitial disease, cricoarytenoid joint involvement ◆ Cardiac involvement; pericarditis, myocardial disease ◆ Ocular involvement; keratoconjunctivitis sicca (Sjögren's syndrome), episcleritis, scleritis, ulcerative keratitis ('corneal melt') ◆ Neurological involvement; entrapment neuropathies, cervical myelopathy, peripheral neuropathy ◆ Hepatic and renal abnormalities, amyloidosis ◆ Vasculitis (e.g. skin and nailfold infarcts, ulcers, sensory neuropathy)	Full medical history and examination with urinalysis, blood screen, and other investigations as appropriate
Assess the effect the disease is having on the quality of the person's life, and their understanding of the disease and management	For example, quality of life measures (generic such as EQ-5D,[82] or disease-specific such as RAQoL[83]), ability to work, enjoy hobbies, participate fully in social roles, ability to manage their own condition, need for educational updates

DAS, Disease Activity Score; DMARD, disease-modifying anti-rheumatic drug; EQ-5D, EuroQol; HAQ-DI, Health Assessment Questionnaire Disability Index; MDT, multidisciplinary team.

The label of RA covers a broad spectrum of disease severity, and there is controversy on

◆ whether the same interventions are needed for all patients
◆ whether monotherapy or combination treatment is appropriate
◆ the role of steroids in RA
◆ the appropriate introduction of biological therapies.

Treating to specified targets is optimal evidence-based practice, where patients are reviewed regularly for disease activity assessments, and inadequate control rectified. Aiming for remission is the ultimate goal, though for some patients minimal disease activity may be appropriate. Patient education addressing self-management is important, and the MDT needs to be involved from the start to minimize the impact on quality of life of the patient.

For established disease, rapid access is important for flares, and to consider whether disease management could be improved. An intermittent overview of established disease is important with access to the MDT, and assessments for comorbidities and complications of the disease itself. An informed patient needs to be central to all decision making.

SECTION 11

Spondyloarthropathies

This page intentionally left blank

CHAPTER 113

Ankylosing spondylitis

Joachim Sieper

Introduction and definition

The hallmarks of ankylosing spondylitis (AS) are inflammation of the sacroiliac joints (SIJ) and spine associated with clinical symptoms such as pain and stiffness in the back, followed in a significant proportion of patients by new bone formation.[1] The name dates from around 1900 when a diagnosis could only be made clinically when a patient had already advanced ankylosis of the spine. With the increased use of radiography it became clear in the 1930s that the disease normally starts in the SIJ and that the SIJs are involved in at least 95% of patients.[2] On this basis radiographic sacroiliitis has become an important part for diagnosis and is an essential criterion in the 1984 modified New York classification criteria for AS (Figure 113.1).[3] But already by this time the term 'ankylosing spondylitis' was no longer really adequate because patients fulfilled these criteria just based on radiographic sacroiliitis, with or without ankylosis of the spine.

However, radiographs detect only structural damage as a consequence of inflammation and not inflammation itself. As a consequence the European Spondylarthropathy Study Group (ESSG) criteria[4] and the Amor criteria[5] for spondyloarthropathies already covered around 1990 patients with back symptoms but normal radiographs. The increasing use of MRI from the 1990s on made it quite clear that chronic changes visible on radiographs (structural damage) is preceded by inflammation,[6] often by several years. Finally, in 2009 the Assessment in Spondylo-Arthritis international Society (ASAS) published new classification criteria for axial SpA which cover both patients with and without radiographic sacroiliitis and for which active sacroiliitis as shown on MRI is an important finding (Figure 113.2).[7] Therefore, instead of AS the term axial spondyloarthritis (SpA) should rather be used in future, with AS being just one part of a continuous spectrum.[7,8]

The term SpA compromises traditionally different diseases such as AS, psoriatic arthritis, reactive arthritis, arthritis/spondylitis associated with inflammatory bowel disease (IBD), and undifferentiated SpA. These diseases have in common that patients present with a similar clinical picture, either predominantly axial or predominantly peripheral or as an overlap between these two patterns, and with a varying association with HLA B27.[9] Recently, ASAS developed and published, in addition to the already mentioned criteria for axial SpA, new classification criteria for predominantly peripheral SpA.[10] For such an approach the pattern of clinical presentation—either predominantly axial or peripheral—is more relevant and the absence or presence of predisposing or associated diseases such as IBD, psoriasis, or a preceding infection is just recorded. In the current chapter only axial SpA is discussed, and peripheral manifestations only if associated with axial disease.

Epidemiology

Axial SpA is a disease which starts normally in the third decade of life, rarely (<5%) at an age older than 45 years, but in 10–20% of patients even between the ages of 10 and 20 years.[11] Thus, mostly young people are affected early in the course of the disease. Interestingly, HLA B27-positive patients have the first symptoms about 10 years earlier in comparison to HLA B27-negative patients.[12]

The male/female ratio is estimated to be 2:1, in early cases without radiographic visible chronic changes approaching even 1:1, indicating that women—for unclear reasons—seem to develop chronic changes later and less often.[1]

The prevalence of axial SpA correlates directly with the prevalence of HLA B27[13,14] in a given population and has been estimated to be between 0.1% and 1.4% in different parts of the world.[9] Recent investigations from France,[15] the United States,[16] and Lithuania[17] showed that the overall prevalence of SpA (including axial and peripheral SpA) is similar to that for rheumatoid arthritis (RA).

No clear data are yet available about the relative prevalence of patients with non-radiographic (nr) axial SpA in comparison to those with radiographic axial SpA (fulfilling the modified New York criteria for AS) among the axial SpA group. Several projects have recently screened for axial SpA patients in primary care. If these patients were then referred to the rheumatologist the proportion of axial nr SpA was reported to be 25–60%, confirming that this a relevant subgroup.[18–20] The progression from non-radiographic to radiographic sacroiliitis has recently been estimated to be around 12% over a follow-up period of 2 years.[21] There is still a gap of 5–10 years between the onset of symptoms and a diagnosis of AS in these patients,[11] probably because diagnosis relied in the past mostly on the presence of structural damage as seen on radiographs.

Classification criteria and diagnosis

For classification and partly also for diagnosis of AS, the 1984 modified New York criteria for AS have been used in the past.[3] The presence of radiographic sacroiliitis (at least either grade 2 bilaterally or grade 3 unilaterally) is essential for the fulfilment of these criteria, plus one clinical criterion: either morning stiffness with improvement by exercise but not by rest or restriction of spinal mobility (Figure 113.1). However, both radiographic sacroiliitis and restriction of spinal mobility occur relatively late in the course of the disease and therefore these criteria are not suitable for classification/diagnosis of early cases. These are included in the recently developed ASAS criteria for axial SpA which cover patients with and without radiographic changes in the SIJ (Figure 113.2).[7] These criteria should be applied in the presence of chronic back pain (> 3 months) starting at an age younger than 45 years. Sacroiliitis on imaging remains important, not only if visible on radiographs but also when subchondral bone marrow oedema as evidence of active bony inflammation can be seen on MRI (Figure 113.3).[22]

Although the imaging arm has good specificity (97.3%) the sensitivity is not optimal (only 66.2%). Therefore a clinical arm was added which is fulfilled if a positive HLA B27 is present plus two other SpA-typical features, always in the presence of chronic back
Fig. 113.3 MRI of sacroiliac joints (SIJ): active sacroiliitis (hyperintense signal) shown on a short tau inversion recovery (STIR) MRI sequence in the ileum and in the upper part of the sacrum of the right SIJ.

pain starting at an age less than 45 years. With both arms these new criteria reach a specificity of 84.4% and a sensitivity of 82.9%.

There are differences between classification criteria and a diagnosis of a certain disease. Classification criteria always give a clear yes/no answer (fulfilled or not), with the aim of getting a relatively homogenous population for inclusion into a clinical trial, for example. A diagnostic approach has to be more flexible, resulting in certain probabilities that a diagnosis can be made, dependent on the number and nature of the parameters being positive (positive likelihood ratio). Furthermore, for diagnosis negative findings should also be taken into account, which is not the case for classification criteria. Finally, the pretest probability of a disease needs to be known if parameters are used for diagnosis, while the pretest probability does not matter for classification criteria because the diagnosis should already have been made before inclusion into a trial.[8] Two overlapping possible diagnostic approaches have been proposed. For the first one, presence or absence of all for axial SpA-relevant parameters are looked for and weighted according to the likelihood ratio (calculated from the sensitivity and specificity of this patameter) and the post-test probability can be estimated based on an assumed pretest probability of 5% for axial SpA among patients presenting with chronic back pain.[8] In Figure 113.4 a more structured diagnostic approach is presented with the evaluation of clinical parameters coming first, together with radiographs of the SIJ, followed by laboratory parameters such as HLA B27 and C-reactive protein (CRP) and, finally, by MRI.[23]

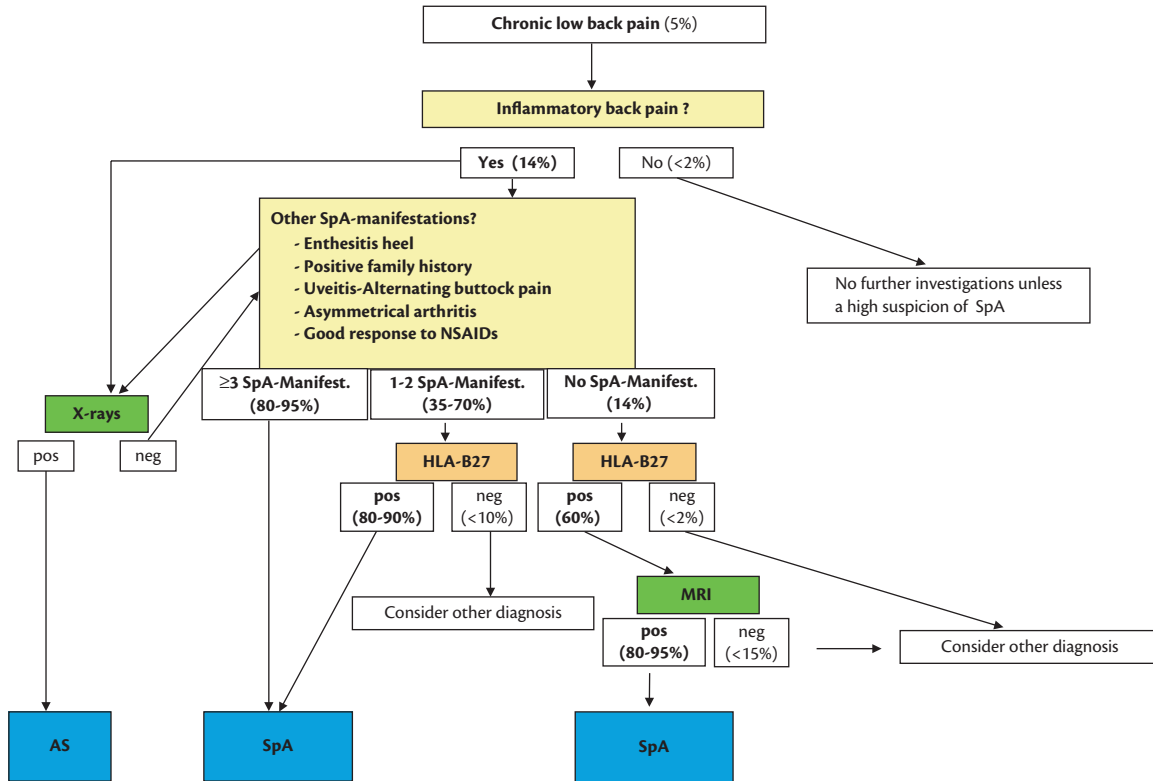
Both for classification and diagnosis MRI has become an important new tool for axial SpA, especially for active inflammatory lesions (subchondral bone marrow oedema). To make this visible one of the following MRI sequences must be used: short tau inversion recovery (STIR), T2-weighted sequence with fat suppression, or T1 sequence with application of a contrast agent (such as gadolinium) with fat suppression. In many centres the STIR sequence is preferred and is normally sufficient. A positive MRI of the SIJ (active inflammation) has been defined as the presence of subchondral bone marrow oedema at at least two sites or


Fig. 113.4 Diagnostic algorithm in axial spondyloarthritis.
With permission from British Medical Journal and with permission from ASAS.

one site visible on at least two subsequent slices.[22] An example of a clearly positive MRI is show in Figure 113.3. Obviously, differential diagnosis of diseases which can also cause subchondral bone marrow oedema, such as mechanical burden, infection, and/or tumour, has to be taken into account and should be excluded. More recently, more attention has also been paid to T1 sequences which can show early chronic changes such as replacement of bone marrow by fatty lesions and/or erosions.[24] However, at the moment the exact value of T1 findings in a diagnostic approach has not yet agreed on.

Normally the spine is affected later in the course of the disease, so classification criteria focus on the SIJ. In the spine, as in the SIJ, the disease starts with inflammation, such as spondylitis anterior, spondylitis posterior, spondylodiscitis or involvement of the facet joints.[25] Figure 113.5 shows a typical example of a patient with advanced disease with multiple syndesmophytes.

An **elevated CRP** (or erythrocyte sedimentation ratio, ESR) is found in only about 60% of AS patients who are clinically active, although CRP-positive patients seem to have a worse prognosis regarding radiographic progression on the one hand,[21] but respond better to TNF blocker treatment on the other hand[26] (see also below).

Recently **referral parameters** have been proposed and have been tested in primary care in patients presenting with chronic back pain. If symptoms start at an age lower than 45 years and if the patient complains about inflammatory back pain and/or if the patient has been tested positive for HLA B27, a diagnosis of

Fig. 113.5 Radiographs of the spine: lateral radiograph view of the lumbar and lower thoracic spine with widespread syndesmophyte formation in a patient with ankylosing spondylitis.

axial SpA was made in 25–60% of these patients after referral to a rheumatologist.[18–20,27]

Aetiopathogenesis

It has been estimated that about 90% of the pathogenesis of AS is genetically determined and that the contribution of HLA B27 is about 50% of the genetic risk, making HLA B27 by far the most important risk factor.[28] The chance of developing AS/SpA in HLA B27-positive individuals is about 5%, in HLA B27-positive first-degree relatives from AS patients it is 12–20%, but in HLA B27-negative relatives from AS patients it is less than 1%.[29] However, despite intensive research, the role of HLA B27 in the pathogenesis of AS/SpA has not yet been clarified.[9,30,31] More than 30 HLA B27 subtypes have been described and HLA B2705, B2702, and B2704 are the ones most often be associated with AS. Interestingly, HLA B2709—present in Sardinia—and HLA B2706—present in Asia—are not associated, although they differ by only one or two amino acids in the peptide-binding groove of the molecule from the disease-associated subtypes HLA B2705 or HLA B2704, respectively. These findings suggest that presentation of certain peptides by HLA B27 to T cells can explain the pathogenesis, although such peptides have not yet been identified. However, HLA B27 subtyping does not have any relevance for daily clinical practice. Further hypotheses are based on the fact that HLA B27 can behave differently from other HLA molecules. The 'HLA B27 misfolding' hypothesis claims that misfolding of the HLA B27 heavy chain in the cytoplasm induces a rather non-specific inflammatory reaction, and the 'B27 homodimer' hypothesis suggests that the B27 heavy chains can form homodimers on the cell surface which can then also present peptides to T cells, but in this case to CD4+ T cells.

ARTS-1 (endoplasmatic reticulum amino peptidase), a peptide relevant for processing peptides in the cytoplasm of cells, and IL-23 receptor (R) genetic polymorphisms have also been associated with AS.[30] The relative contribution of the genes to the susceptibility to AS can be estimated by using the population-attributable risk fraction analysis, which is 90% for HLA B27, 26% for ARTS-1, and 9% for IL-23.[32] Most recently it was found that the ARTS-1 polymorphism is only relevant in HLA B27-positive but not HLA B27-negative patients, indicating that the interaction between peptide processing and peptide presentation might play a relevant role in the pathogenesis of AS.[33] Associations of other genes with AS have also been described,[9] but they are less strong than the ones discussed here.

AS/SpA can be found worldwide and its occurrence is predominantly dependent on the frequency of HLA B27 in a given population. Therefore, the environmental factors contributing to the pathogenesis are probably rather non-specific. Because AS can occur after a preceding reactive arthritis (ReA) or in the context of IBD and exposure to bacteria (bacterial infection of the urogenital or gastroenteral tract in case of ReA, or exposure to gut bacteria because of a damaged mucosa in case of IBD) bacteria seem to be an important environmental factor.[1] Although present or past ReA and IBD can normally only be found in less than 10% of AS patients it has been claimed that sublinical IBD[34] or subclinical chronic infections with bacteria such as chlamydia[35] are much more prevalent.

Numerous MRI studies in recent years,[6] supplemented by immunohistological investigations, suggest that the primary inflammation in AS takes place in the subchondral bone marrow at the cartilage–bone interface.[36] Indeed, mononuclear cell infiltrates were found only if cartilage was left on the bone surface when femoral heads from AS patients were investigated histologically, indicating that cartilage (antigens) might be a primary target of the immune process.[37] However, it is currently not clear how HLA B27, bacterial exposure, and cartilage interact and which part of the immune system is responsible for the link between these components. An additional necessary and possibly initiating factor might be microtrauma of cartilage/bone at weightbearing parts of the skeleton, which are almost exclusively affected in AS/SpA.[38]

Inflammation in the bone can be followed by new bone formation as part of a repair process. Once inflammation has caused damage of the bone, the process of new bone formation can probably no longer be influenced and/or prevented by anti-inflammatory drugs such as TNF blockers.[39] The molecular basis of the interaction between inflammation and new bone formation is currently not clear but is under intensive investigation.[40]

Clinical features

Spinal symptoms—pain and stiffness

The symptoms are dominated by pain and stiffness in the spine, focusing on the lower back, reflecting inflammation in the SIJ and/or lumbar spine. Mostly later in the course of the disease the thoracic and cervical spine can also be affected.[1] Typical is the so called 'inflammatory back pain' (IBP) which is characterized by morning stiffness (normally >30 minutes) which improves with exercise but not with rest, and/or by awakening in the second half of the night because of back pain. This kind of pain starts normally at an age less than 45 years. Several sets of clinical criteria for the characterization of IBP have been developed (Figure 113.6),[41–43] with comparable sensitivity and specificity. However, these do not go beyond about 80% each, clearly indicating that the presence of IBP alone is

Calinet al.[1]	Rudwaleit et al.[2]	IBP experts (ASAS)[3]
• age at onset < 40 yrs	• morn. stiffness > 30 min	• age at onset < 40 yrs
• duration of back pain > 3 months	• improvement with exercise, not with rest	• insidious onset
• insidious onset	• awakening at 2. half of the night because of pain	• improvement with exercise
• morning stiffness	• alternating buttock pain	• no improvement with rest
• improvement with exercise		• pain at night (with improvement upon getting up)
IBP if 4/5 are present.	**IBP if 2/4 are present.**	**IBP if 4/5 are present.**

not sufficient for the diagnosis of SpA and that absence of IBP does not exclude a diagnosis of axial SpA.

Disease activity is normally measured by using the Bath Ankylosing Spondylitis Activity Index (BASDAI) which is a composite index from 0 (= no symptoms) to 10 (= maximal symptoms) on a numeric scale.[44] The BASDAI is a patient-based questionnaire including questions about fatigue, pain in the spine, pain at peripheral joints and entheses, and morning stiffness (Figure 113.7). Function is measured, again by using a patient-based questionnaire, using the Bath Ankylosing Spondylitis Functional Index (BASFI) on a similar numeric rating scale between 0 and 10.[45] Recently, ASAS has developed and proposed a new Ankylosing Spondylitis Disease Activity Score(ASDAS) which includes the CRP value as well as patients' reported outcome measures (Figure 113.8).[46,47]

Restriction of spinal mobility

Restriction of spinal mobility and function is caused early in the course of the disease by inflammation in the axial skeleton, but later on by new bone formation in the spine.[48] Most typically, syndesmophytes develop from the corner of the vertebral bodies, potentially resulting in an ankylosis of the spine. But ossification of the facet joints, for example, can also contribute to restriction of spinal mobility. However, it must be emphasized that only a small proportion of patients with axial SpA develop an advanced ankylosis. Spinal mobility should be measured using the established Bath Metrology Ankylosing Spondylitis Index (BASMI), which quantifies forward motion of the lumbar spine (modified Schober test), lateral flexion of the lumbar spine, tragus to wall (or occiput to wall) distance, cervical rotation and intermalleolar distance (measuring mobility of the hip joint). A BASMI score between 0 (no restriction) and 10 (maximal restriction) is preferred[49] over a score between 0 and 2 because the former is more sensitive to change. In addition, chest expansion (difference between inspiration and expiration) can be measured in the fourth intercostal level anteriorly.[25]

Long-term outcome is closely related to formation of syndesmophytes in the spine, potentially resulting in ankylosis. The strongest predictor for syndesmophyte progression on follow-up is the presence of syndesmophytes at baseline.[50,51] Interestingly, an elevated CRP has most recently also been be associated with radiographic progression both of the spine[51] and the SIJ.[21]

In more advanced disease osteoporosis of the spine, can occur with the potential consequence of osteoporotic fractures.

Calculation of the ASDAS

ASDAS$_{CRP}$

$$0.12 \times \text{Total Back Pain} + 0.06 \times \text{Duration of Morning Stiffness} + 0.11 \times \text{Patient Global} + 0.07 \times \text{Peripheral pain/Swelling} + 0.58 \times \text{Ln(CRP+1)}$$

ASDAS$_{ESR}$

$$0.08 \times \text{Total Back Pain} + 0.07 \times \text{Duration of Morning Stiffness} + 0.11 \times \text{Patient Global} + 0.09 \times \text{Peripheral pain/Swelling} + 0.29 \times \sqrt{\text{ESR}}$$

ASDAS$_{CRP}$ is the preferred ASDAS but the ASDAS$_{ESR}$ can be used in case CRP is not available.

CRP in mg/l; all patient assessments on a 10 cm scale.

Extraspinal rheumatic manifestations

Peripheral arthritis—often transient—is reported by about 30% patients with axial SpA. Typically, the arthritis is asymmetrical and affects predominantly the lower limbs. Mono- or oligoarthritis is most frequent, but polyarthritis is possible. Structural bone damage such as erosions or ankylosis is rare in peripheral joints.[1,52]

Enthesitis

Inflammation at the insertion sites of tendons or ligaments at bone is called enthesitis and is a typical manifestation in any SpA, including axial SpA patients. Enthesitis is reported in 30–50% of patients with axial SpA/AS. Similarly to arthritis, it occurs predominantly at the lower limbs, such as the insertion site of the Achilles tendon or the plantar fascia at the calcaneus or in the pelvis, but it can also occur in the upper limbs, such as the elbows or at the insertion of the supraspinatus tendon at the greater tuberosity of the humerus.[10,52] Enthesitis is normally quite painful and can be accompanied by a considerable restriction of function, especially if occurring in a lower limb. Swelling is normally only observed if the adjacent soft tissue, such as the bursae, is also affected. Currently there is no general agreement on which imaging method can or should be used for the investigation of enthesitis. MRI seems to be superior for the detection of subchondral bone marrow oedema, while ultrasound seems to be better for the investigation of soft tissue inflammation.

Extra-articular manifestations

Current or history of uveitis anterior can be found in 30–40% of AS patients. Flares of uveitis are reported in 15–20% of AS patients per year. Uveitis is typically anterior, sudden in onset (painful red eye), acute, self-limiting, and unilateral but alternating from one eye to the other.[53]

A concomitant diagnosis of psoriasis is found in about 10% and of IBD in about 5% of AS patients. Psoriasis and IBD most often, but not always, precedes the diagnosis of AS.

Other organs can be involved such as kidney, lung, or heart, but these are rare manifestations.[1] Whether these manifestations are related to the level of clinical disease activity and inflammation is not known, but seems to be likely. Amyloidosis can occur in patients who are highly active over a long time.

Management

Recently, an updated version of the ASAS/EULAR recommendations for the management of AS[54] (Figure 113.9) and of the more specific ASAS recommendation for the treatment of axial SpA with TNF blockers[55] have been published (Figure 113.10).

Physiotherapy

This is still an important part of the treatment strategy. It helps to improve spinal mobility and to reduce pain and stiffness in the spine. Patients should be educated by a physiotherapist about an exercise programme and should carry this out daily, long term. Exercises concentrate on extension and rotation of the spine to prevent fixed flexion of the spine.

Non-steroidal anti-inflammatory drugs

NSAIDs form the basis of drug treatment. Their efficacy has been proven in many trials and is most probably due to their anti-inflammatory properties.[56,57] There is no evidence that one NSAID, including the COX-2 selectives, is better than another. However, for unknown reasons patients might respond differently to available NSAIDs and treatment with at least two should have been tried before a patient is regarded as being NSAID-refractory. As long as patients are symptomatic and the NSAID is well tolerated, patients should be treated with a full dose on a daily basis. Upper dose limits of NSAIDs normally used for the treatment of AS have recently been published.[58] A small reduction of the CRP serum level in AS patients treated with NSAIDs has been reported.[59]

There is also evidence from one prospective randomized clinical trial (RCT) that patients treated with continuous (daily) NSAIDs show less radiographic progression in the spine over a 2 year follow-up period compared to patients treated only on demand.[60] However, further confirmation of this interesting finding is needed before definite conclusions can be drawn. Thus, currently the aim in the treatment of axial SpA patients with NSAIDs is to get the patient free of symptoms.

There is less data about the efficacy of NSAIDs for the treatment of peripheral SpA manifestations such as peripheral arthritis or enthesitis, but they are nonetheless used as first-line treatment here also.

Glucocorticoids

Steroids do not play a major role in the treatment of axial SpA. Normally a dose of 20–30 mg prednisolone per day, a treatment quite effective in RA, for example, shows only a small or no effect on spinal symptoms. Glucocorticoid treatment might be tried for peripheral arthritis, while its effect in enthesitis is less clear. Short-term effects of high-dose glucocorticoid pulse therapy has been reported but its long-term effect is not clear and has not been studied in a controlled trial. Local glucocorticoid injection in the SIJ, peripheral joints, or entheses can be effective and should be considered especially when just one site is affected.[54]

Disease-modifying anti-rheumatic drugs

Similarly to steroids, conventional disease-modifying anti-rheumatic drugs (DMARDs) such as methotrexate, sulfasalazine, or leflunomide have shown no efficacy in the treatment of patients with AS or axial SpA.[54]

TNF blockers

Treatment with a biological TNF blocker is quite effective in patients with active AS who fail conventional therapy such as NSAIDs. In addition to the already mentioned BASDAI, BASFI, and ASDAS the ASAS improvement criteria are used for the evaluation of a treatment effect in clinical trials. For this, four domains—patient global, pain, function, and inflammation (the mean value for questions 5 and 6 on morning stiffness in the BASDAI)—are used. ASAS 20 (%), ASAS 40 (%), and ASAS partial remission are the normal improvement criteria.[61,62] An ASAS 40 or a BASDAI 50 (%) improvement is seen in 40–50% of patients treated with any of the approved TNF blocking agents: infliximab (5 mg/kg body weight intravenously every 6–8 weeks),[63] etanercept (50 mg subcutaneously once a week),[64] adalimumab (40 mg subcutaneously every other week),[65] or golimumab (50 mg subcutaneously once a month).[66] An improvement of clinical symptoms can often be observed after a few days, and a plateau of the clinical response rate is normally reached after 3–6 months of treatment. Follow-up data from the first clinical TNF blocker trials are now available for up to 8 years without new or specific safety signals over time. Between 10 and 20% of patients per year stop TNF blocker treatment in the clinical trial follow-ups and in the registries. The reasons for stopping are side effects, inefficacy, and others, but no specific reason is obvious. For those who stay on the drug a further small improvement of signs and symptoms can even be observed over the years. Small clinical trials and clinical experience indicate that in a proportion of patients the interval between the injections can be prolonged. This should be considered after about 6 months if patients are in remission. The interval should be adjusted to the patient's symptoms. Normally patients can tell quite accurately when symptoms come back. However, it is not clear at the moment in how many of the patients an interval prolongation (or a dose reduction) is possible. About 80–90% of patients relapse if TNF blockers are withdrawn completely.

Objective signs of inflammation such as CRP or active bone inflammation on MRI also improve considerably, although the reduction of the MRI-visible inflammation is reached only by 70–80% of patients and only a minority of AS patients become free of inflammation on MRI when treated with a TNF blocker.[67,68]

There have been reports in AS that immunogenic antibodies can develop against TNF blockers, especially against the monoclonal antibodies,[69] which can reduce efficacy and might increase the likelihood of a hyperergic reaction to the drug. It has therefore been discussed, based on data from combination therapies in RA and Crohn's disease, that combining TNF blocker treatment with a DMARD might increase efficacy. However, two trials comparing infliximab treatment alone vs infliximab plus methotrexate did not show superiority for the combination therapy.[70,71] Thus, currently TNF blockers should be given only as monotherapy in AS.

Although the development of immunogenic anti-drug antibodies might be overcome by increase of the drug dose in some cases, this has not been formally tested and the role of dose increase in case of inefficacy or loss of efficacy has not been well investigated. However, if treatment is switched from one TNF blocker to another an ASAS 40 response rate can still be expected in 38% of patients (compared to 59% in case of no prior TNF blocker exposure) in one investigation.[72] Patients respond better if response is lost over time compared to patients who show no response at the start of treatment. In another report a decrease of the BASDAI by 2 points was still observed in patients who switched to a second and third TNF blocker in comparison to a decrease of 3 BASDAI points in patients on their first TNF blocker.[71]

Some of the other biologics which are effective in RA have also been tested in AS. Anakinra,[73] rituximab,[74] abatacept,[75] and monoclonal antibodies against the IL-6 receptor are not effective in AS. Trials with other biologics directed against IL-17 or against the p40 chain of IL-12 and IL-23, for example, are currently ongoing.

More recently, TNF blocker trials have also been performed in patients, or including patients, with non-radiographic axial SpA. The clinical response rate was even higher in these trials compared to AS patients (with radiographic sacroiliitis) with a clinical remission rate of up to 50%.[76–78] A good response on MRI inflammation in the SIJ and/or spine was also found. Currently several phase 3 clinical trials with the TNF blocking agents that are approved for AS are under way in patients with non-radiographic axial SpA according to the ASAS classification criteria with the aim to get an extension of the AS label. In 2012, adalimumab became the first TNF blocker to be approved by the European Medicine Agency (EMA), based on the results of a phase 3 trial,[79] for the treatment of adults with severe axial SpA without radiographic evidence of AS but with objective signs of inflammation by elevated CRP and/or MRI, who have had an inadequate response to, or are intolerant to, NSAIDs.

TNF blocker treatment did not retard formation of syndesmophytes if AS patients were treated over 2 years.[80] Whether this is

the case when patients are treated earlier before the occurrence of early structural damage or whether TNF blockers have to be combined with other treatments to avoid new bone formation has yet to be seen.

Prediction of response to TNF blockers

In the analysis of several AS trials and one study in patients with non-radiographic axial SpA, short symptom duration (overlapping with young age at time of treatment) and elevated CRP performed very consistently best as predictors for a good clinical response.[80] Better function was also predictive, probably indicating reversible changes.[26] Active bone inflammation on MRI and positivity for HLA B27 were less predictive, and less consistent in the different analyses. Furthermore, in two trials in patients with axial SpA (including patients with nr axial SpA) using active MRI inflammation and short symptom duration as an essential inclusion criterion, clinical remission was reached in 50%, confirming that short symptom duration and objective signs of inflammation (such as positive CRP and/or inflammation on MRI) are the most important predictors.[77,78] It has also been proposed that these prediction parameters can be combined in a kind of matrix to predict response even better.[81]

Effect of TNF blocker treatment on peripheral and extra-articular manifestations

Manifestations of peripheral SpA such as arthritis, enthesitis, or dactylitis were not primary outcome parameters in any of the AS trials. However, an improvement was reported in most of the studies, although this was mostly non-significant, probably because of the small number of patients in these subgroups.

Infliximab, etanercept, and adalimumab have also been approved for the treatment of psoriasis; infliximab and adalimumab are licensed for the treatment of Crohn's disease and ulcerative colitis. Thus, it can expected that these associated manifestations, if present, also improve when patients are treated with a TNF blocker licensed for this indication. No controlled trials are available for the treatment of active uveitis anterior; however, the flare rates are reduced if AS patients are treated with a TNF blocker.[82–84]

Recommendations for the treatment of AS/axial SpA with TNF blockers

ASAS has recently updated the international recommendations for the treatment of active AS.[55] Failure of conventional treatment includes only NSAIDs; no previous DMARD therapy is asked for the axial manifestations. Importantly, the correct diagnosis now includes, in addition to AS according to the modified New York criteria, also patients who fulfil the new ASAS criteria for axial SpA (Figure 113.3), based on the published results on the good efficacy of TNF blockers in this indication. The judgement on disease activity is based on an elevated BASDAI (≥4), but should be supplemented by a positive expert opinion, normally based on other (objective) signs of inflammation such as CRP, MRI-visible inflammation, or other clinical manifestations. The expert is normally the treating rheumatologist with experience in spondyloarthritis and in TNF blocker treatment. Response should be assessed after at least 12 weeks of treatment, which should be continued if there is an improvement in the BASDAI of at least 50% or an improvement of at least 2 points on the 0–10 BASDAI scale.

National recommendations e.g. in the United Kingdom,[85] Canada,[86] and the United States (www.spondylitis.org/physician_resources/guidelines.aspx) have normally followed these ASAS recommendations, partly with small modifications, but have not yet extended the indication to patients with axial SpA according to the ASAS criteria. The British National Institute for Health and Clinical Excellence (NICE) (www.nice.org.uk/143) recommends only adalimumab or etanercept for the treatment of severe active AS if all of the following criteria are fulfilled: (1) diagnosis of AS according to the modified New York criteria; (2) sustained active spinal disease demonstrated by a BASDAI score of at least 4 and at least 4 cm on the 0–10 pain visual analogue scale; (2) these should be demonstrated on two occasions at least 12 weeks apart; (4) conventional treatment with two or more NSAIDs taken sequentially at maximum tolerated or recommended dosage over 4 weeks has failed to control symptoms.

Conclusion

The new term 'axial spondyloarthritis' comprises both patients with early inflammation in the SIJ and patients with radiographic evidence of sacroiliitis. New diagnostic approaches and new classification criteria have been developed to cover the whole group and to allow an early diagnosis. Active inflammation of subchondral bone marrow as shown on MRI plays an important role for early diagnosis. HLA B27 is the strongest known pathogenetic factor. Symptoms are present predominantly in the pelvis and the spine, but extraspinal manifestations are frequent. Besides regular physiotherapy there are only two types of drugs which have been proven to be effective: NSAIDs and TNF blockers. Recommendations for the treatment of ankylosing spondylitis and axial SpA with TNF blockers have been developed.

Psoriatic arthritis

Laura C. Coates and Philip S. Helliwell

Introduction

Although inflammatory arthritis associated with psoriasis has been recognized for many years, there was controversy about whether it represented a separate disease entity, or simply the co-existence of rheumatoid arthritis (RA) and psoriasis. Psoriatic arthritis (PsA) was recognized as a separate disease by the American Rheumatism Association (now the American College of Rheumatology) in 1964, and is now classified as a member of the spondyloarthropathy spectrum.[1,2] PsA was initially defined by Moll and Wright as 'an inflammatory arthritis in the presence of psoriasis with a usual absence of rheumatoid factor',[3] but more robust classification criteria have now been developed.[4] Although it was thought initially to be a relatively benign disorder, more recent work has demonstrated the destructive and progressive nature of the disease with increased mortality and significant cardiovascular comorbidity. At the same time advances in treatment, and in particular with biological drugs, have provided effective tools with which to control the disease.

Epidemiology

Although there is a relative paucity of research in this area, it has been suggested by multiple studies that the prevalence of arthritis in patients with psoriasis, particularly those with peripheral inflammatory arthritis, is higher than population controls.[5] In the Norfolk Arthritis Register (NOAR) cohort, the prevalence of psoriasis was 9.5% in patients with new-onset arthritis, higher than in the general population.[6]

A number of studies have attempted to estimate the incidence and prevalence of PsA but results have varied. A systematic review of papers revealed a median incidence rate of 6 per 100 000 population (range 0.1–23) and a median prevalence of 180 per 100 000 population (range 1–420).[7] However, there is an increase in the incidence and prevalence of PsA,[7,8] possibly as a result of increased recognition.

Among patients with psoriasis, the prevalence of PsA has been reported as varying between 6% and 42%,[9] highlighting the variable definitions used in these studies. However, the development of the CASPAR criteria has provided a more robust tool for classifying disease and a recent study showed a prevalence of approximately 14% when using these criteria among patients with psoriasis in a community setting.[10]

Recently, significant research effort has been invested into the development of screening tools to identify PsA among populations of psoriasis patients.[11] These instruments are self-completed questionnaires which, when scored, provide cut-offs for detecting PsA: they are used to identify patients who should be referred to rheumatologists. The use of such tools should increase the identification of PsA as it is known that cases of PsA exist undiagnosed in dermatology clinics.[12] This work has been given further impetus by the finding of asymptomatic ultrsonographic enthesitis in psoriasis patients.[13]

The majority of patients develop psoriasis prior to the onset of arthritis, even though it may not have been diagnosed by a physician previously. However, up to 20% of patients develop arthritis first, which may cause misdiagnosis and confusion until the psoriasis becomes apparent.[14] A longitudinal cohort over a 30 year period found the following clinical features were associated with the development of PsA: psoriatic nail changes, scalp psoriasis, and intergluteal/perianal psoriasis.[15] No specific association with subtype of psoriasis was found. Also of interest is the usual lack of association between disease activity in the skin and joints, although clinical anecdote suggests that this may occur in those cases which have simultaneous appearance of skin and joint disease.

Classification

The concept of the spondyloarthropathies (SpA) was first introduced by Moll and Wright in the 1970s.[16] Anklyosing spondylitis (AS) is considered as the 'prototype' SpA with typical features such as sacroiliitis, a high prevalence of HLA B27, and only minimal clinical variation. However, PsA shows significant clinical heterogeneity, which provides additional challenges for classification. New classification criteria are either 'standalone' such as the CASPAR criteria (see below) or the inclusive axial and peripheral spondyloarthropathy criteria which subsume PsA.[17]

The CASPAR criteria (Table 114.1) include characteristic dermatological, clinical and radiological features and have both high sensitivity and very high specificity.[4] Reassuringly, the Moll and Wright criteria are nested within the CASPAR criteria. Despite the wide acceptance of the CASPAR criteria a number of areas require further clarification. First, there have been doubts on the suitability of the criteria for early disease,[18] but a recent study found good sensitivity/specificity for these criteria in people presenting with less than 2 years of disease.[19] Secondly, the criteria have inevitably been used as diagnostic criteria and, although they were not designed for this purpose, there is some evidence that they work

Table 114.1 The CASPAR criteria

Inflammatory articular disease (joint, spine, or entheseal), with three or more points from the following:		
1. Evidence of psoriasis (one of a, b, c)	(a) Current psoriasis[a]	Psoriatic skin or scalp disease present today as judged by a rheumatologist or dermatologist
	(b) Personal history of psoriasis	A history of psoriasis that may be obtained from patient, family doctor, dermatologist, rheumatologist, or other qualified healthcare provider
	(c) Family history of psoriasis	A history of psoriasis in a first- or second-degree relative according to patient report
2. Psoriatic nail dystrophy		Typical psoriatic nail dystrophy including onycholysis, pitting and hyperkeratosis observed on current physical examination
3. A negative test for rheumatoid factor		By any method except latex but preferably by ELISA or nephelometry, according to the local laboratory reference range
4. Dactylitis (one of a, b)	(a) Current	Swelling of an entire digit
	(b) History	A history of dactylitis recorded by a rheumatologist
5. Radiological evidence of juxta-articular new bone formation		Ill-defined ossification near joint margins (but excluding osteophyte formation) on plain radiographs of hand or foot

Specificity 0.987, sensitivity 0.914.
[a]Current psoriasis scores 2 whereas all other items score 1.

well in this context.[20] Thirdly, the criteria are only applicable to people with inflammatory musculoskeletal disease: defining what is meant by this requires further work.

Clinical spectrum

PsA is a heterogenous disease and there have been a number of attempts to subgroup patients according to their clinical presentation. Moll and Wright described the five classic subgroups (monoarthritis/oligoarthritis, distal interphalangeal (DIP)-predominant disease, RA-like polyarticular disease, pure axial involvement, and arthritis mutilans) (Figure 114.1).[3] More recently it has become clear that these groups are not robust and can change with time and treatment.[21] It is also clear that assessing joints with other modalities, such as imaging, can alter the subgroup to which patients belong, ultrasound being more sensitive than clinical examination.[22] A more simple grouping of patients into axial and peripheral, with the latter divided into oligo- and polyarthritis, has the advantage of simplicity and may provide a better basis to take forward as there is evidence that a polyarticular onset is associated with a worse outcome.[23]

Certain clinical features suggest PsA. Common presentations are oligoarticular disease, with perhaps just one or two very swollen joints, nail disease, and enthesitis. The presence of dactylitis is very suggestive, although other causes of dactylitis (such as gout, sarcoid, and tuberculosis) should be considered in the differential diagnosis.[24] DIP involvement can be misleading as inflammatory osteoarthritis (OA) in this joint can look identical: sometimes the age of the patient and the lack of family history of OA indicate the significance of involvement at this joint. Symmetrical polyarthritis is probably the most frequent subtype of PsA and overlap with RA can lead to misidentification and problems with nosology. It is of paramount importance to take a good family history and to inspect both nails and 'hidden' areas for psoriasis, particularly the natal cleft (Figure 114.2). Despite typical clinical presentations,

rheumatologists in practice still overlook some of the vital clinical signs.[25]

The foot is commonly involved in PsA and first presentation may be to a podiatrist. PsA may present with dactylitis (more common than in the hands), enthesitis (at the calcaneum but also at the insertion of tibialis posterior and peroneus brevis), arthritis (in metatarsophalangeal and midtarsal joints), and skin and nail changes, although the latter are easily confused with fungal infection. Foot problems are often overlooked in rheumatology and may result in unnecessary disability and pain.[26]

Dactylitis

Dactylitis (Figure 114.3A) is one of the hallmark clinical features of PsA, occurring in up to half of all cases.[27,28] Dactylitis is seen more often in the foot, and more often in the fourth toe.[29] Of interest is the fact that most tissues of the digit are affected by inflammation in active, tender dactylitis.[30] Dactylitis is a marker of severity in the ipsilateral digit and may be a marker of severity overall.[29] Chronic, non-tender, diffuse dactylitic swelling occurs in PsA and is regarded as less of an indicator of active disease although MRI abnormalities differ in quantitative terms only.[30] Rarely unilateral limb oedema is seen in PsA and this may be an extreme example of 'limb dactylitis'.

Enthesitis

Entheses, the point of attachment of ligaments and tendons to bone, are widely distributed in the body. The major entheses of the lower limb around the calcaneum provide the hallmark features of enthesitis (Figure 114.3B) in PsA and other spondyloarthropathies.[1] However, enthesitis may underlie most of the changes found in the spine and it has even been suggested that enthesitis is the primary pathological lesion in the peripheral joints in PsA.[31] Reliable clinical assessment of enthesitis has remained elusive, with poor correlation between ultrasonographic enthesitis and tenderness, with higher sensitivity of ultrasonography.[32]

Fig. 114.1 The five clinical subgroups described by Moll and Wright [3]: (A) symmetrical polyarthritis resembling rheumatoid arthritis; (B) oligoarthritis; (C) distal interphalangeal joint predominant; (D) arthritis mutilans; (E) predominant axial involvement.

Reproduced with kind permission from Springer Science+Business Media from Atlas of Psoriatic Arthritis, Mease, Philip J.; Helliwell, Philip S. (Eds.) 1st Edition., 2008.

Axial involvement

It is to be expected that axial disease similar to AS is found in PsA, but notable differences in radiological phenotype have been described.[33,34] The differences can be summarized as both quantitative (less of sacroiliitis and new bone formation) and qualitative (paravertebral ossification and morphologically different syndesmophytes in PsA). In PsA it is also likely that syndesmophytes occur in the absence of sacroiliitis, something of an anathema in AS where sacroiliitis is assumed to precede syndesmophytes.[35] It is also noteworthy that axial involvement defined radiologically is more prevalent than clinical axial involvement, perhaps reflecting the lower pain thresholds observed in PsA.[36]

Juvenile psoriatic arthritis

The classification criteria for juvenile arthritis continue to be the subject of much debate. Juvenile arthritis is uncommon, and juvenile PsA uncommon within this group. The Edmonton (ILAR) criteria provided a clear division for PsA within children but at the expense of excluding those who have enthesitis or inflammatory back pain and those who are rheumatoid factor (RF) positive.[37] It is clear that juvenile PsA is biphasic in onset with peaks at less than 5 years, where the skin disease may present with guttate psoriasis, and over 10 years. The older children tend to have an equal sex ratio and present with peripheral and axial symptoms with enthesitis. Younger children are female predominant, have more wrist and small joint involvement in hands and feet, and may be anti-nuclear antibody (ANA) positive, but are distinguishable from oligoarticular juvenile idiopathic arthritis (JIA) by the pattern of joint involvement and the association with psoriasis.[38]

Prognosis and mortality in psoriatic arthritis

Early studies suggested that PsA was a relatively mild arthropathy and, by implication, that there was little morbidity and no increase in mortality in this condition.[39] However, even these early studies reported a high prevalence of deaths due to cardiovascular disease. This is now increasingly recognized as an important comorbidity of psoriasis and PsA and has been amply demonstrated in a number of studies.[40–42] The mechanisms behind this risk continue to be investigated but a higher prevalence of the metabolic syndrome and therefore traditional risk factors for cardiovascular disease (hypertension, obesity, diabetes) are likely to be significant factors.[43,44]

Laboratory features

C-reactive protein (CRP) is elevated in only about one-half of cases with PsA and the search for a reliable biomarker for outcome in PsA continues.[45] Although PsA is typically considered to be seronegative for RF, RF positivity does occur in PsA and has been recorded in up to 13% of cases.[28] In the 588 patients with PsA recruited to develop the CASPAR criteria, approximately 5% of patients had a positive RF compared to 76% in the RA control group. The estimates for prevalence of anti-CCP antibodies in PsA vary from 6% to 16% in

Fig. 114.2 'Hidden' psoriasis in the natal cleft. This may be the only skin manifestation, and the patient may be unaware of it.

Fig. 114.3 Dactylitis and enthesitis: (A) dactylitis of toes; (B) enthesitis of Achilles tendon insertion

different cross-sectional studies.[46–49] Interestingly, patients with polyarticular PsA are no more likely to be RF positive than those with oligoarthritis but nearly all studies have shown a significant association between polyarthritis and CCP. CCP positivity in PsA seems to be associated with a greater risk of aggressive, erosive disease and higher joint counts and may be a marker for developing arthritis mutilans.[46]

Imaging features

Plain radiography

In PsA radiographic damage is not as severe as that seen in RA matched for disease duration,[50] but even early on in the course of disease around 27% have evidence of erosions on radiographs and this increases to 47% at 2 years despite conventional treatment with disease-modifying anti-rheumatic drugs (DMARDs).[51]

Key radiographic features of PsA have been defined as joint erosions, joint space narrowing (JSN), bony proliferation, osteolysis (including pencil-in-cup deformity), ankylosis, and new bone formation at entheses, both central and peripheral.[52] Erosive changes are marginal (similar to RA) but become irregular with disease progression because of new bone formation adjacent to the erosions.[53] Severe erosions lead to the pencil-in-cup deformity due to new bone formation in conjunction with osteolysis (Figure 114.4A).[54] Whiskery juxta-articular new bone formation was the only radiographic feature that separated PsA from other inflammatory arthritides in the CASPAR study (Figure 114.4B).[4]

However, some of these findings have been challenged. For example, in the CASPAR study, comparing RA with PsA (where radiographs were read blind to diagnosis) found a limited number of unique features.[4] For example, osteolysis at a peripheral joint was not found to discriminate between RA and PsA. Osteolysis was characteristic of PsA only if it occurred at the DIP joint—osteolysis at proximal interphalangeal (PIP) joints and metacarpophalangeal joints (MCP) was seen equally in RA. Further, the only distinguishing plain radiographic features of PsA were irregular new bone formation adjacent to small joints of the hand and foot and irregular new bone in the pelvis, particularly at sites of attachment of inguinal ligament, Sartorius, and rectus femoris muscles.[55] Axial changes (discussed above) did not appear as distinctive radiological features of PsA because there were a significant number of cases of AS in the matched controls.

MRI

Although synovitis in PsA and RA is indistinguishable on MRI scanning,[56] features of enthesitis, dactylitis, and spondylitis are in accordance with the appearances of the SpA group of disorders and can be used to differentiate the two conditions.[57] Jevtic and coworkers[58] first described the extensive extracapsular inflammation seen in PsA. Bone oedema, widely accepted to be a surrogate for inflammation, is commonly described as an MRI feature of PsA and can be found extensively at juxta-articular sites.[57]

Ultrasonography

Ultrasound (US) has emerged as an extremely useful non-invasive means of imaging soft tissues and, in particular, entheses.[59] Entheseal imaging with US provides a bedside assessment of the morphological and vascular changes and is more sensitive than clinical examination. Indeed, there may be a role for US examination of cases of psoriasis as a means of early diagnosis of PsA.[13]

Pathogenesis

It seems likely that PsA results from an interplay between genetic susceptibility and environmental triggers. Of the latter, the two most recorded are infection and trauma. The relationship between guttate psoriasis, streptococcal infection, and PsA was discussed in the early 1980s,[60] and more recently infections in general have been associated with the onset of PsA in people with psoriasis.[61] Studies have suggested that acute physical trauma may be associated with the onset of PsA,[62] and many are aware of the concept of PsA as a deep Koebner phenomenon, originally posited by Moll and Wright.[16] However, the relationship between trauma and onset of arthritis is not unique to PsA: this phenomenon is well known in OA and has also been reported in RA.[63]

Genetic factors

PsA is known to be a highly heritable disease: the recurrence risk (ΛS; risk to siblings/risk in general population) of PsA is estimated at 27,[64] which is higher than for psoriasis (ΛS between 4 and 11).[65] An Icelandic study found risk ratios of 39, 12, 3.6, 2.3, and 1.2 respectively in first- to fifth-degree relatives.[66] Thirty per cent of the genetic susceptibility to psoriasis is found in the major histocompatability complex (MHC) class I region on chromosome 6p21.3 (psoriasis susceptibility 1, *PSORS1*) where *HLA Cw*0602* is
Fig. 114.4 Plain radiographic findings: (A) osteolysis in toes; (B) whiskery new bone formation in toes (arrow).

the susceptibility allele.[67] The frequency of *HLA Cw*0602* is also increased in PsA but only for patients with type I psoriasis and not those with type II psoriasis,[68] suggesting that its major influence is on the age of onset of psoriasis, not susceptibility to PsA.

HLA B27, typically associated with AS, is also found to be associated with psoriatic spondylitis although the frequency of B27 positivity is much lower overall in PsA patients.[69] HLA B38 and HLA B39 have been shown to be associated with peripheral PsA and, additionally, the shared epitope (HLA DRB1) in association with erosive polyarticular disease.[70]

Genome-wide association studies (GWAS) have also shown associations including alleles of the interleukin (IL)-12B and IL-23 receptor gene in both psoriasis[67] and PsA.[71,72] Later GWAS have confirmed the above associations and discovered new loci in signalling pathways in both skin barrier dysfunction (for psoriasis) and innate (NFκB and INF) and adaptive (CD8 and Th17) immune systems.[73]

Pathways for inflammation and new bone formation

Since PsA is such an heterogeneous disease it is not surprising that there is wide heterogeneity in the cells and cytokines found in this disorder. As a marker of the end result of these processes bone morphology provides an insight into the mechanisms involved. As mentioned above, both bone destruction and bone formation can be observed: separately these processes are seen exclusively in RA and AS respectively, thus emphasizing the mixed manifestations of this disease. In AS there is evidence that inflammation and new bone formation occur independently,[74] and this may be a clue to the different manifestations of PsA. In a mouse model of inflammation and ankylosing enthesitis, inhibition of tumour necrosis factor (TNF) has no impact on ankylosis,[75] whereas targeting bone morphogenetic protein is effective.[76] In addition to the TGFβ superfamily of growth factors and cytokines, other morphogenetic signalling pathways may also have relevance in spondyloarthropathy and in PsA. For example, blocking Dickkopf-1, a Wnt receptor antagonist, causes fusion of both sacroiliac and peripheral joints in an animal model.[77]

Immunological mechanisms

The acquired immune system may be less important in PsA than in RA. Material taken from synovial biopsies may be helpful in determining the key cells and cytokines. Beaten et al.[78,79] found significant differences between RA and PsA synovium. In the RA group were highly specific intracellular citrullinated peptides and monoclonal antibody 12A (in 44% and 46% respectively) and increased lining layer thickness, whereas the SpA group showed greater vascularity, increased CD163 and ICAM-1, and a higher number of polymorphonuclear cells. The mononuclear cell may provide the link between the articular and extra-articular manifestations of this disease.[80] The mononuclear cell can differentiate into macrophages, dendritic cells, and osteoclasts. Elevated osteoclast precursors have been found in PsA,[81] and monocytes may have a role in the development of atherosclerotic plaques.[82] Mention has already been made of the IL-23 gene in psoriasis and PsA. IL-23, released by dendritic cells and keratinocytes in psoriatic skin, leads to proliferation of Th17 lymphocytes which in turn produce IL-17, an important cytokine in inflammatory arthritis and psoriasis. This may explain

in part the relative efficacy of anti-T-cell therapies in psoriasis and RA and, to a lesser extent, PsA. TNF is a key proinflammatory cytokine, and blockade of TNF in vitro causes a downregulation of multiple proinflammatory cytokines. Research in PsA found high levels of TNF both in psoriatic plaques in the skin and in synovial fluid taken from active arthritic joints,[83] providing a rationale for treatment of PsA with this class of drugs.

Disease assessment

PsA is a heterogeneous disorder affecting peripheral and axial joints as well as having other features such as dactylitis, enthesitis, and skin and nail disease. Although not all these clinical features may occur together at any one time, it is important to be able to capture them all in order to assess their impact on the patient and the response, which may not be consistent across features, to treatment. This may be carried out in each individual domain or as a composite measure. A composite measure is one way of assessing all relevant clinical outcomes in one single instrument. In PsA the science of outcome measurement has lagged behind other diseases, such that many current measures are 'adopted' from RA. These include the American College of Rheumatology (ACR) responder index,[84] a simplified version adapted for PsA (Psoriatic Arthritis Response Criteria, PsARC)[85] and the Disease Activity Score for 28 joints (DAS28)[86] although the latter does not assess the joints of the foot and ankle which are commonly involved in PsA.

A number of additional composite measures for assessing disease activity in PsA have been proposed. A composite measure for defining 'minimal disease activity' (MDA) has been validated and includes assessments of joints, skin, entheses, and physical function.[87] The MDA criteria define a low disease state and can be used as a responder index in addition to a target for treatment interventions. Three other disease-specific measures have been suggested. First, an adaptation of the Disease Activity index for Reactive Arthritis (DAREA) has been renamed the Disease Activity index for PSoriatic Arthritis (DAPSA).[88] Second, a weighted articular responder index, the Psoriatic Arthritis Joint Activity Index (PsAJAI), has been developed from pooled data from RCTs of biologic agents in PsA.[89] In both of these instruments, the analytic method used in their development led to factoring out skin disease, which was therefore recommended to be measured separately from the musculoskeletal components, as has been the case with the ACR and DAS scoring systems. Third, a domain-based approach has been proposed with the development of a composite measure known as the Composite Psoriatic Disease Activity Index (CPDAI) which assesses disease severity separately in joints, skin, entheses, dactylitis, and spine and sums the individual scores.[90] In addition, two new disease activity scores have been developed; the first uses similar methodology to the DAS and is called the PASDAS, and the second uses an approach using predefined cut-offs for acceptable disease states, the so-called desirability function.[90a]

Treatment

As indicated in the previous section, PsA is a complex and heterogeneous disease and the key to optimal treatment is to consider all aspects of the disease. The more complex patients with PsA will require treatment input from both a rheumatologist and a dermatologist to allow optimal management of their condition. Good communication between these specialties and with primary care is important for managing treatment.

Little research has been done on different treatment regimes and protocols for PsA, particularly in comparison to RA. Given the complexities of presentation it seems likely that different algorithms will be required for different subgroups, particularly since a polyarticular onset is likely to indicate the group with the worst prognosis. The most commonly used regime in PsA is a step-up model where treatment is escalated gradually in the case of non-response. Treatment guidelines were published by the GRAPPA group in 2006 based on a full literature review and expert consensus.[91] They outline the different treatments that are considered efficacious for the five main domains of PsA (see Figure 114.5). More recently the European League Against Rheumatism (EULAR) has published evidence-based recommendations with a detailed algorithm independent of clinical subgroup.[92] Evidence for individual drugs and approaches, with the exception of topical treatments is summarized below.

The use of intra-articular steroids

Despite widespread use, there is little data to support the use of intra-articular (IA) steroids in PsA. Expert opinion is that IA glucocorticoid injections may be used in persistent mono- or oligoarthritis with good clinical results.[93] There is observational evidence of benefit in a longitudinal database with 41% of joints improved at 3 months, although one-third of these relapsed within 12 months.[94]

Non-steroidal anti-inflammatory drugs

The use of NSAIDs to treat PsA has been recommended for many years, and in mild cases, they are often recommended as the only therapy.[95] However there is a lack of randomized trials to support their use. Only one randomized controlled trial (RCT) has compared a standard NSAID to placebo,[96] with four RCTs comparing different NSAIDs.[97,98] In addition to the standard concerns about gastrointestinal (GI) toxicity caused by NSAIDs and their risks in renal impairment, there is a concern about NSAIDs worsening skin psoriasis. The potential for this flare of skin lesions was highlighted by dermatologists in case reports.[99] However, in the five RCTs discussed above, there was no evidence of an effect on psoriasis.[93]

Disease-modifying drugs

Small molecules

Standard DMARDs are routinely used in PsA despite a paucity of evidence for their use in this condition. There is no evidence

to support the use of gold salts in PsA,[93] although anti-malarials may have weak benefit. The use of these two drugs has been discouraged because of an anecdotal risk of deterioration in skin, although the evidence for the latter with the use of anti-malarials seems fallacious.[100] Interest in methotrexate (MTX) for the treatment of PsA evolved following its use in RA for arthritis and studies showing efficacy in psoriasis. Historically the evidence is poor,[101–103] and a Cochrane review calculated only a moderate effect size of 0.65 based on both patients' and physicians' global assessments, but the confidence intervals included zero.[104] An analysis of the Norwegian DMARD (NOR-DMARD) register identified 526 cases treated with MTX (n = 380) or anti-TNF ± MTX (n = 146). Those patients in the MTX group showed a similar improvement in both tender and swollen joint counts to those treated with TNF. The drug adherence rates at 6 months were similar in both groups, with adverse event being the commonest reason for withdrawal in both groups.[105] The only fully powered RCT of oral MTX found no significant difference from placebo in the primary outcome but doses of MTX were only 15 mg weekly in the majority of patients.[106]

The evidence for the use of sulfasalazine is supported by multiple RCTs, reported in a Cochrane review,[104] although effect sizes were small. Only one small study has attempted to assess the impact of sulfasalazine on radiographic damage, with no evidence that sulfasalazine slows or stops the progression of radiographic joint damage.[107]

The benefit of leflunomide for both skin and joints has been demonstrated in an RCT[108] and a further 24 week open-label study confirmed the efficacy and safety of leflunomide in daily clinical practice.[109] Radiographic outcomes were not assessed.

Ciclosporin is more often used for the skin than the joints but may be of use where both skin and joints are problematic and therapy with MTX is suboptimal. The latter strategy is supported by an RCT using ciclosporin added to MTX partial responders which found both PASI score and US-detected synovitis showed a greater improvement with combination treatment.[110]

Biological agents

A summary of the results from the key trials of TNF blockers is shown in Table 114.2. In the United Kingdom, National Institute of Clinical Excellence (NICE) guidance on the use of TNF inhibitors in PsA advises that the patient must have active disease (three

Peripheral arthritis	Skin and nail diseases	Axial diseases	Dactylitis	Enthesitis
Initiate therapy: NSAID IA steroids DMARD (MTX, CsA, SSZ, LEF) Biologics (anti-TNF)	Initiate therapy: Topicals PUVA/ UVB Systemics (MTX, CsA, etc) Biologics (anti-TNF, etc)	Initiate therapy: NSAID PT Biologics (anti-TNF)	Initiate therapy: NSAID Injection Biologics (anti-TNF)	Initiate therapy: NSAID PT Biologics (anti-TNF)

Reassess response to therapy and toxicity

Table 114.2 Summary of trials of TNF inhibitors in psoriatic arthritis

Drug	N	Inclusion	Baseline TJC	Baseline SJC	PsARC	ACR20	ACR50	ACR70
Adalimumab 40 mg eow[128]	100	≥3 TJC and ≥3 SJC	25.3	18.2	51	39	25	14
Adalimumab 40 mg eow[117]	313	≥3 TJC and ≥3 SJC	23.9	14.3	62	52	36	20
Etanercept 25 mg biw[111]	60	≥3 TJC and ≥3 SJC	20 (median)	14 (median)	87	73	50	13
Etanercept 25 mg biw[129]	205	≥3 TJC and ≥3 SJC	20.4	15.9	72	59	38	11
Golimumab 50/100 mg monthly[118]	405	≥3 TJC and ≥3 SJC	22.5	12	73/72	51/45	30/28	12/17
Infliximab 5 mg/kg 8 weekly[113]	104	≥5 TJC and ≥5 SJC	23.7	14.6	75	65	46	29
Infliximab 5 mg/kg 8 weekly[115]	200	≥5 TJC and ≥5 SJC	24.6	13.9	77	58	36	15

biw, twice a week; eow, every other week; SJC swollen joint count; TJC, tender joint count.

swollen and tender joints) and have failed two or more conventional DMARDs (http://guidance.nice.org.uk/TA199).

Etanercept was the first anti-TNF therapy to be tested in a randomized trial in patients with PsA, demonstrating an impressive response to treatment with 87% of etanercept-treated patients achieving a PsARC response compared with 23% of placebo-treated patients.[111] A larger phase 3 study, demonstrated retardation of radiographic disease progression at 12 months.[112]

Following on from successful trials of infliximab in the treatment of psoriasis, a phase 2 RCT of infliximab in PsA (Infliximab Multinational Psoriatic Arthritis Controlled Trial or IMPACT) showed a significant benefit in terms of arthritis, skin disease, enthesitis, and dactylitis.[113] Further analysis on this trial showed a halt in radiographic progression with infliximab therapy over the 12 month treatment time.[114] A larger phase 3 study (IMPACT 2) followed, confirming the efficacy of infliximab in terms of improving disease activity and reducing progression in radiographic damage compared to placebo.[115,116] This larger group also allowed a more thorough assessment of safety. Further studies of other anti-TNF drugs have included adalimumab[117] and golimumab.[118] The safety profile of anti-TNF drugs within the studies seems acceptable, with infection and elevation of liver transaminases the most worrisome.

New drugs and other biologicals

Many biologics used in RA have shown relatively disappointing results in PsA, including abatacept[119] and rituximab.[120] Results of trials with tociluzimab (an IL-6 blocker), and secukinumab (anti-IL-17) are awaited. Apremilast, an orally active inhibitor of phosphodiesterase-4, shows efficacy in psoriasis and PsA equivalent to methotrexate but less than monoclonal antibody inhibitors of tumour necrosis factor (TNFi).[121–123]

Ustekinumab is a human monoclonal antibody that binds to the p40 subunit present on both human IL-12 and IL-23. It therefore prevents binding of these interleukins to the IL-12Rβ1 receptor, blocking this signalling pathway. Studies in skin psoriasis have shown a significant response to ustekinumab,[124] and a phase II trial has shown benefit in PsA.[125]

Surgical options

Surgery may be required for 'endstage' large joints such as the hip and knee. Unless routine antibiotic cover is used there is evidence to suggest a higher rate of superficial and deep infection in PsA.[126]

Patients may also develop psoriasis in the operation scar as part of the Koebner phenomenon.

Reactive arthritis and enteropathic arthropathy

J. S. Hill Gaston

Definitions

The term 'reactive arthritis' is often used loosely to cover any form of arthritis which can be linked to preceding infection. This produces a large group of diseases with little in common as far as their clinical features or pathogenesis are concerned, for example, postviral arthritis, poststreptococcal arthritis, and Lyme disease. It is preferable to reserve the term 'reactive arthritis' (ReA) for the clearly identified clinical syndrome which falls naturally within the spondyloarthropathies on clinical, immunogenetic, and pathogenetic grounds. This syndrome is usually triggered by infection with a relatively small number of organisms and forms an important part of the differential diagnosis of acute oligo- and mono arthritis (Table 115.1). Other forms of arthritis seen in relation to infection are best termed 'postinfectious'.

There are several examples of disorders linking the gastrointestinal tract and arthritis, ReA following gastroenteritis being an obvious example, along with the arthritis associated with Crohn's disease or ulcerative colitis. Both the latter are classified within the spondyloarthropathies, but other forms of arthritis are sometimes included in the 'enteropathic' grouping such as Whipple's disease, arthritis associated with coeliac disease, and other syndromes. This chapter is divided into two sections, the first dealing with ReA, and the second with other forms of enteropathic arthritis.

Reactive arthritis

Historical perspective

An association between urethritis and arthritis has been known for nearly 500 years. Many authors attribute the first description of ReA to van Forest in the 1500s, and a description in Spanish literature by Lopez de Hinojosos in Mexico City in 1578 has been recognized. By the beginning of the 19th century the syndrome was clearly recognized, but inevitably in a prebacteriological era 'venereal arthritis' encompassed both postgonococcal arthritis and true ReA, mainly due to *Chlamydia trachomatis*. Nevertheless, some of the case descriptions, particularly those which mention prominent eye involvement, very likely represent ReA. Brodie described six cases in 1818 and a survey of early case records in London

Table 115.1 Infections that trigger arthritis

Reactive arthritis	Postinfectious arthritis
Common triggering infections	Postviral arthritis
Salmonella	Parvovirus
Campylobacter	Rubella
Yersinia	Mumps
Shigella	HIV
Chlamydia trachomatis	Hepatitis B and C
Occasional triggering infections	Arboviruses
Chlamydia pneumoniae	Other case reports (e.g. herpesviruses)
Clostridium difficile	Bacterial infections
M. bovis BCG (intravesical)	Streptococci
Mycoplasma (e.g. *U. urealyticum*)	Rheumatic fever
Rare triggering infections	Poststreptococcal arthritis
Many case reports of infection, particularly of the intestine, including:	Neisseria
	Gonococcal arthritis
Giardia	Meningococcal arthritis
Cryptosporidium	Lyme disease (Borrelia)
Chlamydia psittaci	Brucella
Hafnia alvei	Whipple's disease (*Tropheryma whippeli*)
Vibrio parahaemolyticus	
and many other single case reports	

hospitals shows that the condition was commonly recognized from 1820 onwards, accounting for a significant proportion of hospital admissions.[1]

A link between gastrointestinal infection and reactive arthritis was noted in the early years of the 20th century and outbreaks of

dysentery in the trenches of the First World War led to classical descriptions by Fiessinger and Leroy in 1916, and also by Hans Reiter. Although the term 'Leroy–Fiessinger–Reiter syndrome' is sometimes encountered, it is the name of Reiter which has come to be associated with ReA, and the terms 'Reiter's syndrome' and 'reactive arthritis' have often been used interchangeably. There are several cogent reasons for bringing this practice to an end and abandoning the term 'Reiter's syndrome'. First, Reiter was clearly not the first to describe ReA; disease associated with dysentery was first reported by Vossius in 1904. Secondly, Reiter did not shed any useful light on its pathogenesis, erroneously attributing it to spiro-chaetal infection. Thirdly, and more practically, the triad of arthritis, conjunctivitis, and urethritis/cervicitis has often been taken to imply that Reiter's syndrome is the form of ReA secondary to genitourinary infection, missing the point that the urethritis in his original description was also 'reactive', following bacillary dysentery. There are no prognostic implications associated with the classical triad and therefore no clinical value in singling out Reiter's triad as a subsection of reactive arthritis. Lastly, several authors have felt the eponym inappropriate in view of Reiter's later enthusiasm for the Nazi party.

Case definition

Classification criteria for reactive arthritis present difficulties. Since ReA is one of the spondyloarthropathies, criteria such as those devised by Amor[2] or the European Spondyloarthropathy Study Group (ESSG)[3] can be applied. More recently the international ankylosing spondylitis assessment group (ASAS) has put forward criteria for both axial and peripheral spondyloarthritis.[4,5] The success of these criteria is variable; on the one hand many cases of ReA do not have sufficient features to satisfy the Amor criteria. On the other hand, most cases would meet the ESSG criteria, or either of the ASAS criteria, but these criteria are very wide-ranging and do not allow ReA to be distinguished from undifferentiated spondyloarthropathy. Unfortunately all current criteria fail to deal adequately with cases with no preceding *symptomatic* gastrointestinal or genitourinary infection. In these cases, a link to preceding infection depends on adequate laboratory investigation (see below). While diagnostic and classification criteria continue to be debated, a suggested working definition is presented in Box 115.1. This groups:

1. patients with classical clinical features (oligoarthritis, predominantly of the lower limbs, and/or inflammatory back pain, with extra-articular signs, including enthesitis) **plus** proven preceding infection with one of the organisms known to trigger reactive arthritis, irrespective of preceding symptoms

2. patients with proven preceding infection **plus** arthritis with no diagnostic features

3. patients with classical clinical features **without** proven preceding infection.

This definition avoids separating patients with identical clinical manifestations on the basis of the skills of the microbiological laboratory, or failing to include patients with new inflammatory disease of joints or entheses after proven, but asymptomatic, infection with reactive arthritis-associated organisms. The latter are often seen in follow-up of cohorts of patients from outbreaks of food poisoning. Indeed, in a recent series, the proportion of patients with

> **Box 115.1** Working definition of reactive arthritis
>
> ◆ Classical clinical features:
>   - asymmetric oligoarthritis, lower limbs predominate
>   - enthesitis
>   - extra-articular signs and proven infection by salmonella, campylobacter, yersinia, shigella, or chlamydia (whether symptomatic or not)
> ◆ Classical clinical features and proven infection by other organisms (e.g. *Clostridium difficile*, *Mycobacterium bovis*, BCG)
> ◆ Any acute inflammatory arthritis (including monoarthritis) and proven infection by ReA-associated bacteria
> ◆ Classical clinical features and preceding diarrhoea or urethritis/cervicitis, infection not proven

a clinical diagnosis of ReA in whom a triggering infection could be identified after appropriate investigations was very similar in patients with a preceding symptomatic infection and those with no such history. Practically, it is worth considering the diagnosis of ReA in any patient presenting for the first time with acute oligo- or monoarticular synovitis, in whom no other diagnosis (sepsis, crystal arthropathies, etc.) can be made. This allows adequate history, physical examination, and diagnostic tests to be performed, so that a definite diagnosis of ReA can be made.

Epidemiology

Given the difficulties in case definition, accurate epidemiological studies on incidence and prevalence present problems. There are two possible approaches. In the first, the proportion of patients with ReA can be measured in clinics designed to examine all cases of early synovitis. One such study in Oslo measured an incidence of 9.6 per 100 000, equally divided between cases due to *Chlamydia trachomatis* and enteric infection.[6] Previous estimates of chlamydia-induced arthritis of 5 per 100 000 have also been recorded.[7] The difficulty with this approach is that it cannot take account of mild cases not referred to early synovitis clinics, cases where arthritis is short lived, or cases with inflammatory back pain or enthesitis in the absence of synovitis. The alternative approach has been to take advantage of food poisoning outbreaks, when an entire population infected with an organism at a particular time can be followed up prospectively. Patients are sent questionnaires on the occurrence of arthritic symptoms subsequent to their exposure to the infection, and those reporting symptoms are examined by a rheumatologist. Although the incidence of ReA in food poisoning outbreaks varies substantially, several series report incidences ranging from 5% to 25%, with an additional percentage of patients developing arthritic symptoms but not meeting criteria for ReA. These figures are interesting in relation to a comprehensive United Kingdom study on the community incidence of enteric infections in a population of 460 000. This showed a combined incidence of campylobacter, salmonella, and yersinia infection confirmed by stool culture of 17.7 per 1000. Interestingly, particularly for yersinia, the number of cases identified in the community survey was substantially higher than those in the same population who presented to their family physician. This means that many of the cases of yersinia infection

were too mild to require medical attention. Combining these results would give an estimate of ReA in the community of 100–200 per 100 000, not including cases induced by chlamydia. Although a large proportion of these cases may have mild self-limiting disease, the figures suggest that the incidence calculated on the basis of patients seen at early synovitis clinics is a serious underestimate.

The incidence of ReA may be declining; this decline seems particularly marked for chlamydia-associated arthritis. This is not due to any decline in the overall incidence of chlamydia infection in Western countries—quite the opposite, with the incidence in the United Kingdom doubling through the 1990s to 50 000 cases per year, with a further doubling over the next decade to 123 000 in 2008. This suggests that other factors must be affecting the incidence of chlamydia-induced arthritis. This could include differences in the organism—whole-genome sequencing of chlamydiae is now able to identify different 'subspecies' which do not necessarily correspond to the serovar classification, so that 'arthritogenic' chlamydiae might be identified. Other changes may involve the host; chlamydia infection is now commonly acquired in early teenage years. At this age few subjects will have been previously infected with related organisms, such as *Chlamydia pneumoniae,* an infection whose overall incidence has declined with improved socioeconomic conditions. In the 20th century many subjects acquiring *C. trachomatis* in their third decade would previously have experienced *C. pneumoniae* infection in childhood or adolescence. It has been shown that such infection has the potential to prime the immune system for more vigorous responses to *C. trachomatis*,[8] which would be relevant to the occurrence of arthritis.

Infections with salmonella and with campylobacter increased substantially in the 1990s in the United Kingdom, without a notable increase in the incidence of ReA, and then have declined in recent years as public health measures have been implemented. Again the lack of a relationship between incidence of infection and ReA is striking, and suggests that changes in immunological memory in those who now become infected has somehow altered their susceptibility to arthritis

Pathogenesis

Since ReA is a member of the spondyloarthropathy group, pathogenesis of these conditions can be considered together, and is discussed in detail elsewhere (see Chapters 113 and 114). However, its clear association with infection by known bacteria, and its usual acute presentation, means that ReA lends itself to investigation, and much work has been done in the last 20 years. From this three factors have emerged as critical to pathogenesis: the infecting organism; the immune response elicited by infection, particularly that mounted by T lymphocytes; and genetic influences, principally HLA B27. Interestingly, all of these are important in rat HLA B27 transgenic models of spondyloarthropathy [9]; in this model arthritis requires infection (gut flora rather than specific pathogens), T lymphocytes (especially CD4+ T cells), and an appropriate genetic background in addition to transgenic B27, since disease incidence varies in different inbred rats.

The list of bacteria which commonly cause ReA is quite short (Table 115.1). Another set of organisms has been implicated in ReA on multiple occasions, but their contribution to ReA incidence is relatively small. Lastly, there are many single case reports implicating particular infections. In these cases, there is always uncertainty about whether the organism provoked true ReA or simply a postinfectious arthritis, but where classical extra-articular features are noted (as distinct from only positivity for HLA B27), the reports are convincing. Very similar organisms, e.g. *Shigella flexnerii* and *Shigella sonnei*, have previously been associated with very different rates of ReA, with *S. sonnei* infection rarely being reported as a cause of ReA in series from the United States; but, interestingly, a recent survey of shigella-infected patients in Finland found a majority of the arthritis cases to be triggered by *S. sonnei*.[10] Thus differences in the ability of an organism to trigger ReA may not be consistent in all populations, and investigations focused on the differences between such organisms to identify arthritogenic factors may not be informative.

Contrary to previous expectations, there is now substantial evidence that bacteria or their antigens reach the affected joints in ReA. Bacterial antigens were first demonstrated in phagocytic cells within the joint using immunofluorescence and immunoblotting techniques.[11,12] This has been shown for salmonella, yersinia, and shigella, and since phagocytic cells in peripheral blood were also shown to contain antigen,[13] it seems likely that there is traffic from the site of infection to the affected joint. Most studies to demonstrate nucleic acids of enteric bacteria in ReA joints have been negative,[14] but by using the more sensitive technique of reverse transcription polymerase chain reaction (RT-PCR), ribosomal RNA from *Yersinia pseudotuberculosis* was unequivocally demonstrated in a ReA joint.[15] The demonstration of bacterial RNA is particularly important since, unlike DNA, this has a relatively short half-life and its presence implies that transcriptionally active organisms can reach the joint, although ribosomal RNA has a longer half-life than that of messenger RNA. Evidence that intact *C. trachomatis* reaches the joint is much stronger, with detection by both PCR and RT-PCR[16,17] and the demonstration of organisms (albeit with atypical morphology) by electron microscopy or immunofluorescence.[18] Interestingly, in all these studies evidence for organisms or their antigens in the joint has been obtained long after the initial infection, strongly suggesting that these organisms can persist at low levels, perhaps in sites such as lymphoid tissue associated with the gut or genital tract. This persistence may relate to their ability to survive intracellularly. Such persistence has been demonstrated, even after 'curative' antibiotics, but dormant intracellular organisms that divide infrequently may be insensitive to conventional antibiotics—this reasoning has led to new attempts to treat chlamydia-associated ReA with novel combinations of antibiotics (see below).

Affected joints in ReA have a substantial infiltrating T-cell population, including both CD4+ and CD8+ T cells. Some of these T cells may have trafficked from the gut or genitourinary tract because the synovium shares 'addressins' (molecules which determine which T cells are recruited) with the mucosal-associated lymphoid tissue (MALT).[19] This may apply to the inflamed synovium since it is unlikely that there is normal traffic of lymphocytes through the normal paucicellular synovial membrane. The preference for weight-bearing joints in ReA might reflect pre-existing microtrauma and hence increased monocyte and lymphocyte traffic to such joints, delivering both antigen and antigen-specific T cells. Prominent responses to arthritis-triggering bacteria have been demonstrated in both CD4+ and CD8+ populations, most work having been done on the experimentally more tractable CD4+ T cells.[20,21] Organism-specific clones have been obtained and their specificities identified (e.g. Goodall et al.,[22] Mertz et al.[23]). In several studies bacterial

hsp60 has emerged as a major target antigen,[24–26] although this is a common feature of T-cell-mediated responses to intracellular bacteria. Hsp60 is a good candidate for 'molecular mimicry', since there are large numbers of conserved peptides in human and bacterial hsp60, so that T cells stimulated by bacterial hsp60 might conceivably cross-react with human hsp60 and generate autoimmunity. This was not found when analysed with T-cell clones,[27] though the possibility was raised in a non-clonal analysis.[26] Generally evidence for molecular mimicry is lacking and the significance of CD4+ T-cell responses to bacterial hsp60 for ReA pathogenesis is not known. Likewise the attractive idea that bacteria-specific CD8+ T cells restricted by HLA B27 would make an autoreactive response to a joint-specific antigen has not received experimental support, although yersinia- and chlamydia-reactive, B27-restricted T-cell clones have been isolated from ReA joints.[28,29] Analysis of T-cell-receptor expression has shown expansions of multiple clones in both CD4+ and CD8+ subsets of blood and joint,[30] with CD8+ expansions commonest in the joint. It may be that both subsets are involved in disease. In the ReA which frequently occurs in HIV-infected individuals in sub-Saharan Africa, the arthritis is associated with modest diminution in CD4+ T-cell counts rather than profound levels of CD4+ T-cell depletion,[31] suggesting that CD4+ T cells are required for arthritis—an observation in agreement with the B27 transgenic model.[32] The cytokines produced by synovial bacteria-specific T cells are generally proinflammatory, particularly interferon-gamma (IFNγ) and/or interleukin (IL)-17 produced by the Th1 or Th17 subsets of CD4+ T cells[33–35]; increased quantities of IL-17 have also been noted in ReA synovial fluid.[36]

HLA B27 is associated with the occurrence of ReA,[37,38] but strikingly with severe disease.[39] Patients with prolonged course, recurrent attacks, or evolution to chronic arthropathy are very likely to be B27+.[40] The B27+ patients also have activated neutrophils and enhanced monocyte production of tumour necrosis factor alpha (TNFα).[41,42] However, B27 is not necessary for ReA to develop, and ascertaining B27 status is not useful diagnostically, although it may help predict prognosis. How B27 acts remains frustratingly unclear. It is assumed, but not proven, that the role of HLA B27 is identical in all spondyloarthropathies. There are currently three main theories proposed for the role of HLA B27 in spondyloarthritis[43]: first, that it involves its classical function in presenting antigenic peptides to T cells, and that there is an 'arthritogenic' peptide which binds to B27: secondly, that HLA B27 is able to form heavy chain dimers which are surface expressed, interact with receptors (KIR and LILR) on lymphocytes and antigen-presenting cells, altering their function[44]; thirdly, that inefficient B27 heavy chain folding in the endoplasmic reticulum generates cellular stress which alters cytokine production, favouring proinflammatory responses, particularly those involving IL-23 and differentiation of IL-17-producing cells.[45,46] Recent genome-wide association studies (GWAS) have revealed a large number of genes associated with ankylosing spondylitis (AS).[47] Several involve responses to IL-23 (especially the IL-23 receptor) and genes expressed by Th17 cells. In addition, ERAP-1 is an enzyme whose function is to trim antigenic peptides to the correct length for fitting into the groove of class I MHC molecules such as HLA B27. Importantly, an association between *ERAP1* polymorphisms and AS is confined to HLA B27+ patients.[48] Whether there is an association between ERAP-1 and ReA remains to be determined. Its association with AS points to the importance of the antigenic peptides which are both presented by HLA B27 and form an important part of its molecular structure. A hypomorphic allele of *ERAP1* is protective[49]; this would fit with either the 'arthritogenic' peptide hypothesis—fewer arthritogenic peptides would be generated—or with models which require efficient surface expression of HLA B27, e.g. for the generation of B27 heavy chain dimers.

Bacterial products are initially detected by the innate immune system, particularly the Toll-like receptors (TLR) expressed on phagocytic cells, and a polymorphism in TLR2 (*R753Q*) has been reported to be associated with acute salmonella-induced ReA, with 6/48 patients having this rare variant as compared to 0/27 patients infected by salmonella without developing arthritis and 2/91 healthy controls.[50] This finding needs confirmation in larger studies, but in principle polymorphisms in TLRs, or other receptors for bacteria products, which could alter cytokine production in response to peptidoglycan, lipopolysaccharide (LPS), or bacterial nucleic acids could play an important role in susceptibility to ReA.

Clinical features

Preceding illness

A history of urethritis (dysuria or discharge) or diarrhoea must be specifically sought for several reasons. The interval between these symptoms and the development of arthritis means that patients may not connect these apparently unrelated events. Moreover, preceding infection may be virtually asymptomatic—chlamydia infection in women is notoriously silent, and in men these symptoms or a sexual history are often not volunteered spontaneously. Of gastrointestinal infections, salmonella and shigella are likely to produce symptoms in those who develop ReA, whereas in yersinia-related arthritis many patients have subclinical or mild gastrointestinal symptoms.

Arthritis

ReA is usually an asymmetric oligoarthritis, generally involving fewer than six joints, with a tendency to affect the lower limbs preferentially. Some patients may have arthralgias at sites in addition to those affected by synovitis. Community surveys of patients infected by ReA-associated organisms also reveal patients with polyarticular arthralgia, but these tend not to present to rheumatologists since the symptoms are mild and resolve spontaneously. In rheumatology practice any joint can be affected, and a proportion of patients have monarthritis. Affected joints generally become rapidly hot and swollen, and large effusions can develop especially in the knee. The evolution of joint involvement is such as to make septic arthritis or crystal-induced arthritis likely differential diagnoses. There is a real possibility of patients being treated for a culture-negative septic arthritis if a full history is not obtained from the patient or careful examination made for extra-articular signs of ReA. The arthritis can have features seen in other forms of spondyloarthropathy. Dactylitis, resembling that seen in psoriatic arthritis, occurs in ReA, and many patients experience low back or buttock pain due to acute sacroiliitis. The arthritis is generally most severe in the first few weeks following its onset, followed by substantial improvement over the next few weeks. However, mild but significant symptoms often persist 6–12 months before full resolution. Patients need reassurance during this phase that complete resolution is still probable. In addition, not all patients experience a 'monophasic' disease and both exacerbations and involvement of new joints can occur, even in those in whom the disease eventually settles completely.

Extra-articular disease

One of the characteristic features of spondyloarthropathies is the presence of **enthesitis** (inflammation of ligamentous and tendinous insertions) and it has been argued that synovitis in spondyloarthropathies is secondary to enthesitis.[51] Whether or not this is so, the presence of enthesitis is often helpful in making a diagnosis of ReA, with the Achilles tendon insertion and plantar fascia the commonest sites of involvement. Enthesitis may be mild, particularly in relation to active synovitis at other sites, and so the patient may not report symptoms, particularly if not weightbearing. Other ligamentous insertions involving the pelvis and chest wall may be symptomatic, and some low back symptoms may represent enthesitis.

Conjunctivitis is a classical feature of ReA but is usually painless and often transitory. It may not be evident when the patient presents with arthritis, and a history should be sought from the patient (or relatives who may have noticed red eyes). Persistent eye inflammation and painful eyes raise the question of acute anterior uveitis, but this is much less common in ReA. It requires full ophthalmological assessment.

Skin and mucous membranes can be involved. Keratoderma blennorhagica is histologically identical to psoriasis, and most commonly seen on the soles of the feet, although it can also involve the hands and trunk. Its site, and the fact that it is painless, means that again it needs to be sought directly, since patients may not have noticed it. **Balanitis** is also asymptomatic and may not be readily apparent, particularly in the uncircumcised. The occurrence of balanitis, like urethritis, does not imply a genitourinary aetiology for the ReA. Ulcerative lesions in the mouth and soft palate are also seen but are usually asymptomatic. Lastly, erythema nodosum has been noted in ReA associated with yersinia.

In general, extra-articular disease is associated with severity of arthritis, a less favourable prognosis, and HLA B27 positivity. The most severe extra-articular manifestations are aortitis and cardiac conduction disorders but fortunately these are rare. Table 115.2 shows the frequency of joint and extra-articular involvement in a number of series of ReA patients.[52]

Differential diagnoses

Differential diagnoses are listed in Box 115.2. In patients who present with an acute arthritis, the principal differential diagnoses are septic arthritis and crystal arthropathies. Other forms of postinfectious arthritis enter the differential, particularly postgonococcal

Table 115.2 Frequency (%) of extra-articular signs in reactive arthritis[a]

Lesion	Enteric infection	Sexually acquired infection
Keratoderma and psoriaform lesions	1–2	10–30
Circinate balanitis	5–25; higher in shigella	40–70
Conjunctivitis	6–20; higher in shigella	25–40
Oral ulcers	2–5	10–30
Erythema nodosum	7 (mainly yersinia)	0
Reactive urethritis	10–30	N/A

[a]Data from Angulo and Espinoza[52] combined with other published series.

Box 115.2 Differential diagnosis of reactive arthritis

- Septic arthritis
- Postinfectious arthritis
  - Lyme disease
  - poststreptococcal or neisseria infection
  - viral arthritis
- Crystal arthropathies
- Other spondyloarthopathies
- Early rheumatoid arthritis
- Behçet's disease
- Sarcoidosis
- Trauma, sports injury

---

or postmeningococcal arthritis, along with arthritis due to streptococci and Lyme disease. Although streptococcal infection rarely gives rise to rheumatic fever, except under conditions of social deprivation, an inflammatory oligoarthritis strongly resembling ReA is seen,[53] but classical extra-articular features are not present. In subacute disease, it is sometimes difficult to distinguish ReA from other forms of spondyloarthropathy, particularly if there is no history of preceding infection and no laboratory evidence to implicate specific infections. The term 'undifferentiated spondyloarthropathy' is rightly applied to these cases, with the possibility that psoriasis or inflammatory bowel disease (IBD) will declare themselves as time goes on.

Laboratory investigations

Investigations are directed towards excluding the major differential diagnoses, and thereafter to establishing the organism responsible for triggering the disease.

General investigations

In acute ReA severe enough to present to hospital, there is usually a major acute-phase response (ESR >100, CRP 100–200 mg/litre) and neutrophilia. Other biochemical investigations are not generally helpful, although serum urate should be checked. Classical autoantibodies such as rheumatoid factor (RF) and anti-nuclear antibodies (ANA) are absent, and although positive anti-neutrophil cytoplasmic antibodies have been described, they are not diagnostically useful. The antibodies are not directed against proteinase-3 or myeloperoxidase, unlike those seen in granulomatosis with polyangiitis (Wegener's) and microscopic polyangiitis.

Microbiology

Tests to exclude septic arthritis or other forms of postinfectious arthritis

Microscopy, Gram stain, and culture of synovial fluid is the single most important investigation to diagnose septic arthritis, together with blood cultures and culture of any other possible site of infection, including throat swab for streptococci. Application of PCR techniques may establish the triggering agent in ReA (see below), but may also be helpful in the diagnosis of mycobacterial infection,

borreliosis, and Whipple's disease. Antibody responses to strepto-coccal antigens, including both anti-streptolysin and anti-DNaseB, should be sought, along with antibodies to borrelia in patients who have been in endemic areas. Viral antibodies may also be checked, particularly IgM antibodies to parvovirus, Epstein–Barr virus (EBV), and cytomegalovirus (CMV). Note that IgG antibodies will very often be present since infection with these viruses is endemic, and so only IgM antibodies are diagnostically useful. In appropriate geographic regions antibodies to Ross river virus or chikungunya can also be measured.

Identification of ReA-associated organisms

An excellent account of microbiological tests useful in the diagnosis of ReA is available.[54] By definition, ReA and associated bacteria are not cultured from affected joints, but the organisms may be identi-fied by stool cultures in enteric arthritis, and cultures of swabs from the genitourinary tract or urine in chlamydia infection. Nucleic acid amplification techniques are now favoured for diagnosing *C. trachomatis* infection and avoid invasive swabs while maintain-ing high sensitivity. Their use should allow a higher proportion of patients with chlamydia-induced ReA to be positively diagnosed. *C. pneumoniae* can also be diagnosed by PCR on sputum. There has been interest in using PCR diagnostically in chlamydia-induced ReA to identify organisms in infected joints, but thus far reliable techniques have not emerged. Although some laboratories have reported that a high proportion of chlamydia-induced ReA cases are positive for the organism by PCR, the test can never establish 100% specificity. This is because, in populations in whom chlamy-dia infection is frequent, chlamydiae may well traffic to joints of those affected by e.g. rheumatoid disease in the same way that they do in ReA.

Serological techniques can also be used to establish preceding infection. Current chlamydia serology is unsatisfactory since there are difficulties in distinguishing antibodies to *C. trachomatis* and *C. pneumoniae*, and the incidence of antibodies to the latter can be very high in the general population. Specialized techniques meas-uring antibody bound to purified organisms, and comparing the titre of antibodies to *C. trachomatis* and *C. pneumoniae*, can estab-lish specificity, but are not used routinely. New techniques using recombinant chlamydial antigens may allow more specific and sen-sitive serological tests for chlamydial infection, but these are not yet in use.

There are also problems with the serology of enteric infections, mainly because certain populations have previously encountered salmonella and campylobacter in foods such as chicken and eggs, and developed antibodies. In acute disease, measurement of sal-monella-specific IgM (the Widal test), or IgM responses to other enteric organisms, can be useful but has low sensitivity. Since high titres of IgG antibodies to organisms such as salmonella or campy-lobacter are not uncommon in the general population, it is prefer-able to demonstrate a rising titre of IgG antibodies or high levels of persistent IgA antibodies to the organism of interest. IgA has a shorter half-life than IgG, so persistence of high titres of specific IgA antibodies is often taken to indicate persistent infection.

ReA-triggering organisms also elicit prominent T-cell-mediated responses and the possibility of these being useful diagnostically has been considered. The responses are most easily detectable in syno-vial fluid, but because they only demonstrate T-cell memory for the organism, they cannot provide more than supporting evidence that a particular episode of arthritis is due to the organism recognized by synovial fluid T cells. They may have some negative diagnostic value—for instance, it would be very unusual for a patient to have chlamydia-triggered ReA without a T-cell response to chlamydia being detectable in the joint. However, as noted in discussion of PCR tests, patients with rheumatoid arthritis (RA) can incidentally become infected with ReA-associated organisms and will then have organism-specific T cells detectable in their affected joints.

In summary, for routine investigation of ReA, stool should be cultured, chlamydia sought by PCR, and antibodies to yersinia and camplyobacter measured. Other tests require further study for their validation.

Tissue typing

HLA B27 testing has no diagnostic value since ReA often occurs in B27-negative patients. However, it is still worth doing to help establish prognosis, since this is less favourable in B27+ patients. HLA B27+ patients may warrant earlier treatment with disease-modifying drugs (see below) or closer follow-up to detect relapse or chronic spondyloarthropathy.

Radiology

Radiological examination of acutely affected joints is not helpful in the diagnosis of ReA, but may aid in establishing differential diag-noses, for example, by showing chondrocalcinosis. Chest radio-graph may reveal hilar adenopathy in sarcoidosis, or occasionally in yersinia infection which can cause a sarcoid-like illness. Although sacroiliac joint involvement is common acutely in ReA, radio-graphic abnormality is not. MRI is a more sensitive indicator of enthesitis and/or synovitis in the sacroiliac joint. Ultrasonography can also demonstrate enthesitis and distinguish oedema of tendon and ligament insertions from bursitis. Bone isotope scintigraphy may also be useful to demonstrate joint inflammation, especially in the sacroiliac joints, and also enthesopathy, but has mainly been superseded by MRI. In patients in whom disease persists, radio-logical changes can develop, with erosion of affected joints, includ-ing the sacroiliac joints, and the formation of new bone, which can be seen as either periostitis in the hands and feet or spur formation at entheses such as the plantar ligament insertion. Erosions may also be present at these same sites. In chronic ReA, paravertebral ossification may be seen in the lumbar spine; unlike ankylosing spondylitis this is often asymmetric. Atlantoaxial subluxation has also been described in chronic ReA.

Treatment

Symptomatic treatment

Patients require conventional measures to treat acutely inflamed joints, including non-steroidal anti-inflammatory drugs (NSAIDs), joint aspiration with injection of depot steroid preparations (when septic arthritis has been excluded), together with analgesia and phys-iotherapy to maintain range of motion and regain the muscle power and bulk which is lost during acute inflammation. In severe disease, systemic corticosteroids may be used but injection of affected joints is preferable. Extra-articular disease does not call for specific treat-ment, with the exception of uveitis which requires topical steroids. Of the triggering infections, only chlamydia infection generally requires specific treatment in its own right, with conventional short-term antibiotic regimes using tetracyclines or azithromycin.

Specific treatment

Current opinion on the pathogenesis of ReA would suggest two specific treatment strategies. If disease is maintained by persistent infection and trafficking of triggering organisms to affected joints and entheses, long-term antibiotics should hasten resolution of the disease. On the other hand, if disease is mainly maintained by an aberrant immune response, triggered by infection but later directed against components of the joint, immunosuppressive treatment would be indicated. Unfortunately, evidence from therapeutic trials does not yet allow us to distinguish definitively between these hypotheses.

There have been several trials of prolonged doses of antibiotics in ReA. When tetracycline was used to treat episodes of non-gonococcal urethritis very promptly, there was a decrease in the number of episodes of ReA, but in this instance treatment was administered prior to the onset of arthritis.[55] The first trial to treat established ReA using lymecycline did not show efficacy overall, but a subgroup of patients with chlamydia-induced arthritis had a decreased disease duration.[56] Patients with chronic yersinia infection, diagnosed by showing organisms in intestinal mucosa or gut lymphoid tissue, and with wider symptomatology than ReA, were reported to respond to ciprofloxacin in an uncontrolled trial. These findings prompted controlled trials but those in enteric ReA have shown no therapeutic advantage of 3 months' treatment with ciprofloxacin,[57–59] nor did a similar trial of azithromycin, which has activity against both enteric organisms and chlamydia, show benefit.[60] Likewise 4 months' doxycycline was no more effective than 10 days' in chlamydia-induced disease.[61] This does not necessarily imply that disease is not maintained by persistent infection, since organisms may be relatively resistant to ciprofloxacin or azithromycin when not actively dividing. This argument led to a recent trial aiming to target both bacterial gene transcription and protein synthesis using combinations of antibiotics—rifampicin and azithromycin/doxycycline for 6 months. The patients chosen had longstanding disease (>10 years) and had RT-PCR evidence of persistent chlamydia infection (*C. trachomatis* or *C. pneumoniae*). In a double blind placebo-controlled trial impressive improvements were noted at 6 months.[62] This intriguing result in a relatively small trial requires confirmation.

Disease-modifying agents used in rheumatoid disease have also been tested in ReA, although in many trials ReA patients have been included along with patients with other forms of spondyloarthropathy.[63] One difficulty in these trials is that the rate of spontaneous remission in ReA is high, so that large numbers of patients would need to be tested to have adequate power to show a therapeutic effect. If extrapolation from other forms of spondyloarthropathy is justified, both sulfasalazine and methotrexate should be useful, but the effect of sulfasalazine is relatively modest.[64] It is reasonable to withhold disease-modifying drugs for the first 3 months in ReA and reserve their use for those whose disease is not settling (particularly if they are B27+), or who have involvement of new joints. Therapies directed against TNFα, having proved useful in both AS and psoriatic arthritis, have been shown to be effective in patients with intractable chronic ReA,[65] with no evidence of recrudescence of infection by 'latent' triggering organisms. An antibody to IL-6 receptor has also recently been reported to be useful in such cases.[66]

Prognosis

Many patients with ReA are young, otherwise healthy, and used to an active lifestyle. To these individuals ReA, even when self-limiting, is a major life event, particularly since cases seen in hospital practice commonly take months to resolve. Patients therefore need considerable reassurance that there is an 80% chance of complete resolution of their symptoms within the first year, with a further 10% settling in the following year. Prognosis is less favourable in those who have disease severe enough to require hospitalization and who are B27+. Progression to chronic disease in 16% was recorded in one series, with recurrent attacks of reactive disease in a further 22%,[67] and some eventually have disease which resembles AS.[68] The tendency to trivialize the disease because its prognosis is generally so much better than that of RA needs to be resisted. Although many ReA patients may have future episodes of gastroenteritis or urethritis without recurrence of arthritis, it is advisable for patients to minimize their risk of recurrent infection, particularly younger patients who may need advice on foreign travel and barrier contraception.

Enteropathic arthropathy

Although ReA due to enteric infection falls within the definition of enteropathic arthritis, this section discusses forms of arthritis other than ReA which are associated with gut inflammation. These include others within the spondyloarthropathy group, along with the arthritis associated with coeliac disease, and Whipple's disease.

Spondyloarthropathies associated with gut inflammation

Crohn's disease and ulcerative colitis

The association between IBD and arthropathy has long been recognized.[69] Although estimates of the incidence of arthritis vary, several large series from different geographical areas suggest approximately 10% of IBD patients have peripheral arthritis, with a somewhat higher incidence in Crohn's disease as compared to ulcerative colitis. An additional proportion of patients (~5%) have axial disease indistinguishable from AS, while asymptomatic sacroiliitis is even commoner (15–20%). Arthritis in IBD is associated with other extragastrointestinal features, and is present in 30–60% of patients with uveitis or skin lesions such as erythema nodosum and pyoderma gangrenosum. Arthritis is also commonly accompanied by enthesopathy, as in other spondyloarthropathies. The idea of linkage between spondyloarthopathies and IBD is given greater credence by ileocolonoscopy studies which have shown that up to 60% of patients with ankylosing spondylitis or undifferentiated spondyloarthopathy have subclinical inflammatory lesions in the gut[70,71]; a proportion of these patients progress to overt clinical IBD. The situation has been further clarified by subclassification of the peripheral arthritis of IBD into patients with fewer than five involved joints (type I) and those with five or more involved joints (type II).[72] Type I patients mainly have asymmetric involvement of predominantly lower limb joints (often a monoarthritis, particularly at onset), whereas type II patients have symmetric polyarticular small joint involvement in a rheumatoid-like distribution. Further analysis suggests that only type I patients can be regarded as falling within the spondyloarthopathy group. Like ReA, 80% with type I arthritis have self-limiting disease and active arthritis is associated with relapse of IBD in 80%. In contrast, 80% of type II patients have persistent disease and a much less marked association between active arthritis and IBD relapse. These clinical observations are underpinned by the associations with the relatively rare MHC class II allele, *HLA DRB*0103*, seen in both type I arthritis

(relative risk 12) and ReA due to enteric infection. The same allele has also been found to be increased in IBD patients with AS, or with IBD and uveitis. An association with B27 was also described, but this was weaker for type I disease than for ReA. In contrast, type II disease showed no association with either B27 or DRB*0103, but instead a weak association with HLA B44. The pathogenesis of the peripheral arthritis in IBD likely has many features in common with ReA. Whereas specific pathogens are required to provoke the gastrointestinal inflammation which produces ReA in the presence of susceptibility genes (HLA B27 and others), the same genes predispose to arthritis in response to the gastrointestinal inflammation of IBD. IBD is considered to be an aberrant response to normal gut bacteria—loss of tolerance of the host microbiome.[73] As in ReA, further genetic influences, again including B27, may lead to chronicity with established sacroiliitis and axial disease, rather than self-limiting peripheral arthritis. Unlike classical AS, HLA B27 is only found in 50% of the IBD patients with spondylitis, suggesting that other genetic factors can substitute for B27. In a different genetic background, other patterns of arthritis are seen, including the rheumatoid-like type II arthritis.

Treatment is directed at the underlying IBD, and for type I peripheral arthritis effective control of IBD allows resolution of arthritis. This is not the case for type II arthritis or for spondylitis, and these require treatment in their own right. NSAIDs and methotrexate, which are generally appropriate in the management of inflammatory arthritis, can both exacerbate IBD, although methotrexate is also sometimes used to treat IBD, and COX-2 selective NSAIDs are suggested not to have the same risks as non-selective drugs. In contrast, sulfasalazine, and more recently, anti-TNFα antibodies, have been found to be effective for both IBD and its associated arthritis.

Pouchitis

Patients treated by proctocolectomy for ulcerative colitis commonly have a pouch fashioned by ileo-anal anastomosis to avoid ileostomy. The pouch develops inflammation in 20–40% of patients, possibly due to bacterial overgrowth, and this 'pouchitis' responds to antibiotics, particularly metronidazole. A proportion of patients with pouchitis also develop an arthritis which has features of spondyloarthopathy including lower limb involvement, enthesitis, and sacroiliitis.[74,75] Other extra-articular features such as iritis and erythema nodosum have been described. The development of pouchitis and associated arthritis is much commoner in patients operated on for ulcerative colitis than in those requiring colectomy for familial polyposis, perhaps indicating a genetic predisposition to make inflammatory responses to gut flora. Some authors have described a close relationship between the severity of pouchitis and arthritis (similar to type I arthritis in IBD) with recovery following pouch removal in some cases. Clinically significant arthritis associated with pouchitis is relatively uncommon, but a larger proportion (30%) of patients complain of arthralgia involving hands and knees; in these cases a relationship with pouch inflammation is not evident.[76]

Coeliac disease

Inflammatory arthritis complicating coeliac disease has been recognized for two decades,[77] but is relatively rare. The disease is generally an oligo- or monoarthritis, with preferential involvement of lower limb joints. Lumbar spine and sacroiliac joint involvment have also been described, but there is no clear association with HLA B27.

In fact the genes which increase susceptibility to coeliac disease are those involved in other autoimmune disorders such as RA, type I diabetes, and autoimmune thyroid disease rather than those associated with spondyloarthritis.[78] The best evidence that the arthritis is causally related to coeliac disease, and not an incidental finding, is the observation that both gut and joint disease respond to a gluten-free diet. Joint symptoms can precede gastrointestinal symptoms; indeed, coeliac disease can be silent in one-third of cases with arthritis, so investigation of unexplained seronegative arthritis by measuring anti-endomysial antibodies is appropriate, followed by endoscopy and biopsy in antibody-positive patients. This approach is justified since untreated coeliac disease carries an increased risk of lymphoma. Note that measuring antibodies to gliadin is much less satisfactory since such antibodies are sometimes present in patients with polyclonal increases in immunoglobulins, such as those with RA. In keeping with genetic predisposition to various forms of autoimmunity, an increased incidence of coeliac disease (~6%) among patients with juvenile idiopathic arthritis (JIA) has been reported.[79]

Whipple's disease

Understanding of this disease was advanced enormously by the discovery of the causative organism, using the molecular approach of amplifying bacterial ribosomal RNA (rRNA) genes which have sequences which are conserved in all bacteria.[80] This allows the use of 'universal' primers which amplify rRNA from all bacteria. Sequencing the product allows particular bacteria to be identified since rRNA genes also possess species-specific sequences. In the case of the Whipple's bacillus, a previously undescribed unique sequence was identified in the rRNA PCR product, and consistently found in jejunal biopsies from Whipple's disease patients. The organism, named *Tropheryma whippelii*, is related to actinomycetes, and has now been cultured, though it grows very slowly. It is not uncommon in the environment, and can be found in normal individuals' saliva or duodenal secretions (but not normal jejunal biopsies). It does not usually establish infection, suggesting that Whipple's patients have some impairment of their immune response. Although bacteria have long been implicated in Whipple's disease, identification of a specific organism has allowed more accurate diagnosis and indicates that there are patients, including some with arthropathy, who do not have the histological changes in the gut previously required for diagnosis. PCR has shown the presence of the organism in the joints,[81] and culture from synovial fluid has also been achieved.[82]

Whipple's disease is a rare (incidence 1:10^6) systemic disorder, and the commonest triad of symptoms is weight loss, diarrhoea, and arthralgia or arthritis.[83] Oligo- or polyarthritis are seen, often with involvement of large joints. Spondyloarthropathy features are generally absent, although a high frequency of HLA B27 has been observed in some series, and uveitis is seen. The arthritis can precede other features by up to 8 years, and PCR diagnosis may allow cases to be identified and treated before they develop systemic symptoms. Diagnosis can also be made by immunohistology using organism-specific antibodies. The diagnosis should be considered in patients with persistent seronegative oligoarthritis. The infection can also involve the central nervous system, heart valves, and lungs; treatment is with long courses of trimethoprim/sulphamethoxazole. Its efficacy can be monitored by determining whether patients remain PCR positive. These have persistent infection which may require a change in antibiotics. Given that some cases of Whipple's

disease will not be recognized, especially in the absence of gut symptoms, such patients may be classified as seronegative RA and eventually receive TNFα-blocking drugs when they fail to respond to disease-modifying anti-rheumatic drugs (DMARDs). Since the disease is driven by an intracellular bacterium, inhibition of TNFα is potentially disastrous, and dissemination of the organism with severe endocarditis has been reported in these circumstances.[84]

SECTION 12

Arthropathies primarily occurring in childhood

This page intentionally left blank

CHAPTER 116

Juvenile idiopathic arthritis

Eileen Baildam

Introduction

Juvenile idiopathic arthritis (JIA) is the current terminology for chronic arthritis in childhood that is not related to another multisystem disorder.[1] JIA is the most common chronic arthritis in childhood with an annual incidence of 1/10 000 in the United Kingdom, with reports from elsewhere varying from 2 to 20 per 100 000 and published prevalences of 16 to 150/100 000.[1–5] JIA is currently defined as arthritis of unknown aetiology beginning before the child's 17th birthday and persisting for at least six 6 weeks and where known causes have been excluded. The term JIA encompasses a heterogeneous group of conditions with variable clinical features and prognosis. The term JIA is also used for patients who reach adulthood and aims to emphasize the difference from adult-onset rheumatoid arthritis (RA).[1–5] It is known that many patients have ongoing problems into adulthood and although lasting disease remission may occur in some patients, as many as 50% of children will go into adult life with ongoing, active disease.[6] A recent multicentre study by Wallace 2005 illustrated the relapsing and remitting nature of the disease.[7] In this study 196 of 437 JIA patients followed for 7 years achieved a 1 year period without any active disease features were taking medication. However, less than 20% had two consecutive years without disease related symptoms and only 4% had a 5 year disease-free period.[7]

JIA affects more girls than boys, although the gender distribution varies with different subgroups; e.g. in the oligoarticular, polyarticular and psoriatic subtypes the gender ratio is 2:1 females to males although it is more equal in systemic JIA and there are more boys affected in the enthesitis-related arthritis (ERA) group.[3] Notably, in patients with associated uveitis, females are more affected.[8] The management of JIA requires specialist multidisciplinary expertise and increasingly the approach is early and aggressive intervention with potent immunosuppressive treatments. Details about management, treatment, outcomes and outcome measures are given elsewhere in this textbook.

Differential diagnosis of juvenile idiopathic arthritis

The differential diagnosis of JIA is broad (Box 116.1). The diagnosis is one of exclusion requiring careful clinical assessment, knowledge of normal development, and judicious use and interpretation of investigations. Serious and potentially life-threatening conditions

---

Box 116.1 The differential diagnosis of pain in childhood

Life-threatening conditions
- Malignancy (leukaemia, lymphoma, bone tumour)
- Sepsis (septic arthritis, osteomyelitis)
- Non-accidental injury

Joint pain with no swelling
- Hypermobility syndromes
- Idiopathic pain syndromes (reflex sympathetic dystrophy, fibromyalgia)
- Orthopaedic syndromes (e.g. Osgood–Schlatter disease, Perthes' disease)
- Metabolic (e.g. hypothyroidism, lysosomal storage diseases)

Joint pain with swelling
- Trauma
- Infection
- Septic arthritis and osteomyelitis (viral, bacterial, mycobacterial)
  - Reactive arthritis (post-enteric, sexually acquired)
  - Infection related (rheumatic fever, post-vaccination)
- Juvenile idiopathic arthritis
- Arthritis-related inflammatory bowel disease
- Connective tissue diseases (systemic lupus erythematosus, scleroderma, dermatomyositis, vasculitis)
- Sarcoidosis
- Metabolic (e.g. osteomalacia, cystic fibrosis, lysosomal disorders)
- Haematological (e.g. haemophilia, haemoglobinopathy)
- Tumour (benign and malignant)
- Chromosomal (e.g. Down's related arthritis)
- Autoinflammatory syndromes (e.g. periodic syndromes, chronic recurrent multifocal osteomyelitis)
- Developmental/congenital (e.g. spondyloepiphyseal dysplasia)

need to be considered (including infection, malignancy, and non-accidental injury); infections must be considered in the context of the immunocompromised and geographical areas where certain infections are endemic (e.g. Lyme disease and rheumatic fever). The reader is directed to other chapters in the textbook (Chapters 1, 5, 12–14, 99) for further information. Misunderstandings about the nature of pain in JIA, the misplaced expectation that children present with pain, and that normal investigations exclude the diagnosis are a cause of many missed or delayed diagnoses.[9] Conversely, many children with chronic musculoskeletal pain are misdiagnosed as having arthritis. In childhood, infective disease is much more frequent, and genetic disorders, immune deficiency states, and metabolic disorders are more commonly diagnosed than in adults. Comorbidity can associate with arthritis, e.g. children with chromosomal disorders (such as Down's syndrome, Turner's syndrome, velocardiofacial syndrome) and inflammatory bowel disease (IBD) have an increased risk of inflammatory arthritis.[10–14]

Early diagnosis of JIA rests on suspicion and awareness that young children and especially preverbal children, may present without apparent pain. Presentations may be vague and based on observations from parents or carers (such as limp) or a change in behaviour, mood, or avoidance of activities. Joint swelling can be difficult to detect especially if the changes are symmetrical. Examination often reveals joint involvement that is seemingly asymptomatic. Investigations including acute-phase reactants are often normal and radiographs are usually normal in early disease. Increasingly ultrasound is used, albeit there is a lack of standardized assessment and interpretation of normal and abnormal changes in the growing joint. Autoantibodies are not diagnostic; anti-nuclear antibodies (ANA) may be detected in many children with transient illness and also normal healthy children. Rheumatoid factor (RF) is invariably negative in JIA and again is not diagnostic. However, in the presence of JIA, autoantibodies are useful regarding prognosis; ANA increase the risk of uveitis and RF associates with a guarded prognosis. The absence of definite joint swelling should not discount a potential diagnosis of JIA; referral for specialist opinion from paediatric rheumatology is advised, and especially before contemplating invasive procedures (such as arthroscopy, synovial biopsy, or MRI), which are invariably not necessary to confirm the diagnosis. If MRI is required, then gadolinium should be given as enhancement is helpful to detect synovitis.

Definitions, classification criteria, and diagnostic criteria

Box 116.2 and Table 116.1[1,15] summarize the International League of Associations for Rheumatology (ILAR) classification of JIA, clinical features, definitions, and exclusion criteria for each subtype.[16–18] The subtypes are largely based on clinical features and in clinical practice some children are unclassifiable; for example, a patient with both systemic-onset JIA and psoriasis. The ILAR criteria have replaced previous criteria and are used internationally but have not been validated prospectively.

Oligoarticular juvenile idiopathic arthritis

This is the most common presentation of JIA and further subdivided into persistent and extended oligoarticular disease by the course (Box 116.2 and Box 116.3). Oligoarticular JIA affects up

---

Box 116.2 ILAR classification of juvenile idiopathic arthritis subtypes

Oligoarthritis—arthritis of 4 or fewer joints within the first 6 months

i   Persistent—affecting not more than 4 joints throughout the disease process

ii Extended—extending to affect more than 4 joints after the first 6 months

Polyarthritis—arthritis of 5 or more joints within the first 6 months

Subdivided according to presence of rheumatoid factor (RF)

i   RF-positive

ii RF-negative

Systemic arthritis—arthritis with or preceded by quotidian (daily) fever for at least 3 days, accompanied by one or more of:

1   Evanescent erythematous rash

2   Lymphadenopathy

3   Hepatomegaly and/or splenomegaly conditions

4   Serositis

(Mandatory exclusion of infective and malignant; arthritis may not be present early in course)

Psoriatic arthritis—arthritis and psoriasis or arthritis with at least 2 of:

1   Dactylitis

2   Nail pitting or onycholysis

3   Psoriasis in first-degree relative

Enthesitis-related arthritis—arthritis and enthesitis or arthritis or enthesitis with 2 of:

1   Sacroiliac joint tenderness of inflammatory lumbosacral pain

2   HLA B27 antigen

3   Onset after age 6 years in a male

4   Acute (symptomatic) anterior uveitis

5   History of HLA B27-associated disease in a first-degree relative

Undifferentiated arthritis—arthritis that fulfils criteria in no or more than two of the above categories

Adapted from Petty et al.[1]

---

to 50–60% of JIA cases[1,19–20]; the majority are girls (80%) with a peak age of onset in early childhood (1–3 years of age). The onset may be insidious and asymptomatic and blood tests may be normal, leading to a delay in diagnosis. However, the joint may be stiff especially in the morning and after rest, and this may lead to limping in lower limb joints or reluctance to push up on an arm in upper limb joints. The joint may feel slightly warm and may be swollen with a reduced range of movements, but these findings may be subtle and difficult to detect (especially in toddlers). Knees and ankles (Figure 116.1) are the most commonly affected joints and

Table 116.1 Summary of clinical features of juvenile idiopathic arthritis (JIA) subtypes

JIA subtype	Clinical features	%	Onset	Gender ratio (female:male)	Uveitis risk
Systemic-onset JIA	Fever, rash, and arthritis. Arthritis may be absent at presentation	4–17	Throughout childhood and in adults	1:1	Very low
Oligoarticular JIA	≤4 joints affected. Monoarthritis most frequent	27–60	Early childhood peak 2–4 years	5:1	High
Persistent oligo JIA	Disease remains oligoarticular at 6 months from onset and throughout its course	(40)			High
Extended oligo JIA	Oligoarticular at 6 months from onset and then subsequent polyarticular extension	(20)			The highest
Polyarticular JIA	Affecting ≥5 joints within the first 6 months from onset				Significant
RF-positive polyarticular JIA	Polyarticular arthritis and most like adult-onset RA	2–7	Late childhood or early adolescence into adulthood	3:1	Low
RF-negative polyarticular JIA	RF polyarticular disease	11–30	Early peak 2–4 years and late peak 6–12 years	3:1	Significant
Psoriatic arthritis	Can be diagnosed without signs of psoriasis, with arthritis and at least 2 of dactylitis, nail pitting or oncholysis, psoriasis in a first-degree relative	2–11		1:1	Significant
ERA	Arthritis and enthesitis or arthritis or enthesitis with at least 2 of: sacroiliac joint tenderness or inflammatory lumbosacral pain (or both), HLA B27-positive, onset in boy over 6 years, acute anterior uveitis, HLA B27-associated disease[a] in a first-degree relative. Spondylitis rare in childhood. Terminology ankylosing spondylitis in adulthood	1–11		1:7	Usually acute anterior uveitis but may be mixed
Unclassified		11–21			Moderate

ERA, enthesitis-related arthritis; JIA, juvenile idiopathic arthritis; RA, rheumatoid arthritis; RF, rheumatoid factor.
[a]Ankylosing spondylitis, enthesitis-related arthritis, sacroileitis with inflammatory bowel disease, Reiter's syndrome, or acute anterior uveitis.
Adapted from the 2001 Edmonton Revision of Durban Criteria.[1]

Fig. 116.1 Swollen ankles in oligo juvenile idiopathic arthritis.

50% present with a monoarthritis.[21–23] However most joints can be involved, including the temporomandibular joint (TMJ). The disease can be relatively mild and self-resolving or remitting permanently after a single intra-articular steroid injection. Repeated injections may be required and there is a low threshold for use of methotrexate and biologics, especially with extended disease. In approximately 50% of cases there will be an evolution to extended oligoarticular disease where after 6 months from onset 5 or more joints become involved.[21,22]

Many cases have a positive anti-nuclear factor (up to 85%) and many will develop uveitis. Although uveitis may occur in most types of JIA, numerically the majority of cases will be in the oligoarticular subtype and the risk is highest in the young girls with a positive anti-nuclear factor. Sequelae of long-standing inflammation of joints in oligo JIA include overgrowth and subsequent premature fusion of the epiphyses. Involvement of the knee, for example, may result in unequal leg lengths leading to secondary scoliosis, and prominent bony enlargement with genu valgum. At other sites uncontrolled inflammation can result in inequality of digit length, micrognathia, and flexion contractures. Joint damage and functional limitation are much less common with modern approaches to treatment but are still seen and usually reflect delay in access to specialist care.

Juvenile idiopathic arthritis involving multiple joints

Many types of arthritis in childhood involve multiple joints (defined as ≥5 joints). This can be seen in both types of polyarticular JIA (RF positive or negative). In systemic-onset JIA with a polyarticular course there is sometimes resolution of the systemic features after the first illness flare, such that the disease course is otherwise very like a RF-negative JIA. Extended oligoarticular JIA involves five or more joints but only after the first 6 months of initial illness where up to four joints have been involved. There is a high risk of associated uveitis in many of the polyarticular types of JIA as well as in oligoarticular disease. Polyarticular involvement is also seen in psoriatic arthritis and in ERA. Constitutional symptoms of fatigue, morning stiffness, poor appetite, anaemia, and raised inflammatory markers do occur. If gastrointestinal features are prominent it is important to exclude coeliac disease and IBD, both of which can have associated arthritis which may precede the bowel symptoms. There is, conversely, an increased risk of coeliac disease in association with JIA also. If fever is a major feature then systemic JIA must be considered.

Polyarticular JIA is subdivided into RF-positive (with positive results on two tests measured at least 6 weeks apart) or RF-negative polyarticular JIA. These subtypes affect 25–40% of JIA cases.[1,19,20] All joints can be involved in polyarticular JIA and in many cases most joints are simultaneously affected. Cervical spine and TMJ disease often coexist. Joints may be swollen (Figures 116.2 and 116.3) or simply painful and tender with reduction in function (this is so-called 'dry synovitis'). RF-positive polyarticular JIA accounts for only 5–10% of JIA and resembles adult-onset RA with a guarded prognosis and propensity for nodule formation. Disease onset is typically in children older than 8 years but more common in adolescence, with 90% being girls. The exact role of anti-citrullinated protein/peptide antibodies (ACPA) in polyarticular JIA is unclear in contrast to adult RA. RF-negative polyarticular JIA may be anti-nuclear factor positive and in either case there is an increased risk of uveitis.

Systemic-onset juvenile idiopathic arthritis

Systemic-onset juvenile idiopathic arthritis (SJIA) is increasingly perceived as an autoinflammatory disorder,[23,24] accounts for

Fig. 116.2 Swollen knees in polyarticular juvenile idiopathic arthritis, with quadriceps wasting.

Fig. 116.3 Swollen fingers and wrists in polyarticular juvenile idiopathic arthritis..

Fig. 116.4 Rash in systemic juvenile idiopathic arthritis..

approximately 10% of JIA,[25] and is characterized by a fever with a daily pattern of one or more regular fever spikes with a subnormal or hypothermic dip after spikes.

There is a characteristic systemic rash (Figure 116.4) which comes and goes, is maculopapular, salmon pink, often pruritic, and can vary from a few small macules 3–5 mm across in the axilla to a widespread confluent and urticarial rash. It is often worse at the time of temperature spikes or in the evening. Koebner's phenomenon (where a rash develops in a scratch line, or an area of pressure) is a useful clinical sign may help to distinguish SJIA from other febrile illnesses.

Features of a systemic illness include significant general malaise with arthralgia, myalgia, serositis causing chest and abdominal pain from pleural effusions, pericardial effusions, and sterile peritonitis. Lymphadenopathy can be generalized and associated with hepatosplenomegaly and these lymph nodes can also be painful. Headaches and irritability are common.

Although pleural effusions are common, pulmonary disease is rare, but interstitial lung disease and deranged pulmonary function tests have been reported.[26] Rare radiographic abnormalities include transient pneumonitis, interstitial reticular and nodular infiltrates, pleural and pericardial effusions, and patchy pleural infiltrates. Pathological abnormalities include pulmonary haemosiderosis, lymphoid follicular bronchiolitis, and lymphocytic interstitial pneumonitis. Arthritis of the cricoarytenoid joints can present with hoarseness or stridor (as can occur in polyarticular disease). Severe chest pain may be caused by pericarditis and may lead to tamponade. Chronic and constricting pericarditis is rare.[27,28] Clinically apparent myocarditis is rare (but potentially fatal without urgent

treatment with steroids), but subclinical myocarditis may occur in up to 10–12%.[27] Some cases with mild coronary dilatation have been observed although no cases of coronary artery aneurysms have been reported.[27,28]

Asymptomatic anterior uveitis is distinctly uncommon, although steroid-induced cataracts can occur, necessitating eye screening. Arthritis can be absent in the early weeks of disease onset and, in an unwell child with fever and rash, the differential diagnosis remains broad and infection and malignancy must be excluded. Neurological features are rare and if present raise the possibility of systemic vasculitis or macrophage activation syndrome (MAS),[29] which is a serious life-threatening complication.

Laboratory findings

Laboratory findings in SJIA include a marked inflammatory response with raised erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), leucocytosis, neutrophilia, anaemia, thrombocytosis, hypoalbuminaemia, and hypergammaglobulinaemia. A markedly raised serum ferritin is helpful, albeit not diagnostic of SJIA with or without MAS. Other suggestive features of MAS include cytopenias, low fibrinogen, unexpectedly normal or low ESR for the level of the CRP, liver derangement, raised triglycerides, and raised D-dimer levels in the serum.

Course of disease

Arthritis usually develops within the first few weeks or months of presentation and can be in an oligoarticular pattern or more commonly polyarticular and severe, resulting in joint damage. Tenosynovitis is common and can be associated with exuberant synovial thickening and bursal formation around the shoulder, wrists, knees, and ankles as well as around the flexor tendons of the hands and toes. This swelling and any associated joint effusions can come and go rapidly in association with temperature spikes and can be very painful. In the long term bony ankylosis is a characteristic feature in SJIA and especially in the cervical spine, wrist, and tarsus. Damage to the growth plates can occur rapidly and can lead to micrognathia or brachdactyly.[30] Chronic destructive arthritis is reported in up to 50% of patients although with modern drug treatment regimes it is anticipated that the prognosis is better.[31]

SJIA is a heterogeneous subtype and can follow a monocyclic, polycyclic, or persistent course. It can be severe, with potential for mortality and severe morbidity; management approaches focus on potent immunosuppression, usually with high-dose corticosteroids initially, parenteral methotrexate, and biologics especially with IL-6 and IL-1RA blockade as detailed in Chapter 96.

Psoriatic arthritis

Initially juvenile onset psoriatic arthritis was diagnosed when a child with arthritis went on to develop frank psoriasis, but it is now generally accepted that the term can be applied to children with arthritis who also have dactylitis, nail changes, and/or a history of psoriasis in a first-degree relative. This subtype is diagnosed in about 5–7% of cases of JIA.[32] There appear to be two peaks in age at onset, one at the age of 2 years and another in late childhood. Younger patients are more likely to exhibit dactylitis and small-joint involvement and to be female, and are more likely to progress to polyarticular disease. Older patients are more likely

to have enthesitis, axial joint disease, and to remain oligoarticular. Psoriatic JIA can be erosive and severely damaging to joints, is usually asymmetrical (Figure 116.5), and can cause significant local bony overgrowth and deformity. Uveitis occurs in around 8–10% of patients with psoriatic disease and it is vital that they are referred for uveitis screening.[33]

Enthesitis-related arthritis

ERA is an HLA B27-associated subtype of JIA characterized by inflammation of the entheses and/or the axial spine as well as peripheral joint disease. It affects 11–16% of children and young people with JIA.[34,35] In the past this type of JIA was called juvenile ankylosing spondylitis, seronegative enthesopathy and arthropathy (SEA) syndrome, or undifferentiated juvenile spondylarthropathy. Enthesitis is defined as discretely localized inflammation at the point of insertion of tendons, ligaments, joint capsules, or fascia to bone.

In a recent cohort study of 32 newly diagnosed ERA patients with a median age of 12.5 years, the median number of tender entheses at presentation was 2 (IQR 0–5); 21 subjects (66%) had at least 1 tender enthesis. The most frequently affected entheses were the patellar ligament insertion at the inferior pole of the patella, the plantar fascial insertion at the calcaneus, the Achilles tendon insertion at the calcaneus, and the plantar fascial insertion at the metatarsal heads. Enthesitis was usually symmetrical. The median number of active joints was 2 (IQR 0–4) and arthritis most commonly affected the sacroiliac (SI) joints, knees, and ankle joints.[34]

Diagnosing sacroiliitis in children and young people is based on reported pain and pain on SI stretch tests in combination with the gold standard of changes on MRI scan. Signs on MRI include synovial fluid in the SI joint, bone marrow oedema, subchondral sclerosis, bone erosions or irregularities, periarticular fat deposition, and SI anklyosis.[35] Sacroiliitis is often over-diagnosed on the plain radiograph with the growing epiphyses mimicking ostieitis to a non-paediatric specialist radiologist.[36]

Symptomatic acute anterior uveitis is present in up to 40% of adult patients[37] and in around 9.8% of children with spondyloarthritis, and chronic uveitis can also occur.[35]

In children the development of sacroiliitis and frank ankylosing spondylitis may take 5–10 years to develop. Juvenile onset ankylosing spondylitis appears to be a progressive disease, associated

Fig. 116.5 Asymmetrical small-joint involvement in psoriatic juvenile idiopathic arthritis.

with a significant delay in diagnosis and with a worse functional outcome.[38]

Extra-articular associated disorders—uveitis

JIA-associated uveitis is one of the leading causes of blindness worldwide and the importance of ongoing screening may not be fully appreciated by families and clinical teams alike. Uveitis can present with symptoms such as blurred vision, reduced visual acuity, photophobia, occasionally with pain and redness around the iris, an irregular pupil, a change in colour of the iris, and sometimes with a visible hypopyon. However, small children adapt so quickly that they do not notice an impairment in their own vision. Parents may only suspect problems when the child becomes clumsy. By this stage there is likely to be severe inflammation and secondary complications such as glaucoma, cataracts, fibrosis, and scarring within the eye, which may be irreversible. For this reason it is vital that all children are referred as soon as possible after diagnosis of JIA for screening to the local ophthalmology department. This needs to be done with regular slit-lamp examinations and usually requires dilation of the pupil at least for the first examination. The frequency and duration of eye screening is dependent on the JIA subtype and the presence of uveitis.

In older published series rates of uveitis in JIA vary from 4% to 24.4%.[39] More recent studies have suggested rates of 13.1% of 1081 patients with JIA in a study by Saurenmann,[40] and 12% of 3271 JIA patients in a large German cohort study.[41] The most frequent incidence was in the extended oligoarticular group where 25% had uveitis and the persistent olioarticular group where 16% were affected. Predictors of uveitis were younger age at onset of arthritis, ANA positivity, and JIA subtype. Uveitis is very unusual in SJIA but rarely can occur, as can steroid-induced cataracts. Uveitis is often acute with a painful red eye in enthesitis-related JIA, but this is not always the case and chronic uveitis can also occur in this group of patients. In all other types of JIA, including psoriatic disease, uveitis can occur. The median onset of uveitis after diagnosis of arthritis was 5.5 months, with uveitismanifesting between 2–5 years in 16% and after 5 years in 7%. In 70% of cases uveitis is bilateral and this increases to 77% of the oligo JIA cases. Approximately 77% developed uveitis before their 7th birthday. Anterior uveitis is the most common anatomical type of arthritis (83%), intermediate uveitis 9%, posterior uveitis 1%, and panuveitis in 7%.[42] In 45% of patients complications of uveitis are already seen at the initial screen, emphasizing the asymptomatic nature of this uveitis and the need for rapid diagnosis of JIA so that the eye screening can be started as soon as possible. Ocular complications are seen in up to 65–86% of patients with uveitis 3–5 years after initial diagnosis and many patients are unfortunately legally blind at first presentation to the ophthalmologist. Long-term follow-up studies after 20 years have revealed surprisingly poor outcomes.[41,43]

The management of JIA-associated uveitis can be complex and requires close collaboration with ophthalmologists and rheumatologists to ensure rapid access to screening, facilitate systemic therapies to be started early and optimize visual outcomes.

CHAPTER 117

Systemic lupus erythematosus—clinical features and aetiopathogenesis

Caroline Gordon

Epidemiology of systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is associated with multiple genetic and environmental risk factors that have been discussed in Chapter 42. The importance of environmental factors acting on the genetic background is manifest by the observation that only 24% of identical twin pairs are concordant for lupus, and for dizygotic twins the risk is 1 in 50 (2%) for both developing the disease.[1]

Prevalence of lupus

The prevalence of lupus around the world is summarized in Table 117.1.[2,3] In the United Kingdom, carefully conducted studies to assess the prevalence of lupus were undertaken in the early 1990s. The largest study from Birmingham using multiple methods of case ascertainment and clinical assessment of all suspected cases referred by hospital doctors or general practitioners confirmed that the point prevalence of lupus in adults in 1992 was 27.7 per 100 000, suggesting that about 1 in 3500 people have lupus.[4] Lupus was 14 times more common in women than men with a prevalence in adult women of 49.6/100 000 and 3.6/100 000 in adult men. Lupus may be underdiagnosed in men, as the gender ratio has been 14 females to each male for over 20 years in the Birmingham study. The prevalence was highest in patients of Afro-Caribbean origin, irrespective of place of birth. Lupus was found to affect 206.0/100 000 Afro-Caribbean adult women compared with 90.6/100 000 South Asian women from India or Pakistan, and 36.2/100 000 women of white European background. Patients of Afro-Caribbean origin aged 30–39 had the highest prevalence (405/100 000), were the youngest at disease onset, and were most likely to have renal disease.

Studies over the last 20 years in the United States have yielded higher prevalence, with rates between 32 and 150/100 000,[5] than either the United Kingdom studies or previous United States studies undertaken between 1965 and 1995, which suggested a mean prevalence of about 24/100 000. Recent studies in Michigan and Georgia (USA) using multiple methods of case ascertainment in

areas with about 50% black population have found a mean annual prevalence rate of lupus of 73/100 000.[6–8] The rates in women were about 10 times higher than the rates in males. Black women not only had the highest prevalence (at about 190/100 000) in both Michigan and Georgia, but also presented younger than white women, were more likely to have renal disease, and to develop end-stage renal disease.

Many studies from around the world have confirmed that lupus is rare before puberty and is most common in women in the reproductive age group, when the gender ratio is about 10 females to each male, whereas there is less female predominance in children and in older age groups (>50 years). Further studies are ongoing in the United States to confirm the prevalence in other racial/ethnic groups such as Hispanics, Chinese and American Indians. The LUMINA study has shown that Hispanics and African-Americans are at increased risk of developing lupus nephritis compared to populations of white European descent.[9] Several studies have shown that populations of Chinese origin have an increased risk of lupus and lupus nephritis.[10]

Incidence of lupus

The incidence of lupus around the world is summarized in Table 117.2.[2,3] Studies undertaken in the United Kingdom in the early 1990s suggested that the incidence of lupus was about 4 per 100 000 in Birmingham and Nottingham, and similar results were obtained from Sweden.[4,11,12] A more recent UK GP Research Database based study suggested than the mean incidence in the United Kingdom in participating general practices was 7.9/100 000 per year between 1990 and 1999.[13] However, the criteria for classification of cases was not standardized, whereas most other studies required at least 4 out of 11 American College of Rheumatology (ACR) classification criteria for SLE. The rate varied widely between geographical regions and was highest in Northern Ireland, although studies on prevalence in Northern Ireland in 1993 had shown similar prevalence to Birmingham, at 25.4/100 000. In this GP database study the West Midlands incidence was 3.6/100 000, comparable to that found in Birmingham previously. The recent United States studies found incidence to be higher at about 5.5/100 000 per year in Michigan and Georgia, and to be highest in black females (about 13/100 000 per year).[6–8]

Pathology of systemic lupus erythematosus

Multiple immune abnormalities involving B and T cells, dendritic cells, and mononuclear phagocytes contribute to the development of lupus. Although cell-mediated mechanisms are involved in the pathology of lupus, it is the formation of immune complexes involving nucleic acids and autoantibodies that is the hallmark of the disease.[14] The mechanisms involved in the activation of B and T cells and the generation of autoantibodies are discussed further below. Tissue damage results from mechanisms resulting from direct binding of autoantibodies and from the activation of complement by immune complexes formed in the circulation or in the tissues. Levels of certain autoantibodies (anti-dsDNA, anti-C1q) and complement consumption can be used to assess disease activity. Lupus can affect all organs of the body and specific histological features may be seen, as for example with lupus nephritis. In general, there is infiltration of the tissues with mononuclear cells together with evidence of fibrinoid necrosis, formation of haematoxylin bodies containing chromatin and immunoglobulin, vascular inflammation and injury, deposition of immunoglobulin and complement, and in the skin disruption of the dermal–epidermal junction.

There is increasing evidence that the processing of immune complexes and of apoptotic cells is suboptimal and that this contributes to the development of lupus and flares at times of physical stress, such as after infection and UV light exposure, when increased production of apoptotic cells and immune complexes occurs. Genetic or acquired deficiency of the early components of complement (C1q, C2, or C4) and polymorphisms of the Fc gamma receptors are important risk factors for lupus because of the resulting deficits in handling apoptotic material and immune complexes.[15–19]

Not only is the adaptive immune response important in the development of lupus but there is increasing evidence for a role for the innate immune activation and production of type 1 interferons which may promote autoantibody formation. Genetic risk factors predisposing to lupus include a single-nucleotide polymorphisms in two interferon-related genes, those encoding tyrosine kinase 2 and interferon regulatory factor 5 (IRF5).[20–23] Even premature atherosclerosis, which is a common complication of lupus, is probably initiated and accelerated by immune mechanisms.[24]

Lupus is most common in women during the reproductive years, suggesting a role for sex hormones. Oestrogens in hormone replacement therapy and contraceptive pills can increase the risk of mild/moderate flares even in patients without severe disease activity.[25–27] Pregnancy, which is associated with much higher hormone levels, can cause the disease to flare severely, especially if lupus presents for the first time in pregnancy or established disease is not well controlled before pregnancy. The molecular mechanisms

whereby oestrogens influence immune cell function and cytokine formation are not well understood but there is evidence that many cells of the immune system bear oestrogen receptors. Furthermore, lupus patients have recently been reported to develop antibodies to oestrogen receptor alpha that are associated with active disease and that on binding can cause activation and subsequent apoptosis of resting lymphocytes or induce proliferation of stimulated T cells.[28,29]

Autoantibodies in lupus

The presence of autoantibodies in the serum, particularly IgG antibodies to nuclear material, is the hallmark of lupus disease. However, autoantibodies directed against a large number of self-antigens (>40) in the cytoplasm and cell membranes as well as the nucleus are found in lupus patients, only a few of which are tested for in the clinic.[30] IgM autoantibodies can occur in healthy people, particularly after infections including glandular fever due to Epstein–Barr virus (EBV), but class switching to IgG antibodies is not usually seen. The anti-nuclear antibody (ANA) test is very sensitive, being positive in over 95% of lupus patients, but is not very specific as it is also positive in other diseases such as dermatomyositis and systemic sclerosis. Studies have shown that IgG autoantibodies can be found in the serum up to 9 years before the development of clinical features of lupus.[31] Deposition of autoantibodies and complement has been observed in the kidneys and skin. Although immunoglobulins that bind to a number of non-DNA antigens, including Ro (a ribonucleoprotein complex), La (an RNA-binding protein), C1q (a subunit of the C1 complement component), and Sm (nuclear particles consisting of several different polypeptides) can be observed in the serum and the kidney, it is the presence of antibodies that bind double stranded (ds)DNA in the kidney and in the serum that is considered one of the most typical features of lupus. Anti-dsDNA antibodies are highly specific for lupus and are present in 40–70% of patients with lupus but in less than 0.5% of healthy people or patients with other autoimmune diseases.[14] The levels of anti-dsDNA antibodies in serum usually reflect disease activity, with rises before flares though sometimes falls at the time of flare due to deposition of the antibodies in the tissues. Indeed, some of the autoantibodies observed in the kidney may be deposited in the tissue only after inflammatory processes expose nuclear antigens during apoptosis (programmed cell death). Nucleosomes are fragments of DNA and histone generated during apoptosis.[30] There is increasing evidence that anti-nucleosome antibodies are formed even before anti-dsDNA antibodies in response to dysfunctional clearance of apoptotic cells at times of stress,[18] and that antibodies to dsDNA, nucleosomes, and α-actinin are important in the pathogenesis of lupus nephritis.[32] Anti-nucleosome antibodies have been observed also in some skin biopsies from patients with lupus nephritis, but without rash.[33]

Photosensitive rashes are associated with anti-Ro antibodies. During pregnancy Ro antigens are exposed on the surface of fetal cardiac myocytes during remodelling of the heart. From about 16 weeks of gestation onwards, maternal anti-Ro or anti-La antibodies can cross the placenta and may interact with exposed Ro or La antigens, resulting in atrioventricular conduction defects. This can cause congenital complete heart block which may present at any time from week 16 to the neonatal period, but usually between weeks 16 and 32 of gestation. Fortunately this only occurs in 1–2% of babies born to mothers with anti-Ro antibodies or anti-La antibodies, though 5–10% of babies may develop UV-induced subacute lupus rash after birth, usually during the first 3 months of life due to placental transmission of these antibodies.[34,35]

Anti-NMDA-receptor antibodies have been found in the brain tissue of patients with cerebral lupus and animal studies have suggested that antibodies against the N-methyl-D-aspartate (NMDA) receptor may be important in the development of central nervous system lupus. NMDA is an excitatory amino acid released by neurons. Intravenous administration of serum from lupus patients containing antibodies against DNA and NMDA receptors induced cognitive impairment and hippocampal damage.[36]

Other autoantibodies are important in autoimmune haemolytic anaemia and thrombocytopenia. In these cases the autoantibody can bind to cell surface antigens, leading to immune-mediated destruction of red cells and platelets. Anti-phospholipid antibodies may also bind to platelets and are associated with thrombosis in lupus patients, as occurs in anti-phospholipid syndrome.[37]

Tissue damage by autoantibodies

There are two main theories of how tissue damage occurs in the kidney in patients with lupus nephritis, and similar mechanisms are thought to explain other lupus manifestations. Berden and colleagues have proposed that pathogenic, high-affinity, anti-dsDNA or anti-nucleosome autoantibodies bind to nucleosomes in the blood of patients with lupus and form antibody–nucleosome complexes that deposit in the renal glomerular basement membrane.[38] These complexes activate complement which initiates the development of glomerulonephritis. IgG antibodies have been shown to colocalize with extracellular chromatin in lupus nephritis in humans and mouse models of lupus.

The alternative model proposes that high-affinity anti-dsDNA and/or anti-nucleosome antibodies cross-react with proteins such as α-actinin in the kidney and have a direct pathogenic effect on renal cells. Renal podocytes are part of the glomerular filtration process and their function is dependent on α-actinin. Mouse monoclonal anti-DNA antibodies that cross-reacted with α-actinin were pathogenic and induced lupus nephritis after transfer into recipient mice, in contrast to monoclonal anti-DNA antibodies that did not cross-react with α-actinin, which were non-pathogenic in two studies. Anti-α-actinin antibodies are not specific for lupus but may act as a marker of renal involvement when found in the serum of lupus patients; however, anti-α-actinin antibodies have not been reported in renal biopsies from patients with lupus nephritis.[14]

Role of T cells

Interaction of a T-cell receptor (TCR) with antigen bound to a major histocompatibility complex (MHC) peptide on the surface of an antigen-presenting cell (APC)—which may be a dendritic cell, macrophage, or B cell—triggers a T-cell response. MHC gene haplotypes such as HLA A1, B8, DR3 are associated with an increased risk of immune responses to self-antigens, resulting in autoimmune diseases such as lupus. IgG antibodies with high-affinity binding to dsDNA are more strongly associated with tissue damage than IgM or lower-affinity IgG antibodies in mouse models of lupus and in humans. Production of high-affinity IgG antibodies requires a process known as T-cell help and is important in the pathogenesis of lupus.[14]

The generation of high-affinity antibodies is a multistep process that starts with the binding of antigen to a specific immunoglobulin

on the surface of B lymphocytes (B cells). This stimulates the B lymphocytes to proliferate, migrate within germinal centres, and differentiate in the presence of signals from T lymphocytes, specifically from T helper (Th) cells.[30] Each T cell carries a surface-receptor molecule that binds to a particular antigen presented to the TCR in a complex with an MHC molecule on the surface of an APC. Presentation of the antigen–MHC complex and interaction with the TCR generates an activation signal but this alone is not sufficient to stimulate the T cell to produce all the signals required to induce B-cell differentiation. A second molecular interaction between the APC and the T cell is required, a process known as costimulation. There are several different pairs of costimulatory molecules, including the CD40–CD40 ligand and CD28–B7, which can generate the second signal required for T-cell activation and the subsequent generation of signals that induce B-cell proliferation and differentiation into the plasma cells that produce antibodies. Furthermore, the interaction of B and T cells and the stimulation of each other generates T-cell cytokines that promote B-cell proliferation and the switching of antibody production from IgM to IgG, and induces a change in the molecular structure of the secreted antibody so that it has higher affinity and binds more strongly to the target antigen. Agents that block costimulation can inhibit immune responses that depend on T-cell help. This includes cytotoxic T-lymphocyte–associated protein 4 (CTLA-4) on T cells that competes with CD28 to bind to B7 and can downregulate B-cell responses. CTLA-4 bound to an IgG1 molecule has been developed as a treatment for inflammatory immune-mediated diseases including rheumatoid arthritis and more recently lupus on this basis.[39]

Nucleosomes consist of a protein core of histones around which DNA winds. Histone-derived peptides H2B10-33, H416-39, H471-94, H391-105,H2A34-48, and H449-63 stimulate T cells from patients with lupus to produce cytokines.[14] Similar peptides stimulate T cells from lupus-prone mice but these peptides do not stimulate T cells from healthy people or non-lupus-prone mouse strains. It has been proposed that stimulation of these peptide-specific T cells would allow them to help B cells that respond specifically to antigenic epitopes derived from nucleosomes resulting in the production of high-affinity pathogenic autoantibodies. Nucleosomes contain B and T cell epitopes, and anti-nucleosome antibodies are present early and play a pathogenic role in the development of lupus. Anti-dsDNA antibodies are thought to be generated by similar process involving nucleosomes with T cells recognizing the histone-derived epitopes and B cells recognizing DNA (as T cells can only respond to protein-based epitopes).[30] This is reminiscent of hapten-carrier induction of antibodies in vaccine development and is likely to apply to the generation of anti-phospholipid antibodies as well, as only B-cell expressed Ig receptors can bind to phospholipids, while T cells react to protein antigens derived from membrane proteins.

The autoantigen-specific B and T cells that interact to produce pathogenic autoantibodies are not found in healthy people. Several mechanisms may be responsible for the absence of these cells, a phenomenon known as tolerance. These mechanisms include removal (deletion) of the autoreactive T and B cells, inactivation of the cells so that they are anergic, or a change in the light chain of the antibody expressed by an autoreactive B lymphocyte (so-called receptor editing) such that the antibody loses the ability to bind autoantigen. Furthermore the activation of Th cells and B cells can be suppressed by regulatory T cells (Tregs). Both the number and

function of regulatory T cells have been reported to be reduced in patients with lupus.[40] There is also an increased number of double negative (CD3+CD4−CD8−) T cells and of interleukin (IL)-17-producing T cells, and various early and late signalling abnormalities that contribute to the autoimmune process and provide novel targets for therapeutic intervention.[41]

Cytokines and lupus

Cytokines are protein messenger molecules that are produced by immune cells and play a key role in the development of innate and adaptive immune responses.[42,43] Cytokines may have stimulatory or suppressive effects depending on the ligand that they interact with and the activation state of the cell. Their production and effects are carefully regulated in a complex interacting network and anything that disturbs the cytokine environment (homeostasis) in one direction can have a variety of downstream effects, which may include effects that are the opposite of what is expected.

B lymphocyte stimulator

B lymphocyte stimulator (BLyS; also known as B-cell activating factor, BAFF) and APRIL (a proliferation-inducing ligand) are expressed by T cells, dendritic cells, monocytes, and macrophages but not by B cells. They are membrane proteins that can be released by proteolytic cleavage that are important for B-cell survival, differentiation, and function. In particular BLyS controls the final differentiation of mature, preimmune B cells and plays an important role in maintaining B-cell tolerance.[44] BLyS binds to three receptors: BCMA, TACI, and BR3 (also known as BAFFR). Pre-plasmablast mature B cells depend on BLyS as they express mostly BR3 and only a little TACI. Plasma cells express BCMA and TACI that bind BLyS and APRIL. Memory B cells are independent of BLyS and APRIL. T cells express BR3, though the role of BLyS in T-cell signalling is uncertain. Dendritic cells also express BLyS receptors and respond to BLyS by upregulating costimulatory molecules, chemokines, and IL-1 and IL-6 production.[42]

Aberrant BLyS expression is observed on many cell types and circulating BLyS levels are increased in some lupus patients. B cells and plasma cells can express high levels of BLyS and APRIL mRNA that correlate with anti-dsDNA antibodies and lupus disease activity. BLyS antagonists being developed for the treatment of lupus include belimumab (a monoclonal antibody that inactivates soluble BLyS)[45,46] and atacicept[47,48] (a fusion protein combining TACI and the Fc portion of IgG to bind BLyS and APRIL).

Interferons

Type I interferons (IFN-α and IFN-β) have important anti-viral, anti-proliferative, and immune modulatory functions.[42,43] Plasmacytoid dendritic cells are the major producers of IFN-α, but most cells can make this cytokine. The stimuli that induce it include viral and bacterial infections, self-nucleic acids, and nucleic-acid-containing immune complexes which engage with Toll-like receptors (TLRs). ssRNA-containing complexes engage TLR7 and TLR8 and dsDNA-containing complexes engage TLR9. IFN-α levels are increased in many lupus patients, especially with active disease, and type I interferon therapy has been found to induce a lupus-like syndrome. Raised IFN-α levels have been observed in healthy relatives of patients with lupus, confirming that other factors are required for disease manifestations to develop in susceptible people. IFN-α

promotes B-cell activation, proliferation, antibody production, and class switching and can potentially promote survival of autoreactive B cells, since it can prevent B-cell apoptosis. Furthermore, IFN-α produced by APCs modulates Treg function, reducing Treg suppression of inflammation and T-cell proliferation.

It has been shown that IFN-α contributes to the initiation and persistence of lupus and is linked to the activation of specific genes involved in the development of lupus (e.g. *IRF5*, *IRF7*).[23] Upregulated expression of IFN-inducible genes has been observed using genome-wide expression profiling and this characteristic gene expression pattern is known as the IFN signature. However, this is not restricted to lupus as it has been found in patients with Sjögren's syndrome and systemic sclerosis as well. There have been two phase 1 trials of anti-IFN-α monoclonal antibodies (sifalimumab and rontalizumab) in which dose-dependent reduction in the interferon signature was observed in association with reduced disease activity,[49,50] and the results of phase 2 trials are awaited.

Interleukins

Interleukin-1 (IL-1) and the IL-1 receptor antagonist (IL-1RA) are produced by activated mononuclear phagocytes. Specific polymorphisms of the IL-1a and IL-1b genes are associated with increased risk for SLE and specific alleles of the IL-1RA gene are associated with increased severity of the disease.[43]

IL-2 levels are low in lupus patients and this may contribute to the reduced number of regulatory Tregs observed in SLE. IL-17 levels are increased in many lupus patients, probably due to increased numbers of double negative T cells and Th17 cells which produce IL-17 and a reduction in Treg cells that control Th17 cells.[41,43] Development of Th17 cells is promoted by increased levels of IL-6, IL-21, and IL-23 which have been observed in patients with lupus, especially with active disease. IL-17 promotes monocyte and neutrophil recruitment and together with BAFF/BLyS, provides help to B cells resulting in B-cell activation, proliferation, and differentiation promoting antibody production and class switching.

IL-4, IL-5, IL-10, and IL-13 are produced by Th2 cells and are involved in proliferation, activation and isotype switching of B cells.[43] Increased amounts of IL-4 and IL-4-producing cells have been reported in SLE patients. IL-10 has anti-inflammatory effects through its effects on Tregs and proinflammatory effects through its effects on B cells. In SLE patients, monocytes and B cells are the main producers of IL-10. Polymorphisms of the IL-10 and the IL-10 promoter gene and increased IL-10 levels in serum have been observed. A monoclonal antibody against IL-10 was tested for 21 days in 6 patients with lupus.[51] There was a beneficial effect on skin and joint manifestations and a steroid-sparing effect at 6 months, but all of the patients developed an immune response to the administered monoclonal antibody which prevented further trials of this agent. IL-13 levels are raised in lupus, which may be associated with a polymorphism of the IL-13 promoter gene.

There is considerable evidence that serum levels of IL-6 are elevated and correlate with lupus activity and anti-dsDNA antibody levels, and an increased frequency of IL-6-producing mononuclear cells that correlates with disease activity and response to treatment in SLE patients.[42,43] Autoreactive T-cell clones have been observed that produce large amounts of IL-6 which promotes B-cell activation and autoantibody formation in lupus patients. Elevated cerebrospinal fluid (CSF) levels of IL-6 have been found in patients with psychosis. Mesangial IL-6 has been observed in kidney samples,

and raised urinary levels of IL-6 have been observed in some active patients to associate with anti-dsDNA antibody levels and to fall after treatment. Tocilizumab is a humanized IgG1 monoclonal antibody against the α-chain of the IL-6 receptor that inhibits binding of IL-6 to membrane-bound and soluble IL-6 receptor.[52] An open-label phase I dose escalation study suggested that tocilizumab may be able to control SLE disease activity but there were concerns about the risk of neutropenia and infections that may limit the development of this therapeutic strategy.

IL-12 stimulates the differentiation of TH1 cells which produce IL-2 and IFN-γ.[43] In mouse models of lupus IFN-γ is pathogenic. The role of IFN-γ and of the IFN-γ receptor in human lupus is less clear. IL-27 synergizes with IL-12 to increase IFN-γ production and has both proinflammatory and anti-inflammatory properties but its role in SLE is not certain.[43,53] In mice, IL-27 can induce T cells to produce IL-21, and IL-27 has been shown to be important for the function of follicular Th cells in germinal centres that are essential for maturation and selection of high-affinity B-cell clones. There is increasing evidence that IL-27 has useful anti-inflammatory effects in several autoimmune models of diabetes and lupus. Deficiency of IL-27 receptor α-chain in a pristine induced mouse model of lupus resulted in a reduction in autoantibodies and glomerulonephritis. In a mouse model of SLE-like skin inflammation IL-27/IL-27 receptor α-subunit signalling appeared to be protective. Finally, there are reports suggesting that levels of IL-27 are reduced in patients with lupus nephritis[54] and that expression of urinary IL-27 mRNA increased significantly in patients with complete response but not in those with no response or partial response after 6 months of immunosuppressive therapy, supporting the concept that IL-27 may be associated with anti-inflammatory effects.[55]

IL-15 and IL-21 are part of the IL-2 superfamily.[43] The receptors of all three cytokines share the same γ-chain, and IL-15 and IL-21 share the IL-2β receptor as well. IL-15 is increased in lupus patients and like IL-2 can induce T cell and NK cell proliferation, but importantly for lupus, also promotes isotype switching in B cells. IL-21, in contrast to IL-15 and IL-2, is involved in B-cell activation and plasma cell differentiation. Certain polymorphisms of the IL-21 and IL-21recepor genes have been reported in SLE patients and decreased IL-21 receptor expression on peripheral B cells is associated with high levels of autoantibodies and nephritis in SLE patients, making IL-21 a therapeutic target.[56,57] However caution is required, as in the BXSB-Yaa mouse model of lupus, IL-21 can regulate immune responses and can have immunosuppressive effects mediated in part by induction of IL-10.

Tumour necrosis factor alpha

The role of Tumour necrosis factor alpha (TNFα) in lupus remains controversial. It is an important mediator of inflammation but may also help to control autoimmunity.[42,58] Patients with a variety of diseases treated with anti-TNFα monoclonal antibodies or soluble receptors may develop anti-nuclear antibodies and occasionally transient lupus-like syndromes. There is some evidence from the New Zealand Black/White (NZB/W) mouse models of lupus that have genetically determined low levels of TNFα that administration of exogenous TNFα is beneficial. However, these and other mouse models of lupus have evidence of TNFα in the kidney, and in humans, elevated levels of TNFα have been observed in serum, kidney, and skin samples of patients with active lupus. Administration of infliximab and rarely other TNF blockers in single cases and

open-label studies involving at least 50 lupus patients have suggested that short-term induction therapy may be relatively safe but that long-term TNF blockade is associated with more risk.[59] Although long-term remission in patients with lupus nephritis, haemophagocytic syndrome, and interstitial lung disease have been reported, lupus arthritis tends to recur after cessation of therapy. Lupus flares do not occur even when there are transient increases in antibodies to dsDNA but increases in anti-phospholipid antibodies have been associated with vascular adverse events and there have been reports of bacterial infections, pneumonia, and urinary tract infections.

Presentation of systemic lupus

Lupus may present as a rapidly progressive condition with several systems involved over a few weeks or months, or as a slowly progressive condition with an increasing number of systems involved initially relatively mildly over several years. There are a wide variety of clinical and laboratory manifestations that may develop over time which are discussed below but each patient usually only demonstrates a few manifestations in a small number of systems at the same time.[60]

When assessing lupus patients it is important to distinguish reversible active inflammatory disease from thrombotic complications of anti-phospholipid syndrome, and to distinguish active lupus from chronic damage due to the accumulated effects of the disease and its therapy: for example lung fibrosis, myocardial infarction, or cataracts.[61] The possibility of infection and other comorbidity should be considered, especially as infection is a common trigger for lupus. Flares of active disease may also be triggered by UV light exposure, hormonal changes (oestrogens), and stress (e.g. major life events).

Constitutional features

The most common complaint of lupus patients is fatigue. It is important to be sure that fatigue is not due to a comorbid condition such as hypothyroidism, iron deficiency anaemia, depression, fibromyalgia, or chronic postviral or isolated chronic fatigue syndrome. Fatigue often contributes to the poor quality of life experienced by lupus patients.[62]

Fever with temperatures above 37.5 °C can occur due to lupus itself. It can also be due to comorbid conditions that need excluding including infection, lymphoma, and occasionally other malignant conditions. It is particularly important to bear in mind that lupus patients are more susceptible than healthy people to atypical infections, including tuberculosis (TB), pneumocystis, and cytomegalovirus (CMV) infection. Occasionally patients develop fungal infection secondary to cytotoxic therapy, or other infections which are more often associated with HIV infection. This is no coincidence, since both HIV infection and SLE are associated with low CD4 Th cell numbers, as lupus patients make antibodies to CD4+ T cells.

Lupus patients may develop reactive lymphadenopathy. This is most often seen in the early years of the disease course. A small number of patients present with Kikuchi–Fujimoto syndrome.[63,64] This is a necrotizing lymphadenitis that is known to predispose to autoimmune diseases including SLE and autoimmune hypothyroidism. Lymphadenopathy can also be due to infection, lymphoma[65] or other malignancy and needs to be investigated if the lymph nodes steadily enlarge. Fluctuating lymphadenopathy is more typical of lupus, particularly when there are other features of active lupus disease.

Anorexia and weight loss occur in some patients with active disease, particularly those with other constitutional features, and have the same differential diagnosis as fever and lympadenopathy. Anorexia and weight loss can also be due to depression or drug side effects. In addition, some patients who reduce their steroid dose or come off steroids altogether report quite marked weight loss, particularly if they put weight on while on higher doses of oral corticosteroids. For patients who have discontinued steroids completely there is always the risk that the original disease will return, but weight loss is rarely the first presenting feature of a lupus flare.

Mucocutaneous manifestations

Photosensitivity occurs in 50–60% of lupus patients, particularly those of white European origin, but is less common in those of African origin. Patients present most often with photosensitive maculopapular, subacute lupus, or discoid rashes. These rashes can also occur in the absence of photosensitivity. Subacute lupus rash may present as non-indurated psoriasiform and/or annular polycyclic lesions that resolve without scarring, but sometimes show postinflammatory dyspigmentation or telangiectasia. Rarer types of lupus rash are recognized.[66,67] The discoid lesions cause the most distress as they can be associated with scarring and may heal with either hypopigmentation or hyperpigmentation. Vasculitic rashes may also leave scarring with or without pigment changes, but subacute lupus and maculopapular lesions, including the generalized butterfly rash, usually resolve without any scarring or pigment change.

Reflex vasoconstriction of the blood vessels known as Raynaud's phenomenon is common in both the hands and feet. The characteristic three-colour change is white to blue with vasoconstriction, then red on rewarming, but two colour change is sometimes seen. It may also effect the other extremities, including the ear and the nose. Raynaud's and severe digital ischaemia can occur in patients exposed to drops in temperature of only 5–10 °C without going down to freezing and can result in significant digital infarction and gangrene. It is important to monitor the skin very carefully in these patients because of the risk of infection which can be difficult to treat due to the poor blood supply. These patients often require intravenous antibiotics and prolonged antibiotic courses to eradicate infection in the ischaemic extremities.

Vasculitic lesions can also progress to infarction and sometimes ulceration with a risk of secondary infection. Vasculitic lesions occur most commonly on the hands and feet, but can occur on all parts of the body and are typically associated with non-blanching purpuric rashes or subcutaneous erythema/nodules such as Janeway lesions as seen in subacute bacterial endocarditis, which is also due to immune complex deposition. Blistering lesions due to lupus are uncommon. The important differential diagnosis for localized areas of blisters in a dermatone distribution is herpes zoster (shingles) which is more common in patients on immunosuppressants. Rarely disseminated herpes zoster can occur with devastating consequences in patients without pre-existing immunity to this virus.[68]

Diffuse alopecia is more common than patchy alopecia. Diffuse alopecia often starts around the hairline and may be associated with

irregular short hairs on the hairline in the frontal region known as lupus frizz, particularly in patients of African origin. Diffuse alopecia may persist longer than other features of active lupus disease after treatment is initiated. Patients may need reassurance that their hair will gradually stop falling out and will regrow. In some cases it may remain thinner than it used to be and it may change consistency and even colour. Patchy hair loss can resolve completely with treatment over time, but if there is an associated discoid rash that heals with scarring, the patch of alopecia is likely to persist.

Nasal and oral ulcers are quite common in lupus patients. They may be painful or painless The oral ulcers are indistinguishable from normal apthous ulcers and those that occur in Behçet's syndrome and Crohn's disease. They tend to occur in crops within the oral cavity including the pharynx, and they may persist longer than in people without lupus. Some patients get mucosal ulceration in other regions including the vagina but this is less common than nasal and oral ulceration. It is important to exclude herpes simplex infection when genital ulcers occur, particularly in immunosuppressed patients.

Oral and ocular dryness due to immune destruction of mucosal glands occurs with increasing age. It is known as secondary Sjögren's syndrome and is more common with patients with anti-Ro and anti-La antibodies. Primary Sjögren's syndrome can be distinguished by salivary and lacrimal gland enlargement at the beginning of the disease associated with early-onset oral and ocular dryness (keratoconjunctivitis sicca). In lupus, other manifestations of lupus precede the ocular and oral dryness. Damage to other mucosal tissues may occur, for example causing dry cough and dry vagina.

Musculoskeletal manifestations

Over 90% of lupus patients suffer from inflammatory synovitis and the remainder usually suffer from arthralgia with early morning stiffness and gelling after a period of rest. Inflammatory arthritis in lupus is usually a symmetrical polyarthritis affecting small joints but it may present as a monoarthritis or oligoarthritis affecting medium and occasionally large joints. It is non-erosive and is associated with joint tenderness and stiffness but more limited amounts of swelling than is seen in other forms of inflammatory arthritis such as rheumatoid and psoriatic arthritis. Nevertheless, effusions of the knees, ankles, wrists, and even the small joints of the hand may be seen. Patients with such severe inflammatory arthritis are prone to develop ligamentous laxity leading to the deformities known as Jaccoud's arthropathy.[69] This looks similar to the deformities of rheumatoid arthritis but is not associated with erosions. During the assessment of joints it is important not to attribute to lupus pain that is due to comorbid conditions such as osteoarthritis. Some patients will develop bony swellings at the distal and proximal interphalangeal joints due to Heberden's nodes or Bouchard's nodes as they get older.

Mild diffuse muscle pain (myalgia) associated with inflammatory arthralgia with a lot of early morning stiffness is likely to be due to lupus. However some patients have persistent diffuse tenderness around the joints and muscles due to fibromyalgia. Studies, particularly in North America, have shown that up to one-third of lupus patients can develop fibromyalgia, which is distinguished by the presence of multiple tender points typical of fibromyalgia. Thus it is important to do a full assessment when patients complain of joint and muscle pain to determine the underlying cause appropriately.

Inflammatory myositis tends to affect the proximal muscles of the arms and legs, and is the least common cause of myalgia. This is characterized by the development of proximal weakness in association with muscle tenderness, stiffness, and raised muscle enzymes. Patients who are anti-RNP antibody positive with features of an overlap syndrome or mixed connective tissue disease[70] consisting of lupus and systemic sclerosis are the most likely to develop inflammatory myositis. Important differential diagnoses to consider in patients with muscle weakness are steroid-induced myopathy and statin-induced myopathy.

Lupus patients are at increased risk of avascular necrosis which may affect the hip, shoulder, knee, wrist, or ankle. It is usually unilateral and presents in a single joint but it may affect more than one joint and become symmetrical over time. Although some studies have suggested that this is directly due to steroids, other studies have suggested that it is more likely to occur after periods of high disease activity[71] and it is probably the result of localized inflammatory vascular damage or thrombosis in certain bones, since it is not a generalized condition like steroid-induced osteoporosis. MRI scan is much better than plain radiographs at detecting early avascular necrosis. Avascular necrosis needs to be distinguished from other causes of acute single joint pain that present in the absence of a generalized disease flare, such as septic arthritis and osteoarthritis.

Respiratory features

Pleurisy is common in SLE and occurs in about 60% of patients. It can be difficult to distinguish left anterior chest pain due to pleurisy and pericarditis clinically, although pericardial pain is typically worse lying down and better sitting forward. It is important to distinguish both of these from musculoskeletal chest wall pain with localized tenderness. Pleuritic chest pain due to inflammation of the pleura is not necessarily associated with a pleural rub or effusion that can be detected clinically but small effusions may be picked up on radiographs (blunting of costophrenic angle), ultrasound, or CT scan. Large pleural effusions are rare and should be aspirated to exclude infection, including TB, and malignancy. Pleural thickening, like respiratory muscle weakness or shrinking lung syndrome which can occur in lupus, is associated with small-volume lungs with a restrictive defect on lung function tests and preserved diffusion factor.

Pulmonary embolism usually presents with pleuritic chest pain and is commonest in patients with anti-phospholipid antibodies. Pulmonary emboli may occur in patients with a prothrombolic tendency for other reasons, with or without a preceding history of deep vein thrombosis (DVT) in the leg. Recurrent small pulmonary emboli may present with shortness of breath on exertion without chest pain. Patients should be investigated with V/Q scan or CT pulmonary angiography (CTPA).

Interstitial lung disease is less common but more serious than pleurisy. It usually presents with increasing shortness of breath on exertion and dry cough. There is an acute form of alveolitis or pneumonitis that can deteriorate rapidly. This needs to be distinguished from pneumonia, heart failure, and adult respiratory distress syndrome (ARDS). Broad-spectrum antibiotics covering atypical infections may need to be started together with immunosuppression while awaiting the results of investigations, as respiratory failure can develop in a few days in up to 50% of patients. The subacute form of alveolitis is more common and progresses more slowly over several weeks or months. Both can result in permanent

lung fibrosis if not treated promptly with intense immunosuppression. Patients should be investigated with lung function tests (restrictive deflect with impaired diffusion) and high-resolution CT (HRCT) scan initially which is much more sensitive than plain radiographs.[72] Lung function tests can be used to monitor for progression and response to therapy.

Cardiac features

Pericarditis occurs in about 60% of patients and presents with chest pain on inspiration that is worse lying down and better sitting forward, without chest wall tenderness. A pericardial rub and ECG abnormalities are not required for a clinical diagnosis of pericarditis. Echocardiography is the best way to assess whether or not there is a pericardial effusion. Rarely pericardial effusions can enlarge sufficiently to cause cardiac tamponade. As with large pleural effusions, large pericardial effusions should be investigated to exclude coexistent infection or malignancy.

Myocarditis due to lupus is rare and presents with heart failure or arrhythmias. Bradycardia or tachycardia may occur and may cause syncope which needs to be distinguished from epileptic seizures or drop attacks due to cerebral ischaemic events. Patients may require 24 hour ECG monitoring to confirm the arrhythmia. Myocarditis is usually biventricular and may be associated with pericarditis. Diagnosis usually requires cardiac enzymes, ECG, echocardiography, and a perfusion scan, cardiac MRI or angiography. Other causes of myocardial dysfunction include systemic or pulmonary hypertension, or myocardial ischaemia. Ischaemic heart disease secondary to atherosclerosis is more common than coronary vasculitis or thrombosis of coronary vessels in patients with anti-phospholipid syndrome (APS) and is an increasingly important cause of death in lupus patients.[24,73,74]

Endocardial disease is most often found as a coincidental finding as the time of echocardiography. Mitral and aortic valve lesions are more common than tricuspid and pulmonary valve lesions. Patients with pulmonary hypertension may present with tricuspid regurgitation and right ventricular failure. Less than 10% of patients deteriorate to the point that they need valve repair or replacement surgery. Some studies suggest that endocarditis is more common in patients with APS. Libman–Sachs endocarditis is the name given to the aseptic vegetations on heart valves in lupus patients. There is a risk that these will become infected during septicaemia, particularly in patients on immunosuppressants. These patients should be considered for antibiotic prophylaxis during surgical procedures, including complex dental procedures, and great care is needed with insertion of central lines.

Pulmonary hypertension is rare (<5%) but most common in patients with lupus anti-coagulant,[75] with or without a history of thromboembolism, and in patients with pulmonary fibrosis. Pulmonary hypertension, irrespective of the underlying cause, is associated with about 50% mortality in pregnancy, so echocardiography should be arranged in patients at high risk of this complication at the time of pre-pregnancy counselling before conception.[75] Prognosis has improved with the advent of therapy such as sildenafil and bosantan.[76]

Gastrointestinal manifestations

Gastrointestinal manifestations of lupus are often overlooked as they may be confused with drug side effects and comorbid conditions.[77]

Anorexia and nausea are the most common manifestations, but are more often due to drug side effects. Abdominal pain due to serositis with localized tenderness and even rebound and guarding can occur. Investigations including ultrasound and CT scan may be needed to look for comorbid conditions, particularly abscess and localized bowel disease. Ascites due to peritonitis from lupus occurs in some cases, but is uncommon. Aspirating the acidic fluid is usually required to exclude infection including TB and malignant cells. Acute abdominal pain with vomiting and constipation raises the possibility of subacute bowel obstruction which has been reported in SLE due to inflammation in the bowel wall. Diarrhoea can occur with protein-losing enteropathy and occasionally gut vasculitis but is usually drug related.

Right hypochrondrial pain with tenderness and thickening of the gallbladder in the absence of gallstones can occur due to vasculitis of the gallbladder wall. The diagnosis is confirmed by histology at cholecystectomy. Patients may develop lupus hepatitis which needs to be differentiated from viral-induced hepatitis and hepatitis due to drugs. Sclerosing cholangitis is less common in lupus than in systemic sclerosis. Acute pancreatitis due to vasculitis can occur in lupus. This is often attributed to steroids or azathioprine but is more often due to active disease that has not been controlled by immunosuppressive therapy.

Renal manifestations

Renal involvement is more prevalent and associated with higher risk of renal failure in patients of African or Chinese origin than in those of white European origin. Proliferative glomerulonephritis is most common in patients who are anti-dsDNA antibody positive, especially by crithidia or radioimmunoassay. Anti-C1q antibodies are associated with class 3 and class 4 proliferative glomerulonephritis as well. The World Health Organization (WHO) classification of lupus nephritis was revised in 2003 and Table 117.3 shows a simplified version of the International Society of Nephrology/ Renal Pathology Society classification of lupus nephritis (LN).[78] More recently a European consensus statement has been developed that covers the classification of patients with LN, how classification affects the selection of treatment options and definitions of response, flare, induction, and maintenance.[79] Usually patients with class 1, 2, and 5 disease present with isolated proteinuria, whereas those with class 3 and class 4 disease present with a positive urinary sediment consisting of red cells, white cells and/or casts, and a lesser degree of proteinuria. However, nephrotic range proteinuria may develop in patients with class 3, 4, or 5 disease and the only way to establish the nature of the renal disease and the amount of activity and damage is by biopsy. It is important to arrange renal biopsy promptly in patients who develop reproducible proteinuria of more than 0.5 g in 24 hours or equivalent by polymerase chain reaction (PCR) (~50 mg/mmol on early morning spot urine), if there are casts, red cells, or white cells which are not attributable to other conditions such as menstrual blood loss or infection. In patients with isolated proteinuria it is acceptable not to biopsy unless the proteinuria rises above 2 g in 24 hours (~200 mg/mmol) unless the patient is developing renal impairment. Patients with anti-phospholipid antibodies, particularly those with APS, are at increased risk of developing APS-related nephropathy which is associated with a worse prognosis. Patients may progress to endstage renal disease requiring dialysis or transplantation with class 3, 4, or 5 disease if not diagnosed early and treated optimally, but class 5 disease is usually more slowly

Table 117.3 Simplified version of the International Society of Nephrology/Renal Pathology Society classification of Lupus Nephritis[78]

Class	Name	Features
I	Minimal mesangial lupus nephritis	Normal at light microscopy Mesangial deposits on immunofluorescence
II	Mesangial proliferative lupus nephritis	Mesangial hypercellularity or expansion with mesangial immune deposits Some subepithelial or subendothelial deposits on immunofluorescence by electron microscopy
III	Focal lupus nephritis	Involves <50% glomeruli. Active or inactive lesions typically with subendothelial deposits
IV	Diffuse lupus nephritis	Involves >50% glomeruli. Active or inactive diffuse, segmental or global endo-or extracapillary glomerulomephritis. Typically with subendothelial deposits. Divided into diffuse segmental when >50% of involved glomeruli have segmental lesions and diffuse global when >50% of involved glomeruli have global lesions
V	Membranous lupus nephritis	Global or segmental subepithelial immune deposits by light microscopy and immunofluorescence or electron microscopy, with or without mesangial changes Class V lupus nephritis may occur in combination with class III or class IV disease in which case both are diagnosed Class V disease may show advanced sclerosis
VI	Advanced sclerosis lupus nephritis	>90% of glomeruli globally sclerosed without residual activity

Table 117.4 The 19 American College of Rheumatology neuropsychiatric lupus syndromes

Central	Peripheral
Acute confusional state	Acute inflammatory demyelinating polyradiculoneuropathy (Guillain– Barré syndrome)
Aseptic meningitis	Autonomic disorder
Anxiety disorder	Mononeuropathy (single or multiplex)
Cerebrovascular disease	Myasthenia gravis
Cognitive dysfunction	Neuropathy, cranial
Demyelinating syndrome	Plexopathy
Headache (including migraine and benign intracranial hypertension)	Polyneuropathy
Mood disorder	
Movement disorders (including chorea)	
Myelopathy	
Psychosis	
Seizure disorders	

progressive unless it is associated with class 3 or 4 disease. Patients who fail to improve with therapy should be rebiopsied to determine whether there has been transformation to another class, increasing damage or other changes.

Neuropsychiatric features

In 1999 the ACR nomenclature and case definitions for neuropsychiatric lupus syndromes were reported.[80] These covered 19 clinical syndromes affecting the central and peripheral nervous systems (Table 117.4). Potential non-lupus causes and associations were described as well as the case definitions and investigations necessary for their reporting in patients with lupus. The aim of this work was to standardize the terminology used, so that these often uncommon syndromes reported by different investigators could be better compared. Sixteen of the syndromes are associated with neuronal damage and are more common in lupus patients than controls.[81] The EULAR SLE Task Force reported more recently on the investigations and treatment of neuropsychiatric manifestations of lupus.[82] Their systematic literature search highlighted that the diagnostic work-up of such patients should be the same as for other patients presenting with the same symptoms and signs, and should focus on excluding non-lupus causes. It can be difficult to attribute neuropsychiatric manifestations to lupus in the absence of other features of active lupus disease, although neuropsychiatric lupus may occur occasionally in the absence of other manifestations of

lupus and without typical lupus serology other than anti-nuclear antibodies.

The most common central nervous system (CNS) manifestations are headache, mood disorders, cognitive dysfunction, cerebrovascular accidents, seizures, psychosis, and acute confusional state. Less common manifestations are aseptic meningitis, movement disorders such as chorea, myelopathy (transverse or longitudinal), and a demyelinating syndrome that is often confused with multiple sclerosis.[83] Oligoclonal bands in the CSF, that are distinct from those in serum reflecting intrathecal immunoglobulin production, occur both in lupus patients with neuropsychiatric lupus disease and in multiple sclerosis. Thus the diagnosis of lupus demyelinating syndrome depends on MRI features being atypical for multiple sclerosis and the clinical situation (active lupus disease elsewhere).

Most headaches in lupus patients are due to migraine and tension headaches and these are not more common than they are in the normal population. Aseptic meningitis is a cause of severe headache where attribution to lupus can be made on the basis of the CSF findings (raised protein and lymphocytes) after exclusion of infection (viral, bacterial, fungal, and protozoal). Rarely lupus patients present with very severe, intractable headache that persists for at least 3 days and does not respond to opiate analgesia but does improve after administration of high-dose corticosteroids. This is what is meant by the term 'lupus headache', and, as with aseptic meningitis, the diagnosis should only be made after investigations to exclude other causes of such severe headache including CT or MRI brain scan and CSF examination. Other causes of such severe headaches in lupus patients that need to be excluded include malignant hypertension, cerebral or subarachnoid haemorrhage, cerebral abscess, uraemia, and other metabolic or drug-related disorders. Occasionally patients present with severe headache and papilloedema due to benign intracranial hypertension which may be due to lupus, obesity, or

with a cerebral venous sinus thrombosis. The latter usually occurs in patients with APS. It is important to obtain CT or MR venography in patients in whom this is a possibility.

Anti-phospholipid antibodies can be associated with cerebrovascular accidents due to arterial thrombosis, seizures, myelopathy, demyelinating syndrome, and chorea. However, the commonest cause of a stroke is atherosclerosis, though occasionally there may be emboli from Libman–Sachs endocarditis or from carotid plaques. Cerebral vasculitis is rare. Seizures are commonest early in the disease course and are often self-limiting when the active disease is controlled, especially if the MRI brain scan is normal. However, if recurrent epileptic seizures occur, especially in the presence of an abnormal MRI scan, long-term anticonvulsant therapy is usually required. Myelopathy usually presents as a rapidly progressive transverse myelitis, but may affect multiple levels, often with early bladder involvement. It can be difficult to establish if the lesions are inflammatory or thrombotic and treatment for both may be needed while awaiting investigation results. It should be noted that the spinal MRI can be normal in the early stages and this should not prevent patients with classic clinical features being treated.

Mood disorders such as depression and anxiety, like headaches, are more often due to non-lupus causes including psychosocial issues than due to lupus. Psychosis may be due to lupus or to corticosteroids but is rare with prednisolone doses equivalent to 30 mg prednisolone daily or less. When in doubt, give patients more, not less, steroid, particularly if there is active lupus in other systems, together with an anti-psychotic agent.

Lupus patients may develop a relatively benign sensory neuropathy or more serious mixed sensory and motor cranial or peripheral mononeuropathy, or polyneuropathies (glove and stocking distribution or mononeuritis multiplex) due to vasculitis of the vasa nervorum. Rare peripheral conditions include acute inflammatory demyelinating polyradiculoneuropathy (presenting like Guillain–Barré syndrome), autonomic neuropathy, brachial or lumbar plexopathy, and myasthenia gravis. Nerve conduction studies are important in confirming and monitoring these peripheral conditions.

Ophthalmic manifestations

All layers of the eye can be affected by lupus.[84] The most common condition is inflammatory destruction of the conjunctival epithelium resulting in chronic irritation of the eyes with reduced tear production, known as keratoconjunctivitis sicca (dry eyes). This usually occurs in patients who are anti-Ro or anti-La antibody positive. In contrast to primary Sjögren's syndrome in which patients develop dry eyes and dry mouth due to mucosal glandular involvement early in the disease course, secondary Sjögren's syndrome tends to occur late in the course of lupus patients.

Patients with lupus may develop a benign, localized, and painless red eye condition due to episcleritis. Less common but more serious is inflammation of the choroid causing anterior uveitis and/or posterior uveitis. Anterior uveitis is distinguished from episcleritis by the more generalized redness and the presence of pain in the eye with photophobia in anterior uveitis. Posterior uveitis or chorioretinitis is more serious as the retina may be involved and this condition causes blurring and loss of vision and needs urgent management by an ophthalmologist. The formation of a hypopyon, as seen in Behçet's syndrome, is rare in lupus.

Scleritis and kerititis can occur in lupus but infectious causes of keratitis need to be sought. Scleritis can occur due to vasculitis in the sclera and occasionally is associated with thinning of the sclera as is seen in rheumatoid arthritis. Retinal vasculitis and optic neuritis are uncommon but devastating conditions that can lead to visual loss. Patients with anti-phospholipid antibodies are at risk of vaso-occlusive disease affecting retinal and choroidal vessels that may lead to anterior ischaemic optic neuropathy. Rarely diplopia and/or proptosis may occur due to orbital inflammation with myositis of the eye muscles. Prompt assessment by an ophthamologist is required to determine the diagnosis and to determine if treatment should be with immunosuppressives, anti-platelet drugs, and/or anticoagulation. Sometimes it is difficult to be sure whether the underlying pathology is inflammatory, thrombotic, or both and it is often important to exclude infection. Significant hydroxychloroquine toxicity causing visual loss is very uncommon.[85] Patients at greatest risk are those that have renal or liver impairment and/or have been treated with high dose (>6.5 mg/kg per day) and/or prolonged therapy (>10 years). In such cases macular degeneration due to hydroxychloroquine toxicity has to be distinguished from age-related macular degeneration.

Haematological manifestations

Leucopenia can be an important clue to the diagnosis of lupus, as it may be observed on a full blood count being done as part of the investigation of a patient not yet known to have lupus. It may also occur as a side effect of cytotoxic therapy in patients on therapy for established disease. The most typical feature due to lupus, found in over 90% of patients, is antibody-induced lymphopenia. This affects CD4 T cells most and leads to a low CD4:CD8 ratio as seen in HIV infection. Antibody-mediated neutropenia is much more uncommon, though it is found most often in patients of African descent. Antibody-mediated leucopenia is rarely associated with infection unless the total white count is less than 1×10^9/litre, but when there is such a severe leucopenia or lymphopenia (<0.4×10^9/litre) there is an increased risk of opportunistic infections.

The most significant but least common haematological manifestation is antibody-mediated thrombocytopenia, which can cause significant bleeding with platelet counts below 50×10^9/litre. Idiopathic thrombocytotenic purpura may present before other features of lupus. Patients with APS often have platelet counts about 70–90 $\times 10^9$/litre and this is paradoxically associated with an increased risk of thrombosis that may be venous and/or arterial, and with or without pregnancy complications.[37] In patients who are known to have APS it is important to not discontinue anti-platelet or anti-coagulant drugs unless the platelet count is less 30×10^9/litre because of the risk that they can develop a clinical thrombosis once the platelet count rises above 30×10^9/litre.

Anaemia of chronic disease is more common than autoimmune haemolytic anaemia. Haemolysis can be diagnosed if there is a positive Coombs' test and low haptoglobins, increased reticulocyte count, and/or raised non-conjugated bilirubin. Anaemia due to chronic inflammation that impairs utilization of iron needs to be distinguished from iron deficiency anaemia due to dietary deficiency and/or blood loss from the gut due to drugs or occasionally bowel involvement by the disease.

Obstetric issues

In the past, patients with lupus were recommended not to become pregnant. It is now recognized that most women can have a successful pregnancy as long as they do not have active lupus disease

in the 6 months preceding conception, significant renal impairment, pulmonary hypertension, or other serious heart, lung, or neurological disease.[86] Infertility due to anti-ovarian antibodies is rare in lupus patients and when infertility occurs it is usually due to cyclophosphamide therapy, especially in those over 30 years of age.[87] It should be noted that low doses and short courses with less than 7 g cumulative dose in patients under 30 years of age is associated with a low risk of infertility. However, in those over 35 years of age cyclophosphamide usually induces the menopause. Lupus patients with anti-phospholipid antibodies may suffer recurrent pregnancy losses, particularly in the second or third trimester. APS also predisposes to pre-eclampsia and thrombosis in the mother during pregnancy.[37,86] The baby should be monitored for intrauterine growth restriction (IUGR) due to placental insufficiency during pregnancy so that the mother can be offered early delivery if necessary to avoid the risk of stillbirth. IUGR is most commonly due to APS but can occur in patients with active lupus, pre-eclampsia, and renal impairment. Fetal heart rate monitoring should start at 16 weeks' gestation in mothers with anti-Ro and anti-La antibodies because of the risk of congenital heart block.[34] This only occurs in about 1% of babies born to mothers with these antibodies though the risk is about 20% if the mother has had a previous baby with this condition. The risk of neonatal lupus syndrome presenting with a photosensitive rash due to anti-Ro and anti-La antibodies is about 10%.

Diagnosis and classification of lupus

The diagnosis of lupus is most reliably made by identifying typical clinical features of lupus associated with evidence of an immune complex mediated disease involving the production of autoantibodies. The ACR (formerly the American Rheumatological Association) classification criteria for SLE are often used as diagnostic criteria (Table 117.5). However, they were designed to provide criteria for patients going in to clinical research and not for diagnosis.[66,88,89] Patients are required to have at least 4 of the 11 criteria listed in Table 117.5 at any point in time to fulfil these criteria. More recently the Systemic Lupus International Collaborating Clinics (SLICC) group have proposed revised criteria for lupus as the ACR criteria do not include many features of lupus and allow patients to be classified even if they have not had autoantibodies or other serological abnormalities documented.[90] These new SLICC criteria allow a patient to be classified as having lupus if they have a classical renal biopsy, e.g. class IV glomerulonephritis and positive ANA or anti-dsDNA antibodies, but otherwise require at least four criteria from an expanded list of which at least one must be clinical and at least one a serological criterion (Table 117.6).[90]

Monitoring disease activity and distinguishing damage

Patients with lupus should be monitored at intervals depending on their disease manifestations, blood results, and therapy.[91,92] Patients with very active disease including renal involvement are usually seen 2–4 weekly and may require blood tests 1–2 weekly for monitoring their disease-modifying therapy, bearing in mind the risk of cytopenias due to the disease and the drugs. For patients with LN assessment is usually at least 3 monthly, even when they appear to be in remission, especially if immunosuppressive therapy is being reduced or has been discontinued, as flare may be asymptomatic. Rising titres of anti-dsDNA antibodies and/or falling complement

Table 117.5 The 11 revised criteria of the American College of Rheumatology for the classification of systemic lupus erythematosus

Malar rash	Fixed erythema, flat or raised, over the malar eminences tending to spare the nasolabial folds
Discoid rash	Erythematosus raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation
Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician
Arthritis	Non-erosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
Serositis	(a) Pleuritis—convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion *or* (b) Pericarditis—documented by ECG or rub or evidence of pericardial effusion
Renal disorder	(a) Persistent proteinuria >0.5 g/day or >3+ if quantification not performed *or* (b) Cellular casts—may be red cell, haemoglobin, granular, tubular, or mixed
Neurological disorder	(a) Seizures—in the absence of offending drugs or known metabolic derangements; e.g. uraemia, ketoacidosis, or electrolyte imbalance; *or* (b) Psychosis—in the absence of offending drugs or known metabolic derangements; e.g. uraemia, ketoacidosis, or electrolyte imbalance
Haematological disorder	(a) Haemolytic anaemia—with reticulocytosis *or* (b) Leucopenia < 4.0×10^9/l on two or more occasions (c) Lymphopenia <1.5×10^9/l on two or more occasions (d) Thrombocytopenia <150×10^9/l
Immunological disorder	(a) Anti-dsDNA: antibody to asDNA in abnormal titre, *or* (b) Anti-Sm: presence of antibody to Sm nuclear antigen, *or*Positive finding of anti-phospholipid antibodies based on: (1) abnormal serum level of IgG or IgM anti-cardiolipin antibodies; (2) positive test for lupus anti-coagulant using a standard method, or (3) false-positive test for at least 6 months and confirmed by *Treponema pallidum* immobilization or fluorescent antibody absorption test
Positive ANA	Abnormal titre of ANA by immunofluorescence or an equivalent assay at any point in time in the absence of drugs

ANA, anti-nuclear antibody.

levels suggest that a lupus flare may occur though it is hard to predict when, so patients may need to be seen more frequently. For patients with stable low level activity or remission, with no renal involvement and no serological changes, lupus assessment may be 3–6 monthly. Assessment of patients requires a review of all systems including blood pressure, urinalysis, and measures of renal function, as well as full blood count and measurement of anti-dsDNA antibodies, C3 and C4.[61] If proteinuria is present, quantification should occur using measurement of 12 or 24 hour urine protein, protein:creatinine ratio, or albumin:creatinine ratio, and urine microscopy to identify red and white cells and casts. A urine sample should be sent for culture to exclude infection and other causes of

Table 117.6 Clinical and immunological criteria used in the SLICC classification criteria for systemic lupus erythematosus (see text)

Type of criterion	No.	Criterion	Description of components
Clinical	1	Acute cutaneous lupus	Lupus malar rash (do not count if malar discoid)
			Bullous lupus
			Toxic epidermal necrolysis variant of SLE
			Maculopapular lupus rash
			Photosensitive lupus rash
			Subacute cutaneous lupus

	2	Chronic cutaneous lupus	Classical discoid rash:
			    localized (above the neck)
			    generalized (above and below the neck)

			Hypertrophic (verrucous) lupus
			Lupus panniculitis (profundus)
			Mucosal lupus
			Lupus erythematosus tumidus
			Chillblains lupus
			Discoid lupus/lichen planus overlap
	3	Mucosal ulcers	Oral ulcers: palate, buccal, tongue
			Nasal ulcers
	4	Non-scarring alopecia	Diffuse thinning or hair fragility with visible broken hairs
	5	Synovitis involving two or more joints	Characterized by swelling or effusion, or
			Tenderness in two or more joints and
			≥30 minutes of morning stiffness

	6	Serositis	Typical pleurisy for >1 day
			    and/or pleural effusions
			    and/or pleural rub

			Typical pericardial pain (pain with recumbency improved by sitting forward) for >1 day
			    and/or pericardial effusion
			    and/or pericardial rub
			    and/or pericarditis by ECG

	7	Renal	Urine protein/creatinine (or 24 h urine protein) representing 500 mg of protein/24 h, and/or
			Red blood cell casts
	8	Neurological	Seizures
			Psychosis
			Mononeuritis multiplex
			Myelitis
			Peripheral or cranial neuropathy
			Acute confusional state (in the absence of other causes)
	9	Haemolytic anaemia	
	10	Leucopenia, or Lymphopenia	White cell count <4000/mm^3 at least once (not due to drugs), or Lymphocyte count <1000/mm^3 at least once (not due to drugs)
	11	Thrombocytopenia	Platelet count <100 000/mm^3 at least once
Immunological	1	ANA	Above laboratory reference range
	2	Anti-dsDNA antibodies	Above laboratory reference range, except ELISA: Twice above laboratory reference range
	3	Anti-Sm antibodies	Above laboratory reference range
	4	Anti-phospholipid antibodies	Lupus anti-coagulant
			False-positive RPR
			Medium or high titre anticardiolipin (IgA, IgG, or IgM)
			Anti-β_2 glycoprotein I (IgA, IgG, or IgM)
	5	Low complement	Low C3
			Low C4
			Low CH50
	6	Direct Coombs' test	In the absence of haemolytic anaemia

red and white cells in the urine should be considered (stone, contamination by menses or vaginal infection). Validated disease activity measures are recommended for use in clinical practice as well as clinical trials and outcome studies.[61,91,92] The most widely used are the BILAG-2004 index and the SLEDAI-2K, though other versions of SLEDAI are in use such as the SELENA-SLEDAI.[93] The patients' perspective should be captured using a generic health survey such as the SF-36 and/or a lupus-specific quality of life instrument such as the LupusQoL, as patients often have poor quality of life.[62,93]

Irreversible damage (scarring) due to the disease or its treatment should be distinguished from disease activity, as this will not respond to immunosuppressive therapy.[61] It is also important to identify comorbid conditions such as infection, malignancy, and drug side effects. Malignancy is slightly more common in lupus patients that expected, especially lymphoma, and lung cancer in smokers. However some cancers such as breast, ovary, endometrial, and prostate are less common than expected.[94] The SLICC/ACR Damage Index can be used to record damage in routine clinical practice and for research studies.[61,91] Damage items are recorded if a feature appears after the onset of lupus and persists at least 6 months or is associated with a classical scar such as myocardial infarction in which case it can be recorded immediately.

Outcome and causes of death

The survival in SLE patients has improved over the last 50 years from about 50% survival at 5 years after diagnosis in the 1950s to

survival figures of up to 98% at 5 years and 95% survival at 10 years.[3] Prognosis for patients with renal involvement, African or Chinese descent, Hispanic ethnicity, and poor socio-economic background has been less good than for patients without these factors. The main causes of death are increasingly infection and cardiovascular disease (especially premature atherosclerosis secondary to lupus) rather than acute lupus disease. However, if access to good health care is limited by availability or cost there are still significant numbers of deaths due to lupus activity and renal failure in certain populations. In the multisite international SLE cohort (23 centres, 9547 patients) studied by the SLICC, the standardized mortality ratio (95% CI) was 2.4 (2.3–2.5).[73] The commonest causes of death in SLE patients (expressed as a standardized mortality ratio) were infections (9.0), renal disease (7.9), non-Hodgkin's lymphoma (2.8), lung cancer (2.3), and circulatory diseases (1.7). Increased risk of death was associated with female gender, younger age, shorter SLE duration, and black/African-American race. To improve outcomes, it is important that patients have access to high-quality care with prompt investigations and treatment of lupus and complications such as infection, hypertension, and atherosclerosis. Monitoring vaccination and smoking status, and ensuring that screening for comorbidities such as hypertension, hypercholesterolaemia, diabetes mellitus, metabolic syndrome, osteoporosis, cancer, and cervical dysplasia due to human papillomavirus (HPV) infection are important in addition to monitoring lupus if outcomes are to be improved.

CHAPTER 118

Systemic lupus erythematosus—management

Ida Dzifa Dey and David Isenberg

The challenge of managing systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is a disease whose manifestations often fluctuate markedly. The most severe manifestations are not necessarily the most symptomatic. The goals of therapy are to control the patient's symptoms, suppress the underlying disease adequately, and prevent secondary organ damage. The correct regimen of drugs is that which achieves these aims, and balances the need to treat aggressively on occasions, mindful of the possible long-term side effects of the agents used.

Patients tend to be young and female. Since the disease is suppressed but not cured by treatment, patients may be faced with the prospect of taking potent drugs for years. The social and psychological effects of both the chronic disease and the necessity for continuing treatment must be recognized and addressed by physicians and patients. Potential effects of the drugs upon fertility or pregnancy are particularly important.

Non-pharmacological management

General measures include avoidance of UV radiation, especially in fair-skinned people since this may cause not only photosensitive rash, but also a more general flare of symptoms. Rest as appropriate, stress avoidance, prevention of infections, a diet low in saturated fats and high in fish oils, not smoking, and avoidance of oestrogen-containing contraceptive pills are also advised.

Recent studies suggest vitamin D deficiency may have a role in the aetiology of SLE and its supplementation may have possible benefits in the treatment of patients.

Vaccinations apart from 'live' vaccines in patients on greater than 10 mg prednisolone and/or immunosuppressives are safe. In patients on immunosuppressive therapy, there may be a reduction in vaccine efficacy but there is satisfactory humoral response to hepatitis A and B, influenza, and pneumococcal vaccine. It is important to update vaccinations before immunosuppressive or biological treatment. The use of hormone replacement in patients past the menopause is still controversial. The risk of disease flares when starting oestrogens after the menopause is small, but can occur.

Pharmacological management

Patients with SLE are treated with four main groups of drugs, often in combination. These are non-steroidal anti-inflammatory drugs (NSAIDs), anti-malarials, corticosteroids, and cytotoxic drugs. However, new biological therapies have been introduced, directed at particular cells or molecules implicated in the pathogenesis of the disease.

Recommendations about precisely when to commence therapy, the initial dose of a given drug, the likely response of a given symptom, and the duration of treatment vary widely. In Table 118.1, the broad indications for use of these four types of drugs are shown. In Table 118.2, suggestions are provided as to the initial doses and duration of treatment with the anti-malarials, corticosteroids, and cytotoxic drugs. These are intended purely as guidelines and there will be patients who require larger doses for longer periods of time. Tables 118.1 and 118.2 both make the point that different regimens of drugs are suitable for different manifestations of the disease.

Non-steroidal anti-inflammatory drugs

NSAIDs have no immune-modulating actions and lupus patients are at no lesser risk of gastrointestinal, cardiovascular, and renal complications of NSAIDs than other patients, and thus careful monitoring is required.

Several long-term studies have shown that both selective and non-selective cycloxygenase (COX) inhibitors, except naproxen, are associated with increased risk of cardiac infarction.

Hydroxychloroquine

Hydroxychloroquine (Plaquenil) is the anti-malarial drug of choice, with a better safety profile and tolerability than other anti-malarials such as chloroquine and quinacrine. The mechanism of action of anti-malarials is not fully understood but it is thought to work by

Table 118.1 Drug therapy in systemic lupus erythematosus

	NSAIDs	Anti-malarials	Corticosteroids	Cytotoxic agents

Alopecia	−	−	?	?

+, usually beneficial; −, not beneficial; ?+, possible benefit; ?, dubious.
[a]Widely prescribed, but doubts remain that steroids are beneficial in many cases.

increasing the pH within the intracellular vacuoles thus interfering with antigen presenting in macrophages and other antigen-presenting cells (APCs) and inhibiting the activation of Toll like receptors.

Anti-malarials, in addition to their immunomodulatory and anti-inflammatory properties, are anti-hyperglycaemic, anti-thrombotic, and anti-hyperlipidemic even in those taking corticosteroids, thereby possibly having an influence on the development of atherosclerosis which is increased in SLE.

Hydroxychloroquine (HCQ) is commonly used in patients in whom the main symptoms are fatigue, rash, and arthralgia, without evidence of major organ involvement. It is, however, now thought to be beneficial to most patients with SLE because of this broad spectrum of beneficial effects. This claim is supported by a small randomized controlled trial (RCT)[1] and supported by findings from other studies of an increased relative risk of severe SLE flares in patients on HCQ who discontinued it compared to those who did not, a negative association in the development of renal flares, hypertension, thrombosis, and infection.

The Lupus in the Minorities and Nature versus nurture (LUMINA) cohort[2] showed a reduced risk of irreversible damage with HCQ use and other beneficial effects including increase survival, reduction in disease activity, thrombotic effects, and low lipid levels, supporting the notion that SLE patients who can tolerate it should be maintained on this treatment.

Anti-malarials occasionally cause mild gastrointestinal and cutaneous effects. The most troublesome but extremely rare side effect has been the effect of long-term use on the eye; this is more common with chloroquine which crosses the blood–retinal barrier more easily. Retinal toxicity sufficient to cause reduced visual acuity occurs in about 1 in 1800 cases. Recommendations for preventing retinal toxicity include not exceeding a maximum dose of 6.5 mg/kg lean body weight (i.e. 200–400 mg), reviewing baseline renal and hepatic tests and visual assessments. Patients should be referred to the ophthalmologist if they have visual impairment or age-related eye disease at baseline and if they develop reduction in peripheral vision, patchy central vision, or distorted central vision while on treatment.[3] Some units choose to carry out such monitoring every 6–12 months, though this is probably unnecessary as severe visual disturbances is very rare.

Many patients with cutaneous SLE respond well to HCQ, but a minority may require treatment with a combination of HCQ and quinacrine or with more potent agents such as dapsone, steroids, or rarely thalidomide.

Treatment with corticosteroids

Corticosteroids remain a mainstay of the treatment of SLE. These drugs (usually in moderate doses orally up to 30 mg/day) are used in severe arthritis, pleuritis, or pericarditis. Corticosteroids are used at higher dosages where SLE causes more severe effects, which may in some cases be life threatening, such as autoimmune haemolytic anaemia, thrombocytopenia, nephritis, and a wide range of neuropsychiatric problems.

Corticosteroids are usually prescribed orally but may also be given intramuscular or intravenously. Intravenous pulse therapy has been widely used. If given over a 15–20 min period there is a danger of reactive arthropathy, and in our experience intravenous pulses are best given slowly over a 3–4 h period. We use pulse therapy: for

Table 118.2 Recommendations for use of conventional immunosuppressive drugs in lupus

Symptom	Drugs to try	Dose and duration
Arthralgia Myalgia Lethargy	NSAIDs Hydroxychloroquine	Avoid in renal failure Start 400 mg/day for 3–4 months then reduce to 200 mg/day for 3–4 months, then to 200 mg five times week for 3–4 months; repeat courses may be necessary and annual retinal checks are probably unnecessary until patient has been on the drug for 5 years
Rash	Hydroxychloroquine Topical steroids or tacrolimus	
Arthritis	Prednisolone Hydroxychloroquine Methotrexate in refractory cases	Prednisolone: 20–40 mg per day initially for 2–4 weeks, reducing in 5–10 mg increments per week, if patient is responding; treatment is likely to be required for several months
Pleuritis and pericarditis	NSAIDs Anti-malarials, low-dose corticosteroids Refractory cases—azathioprine, MMF or cyclophosphamide	20–30 mg prednisolone per day then tapering doses, along the lines of arthritic treatment (above)
Autoimmune haemolytic anaemia/thrombocytopaenia	Corticosteroids often accompanied by azathioprine or cyclophosphamide ?Rituximab	60–80 mg prednisolone for 1–2 weeks reducing in 10 mg increments in response to the blood test results; aim for 2–2.5 mg/kg azathioprine; treatment will last for several months
Renal	Prednisolone plus cyclophosphamide or MMF Azathioprine or MMF for maintenance Rituximab for refractory cases	Induction: cyclophosphamide can be given by intravenous boluses—the Euro-Lupus nephritis regimen six fortnightly pulses of IV cyclophosphamide 500 mg. The older (NIH) regime using IV Cyclophosphamide of 750 mg–1g monthly for 6 months followed by 3 monthly infusions for 2 years is regarded as far too toxic Mycophenolate 1–3g/day may be required for several months to years; the ALMS trial showed this to be equivalent to cyclophosphamide use for getting patients into remission Maintenance: MMF 1–3 g/day is better than azathioprine at 2–3 mg/kg; treatment is likely to be required for several years
Central nervous system	Corticosteroids plus an appropriate drug, e.g. an anti-depressant, anti-convulsant, etc. ?Cyclophosphamide ?Rituximab	Controversial—but 20–60 mg prednisolone have been prescribed or IV pulse methylprednisolone (sometimes accompanied by azathioprine or IV cyclophosphamide pulses); treatment is likely to be required for months

IV, intravenous; MMF, mycophenolate mofetil; NSAIDs, non-steroidal anti-inflammatory drugs.

example, 500 mg–1 g methylprednisolone on three successive days for patients with severe disease not responding to oral corticosteroids. However, smaller pulse doses (100 mg) may be as efficacious and associated with fewer side effects.

Mild to moderate flares may be managed by increase of the normal steroid dose then rapid tapering down or by administration of an intramuscular steroid, e.g. depomedrone or triamcinolone.

The major side effects of corticosteroids include increased risk of infection, osteoporosis, diabetes, and hypertension. Chronic corticosteroid use has also been linked to the development of premature atherosclerosis. They are thus no panacea. It is important to take these side effects into account in planning a course of high-dose corticosteroids. The risk of osteoporosis must be considered in all patients who are going to take 7.5 mg prednisolone/day or more for a period of several months. Patients are advised to take calcium and vitamin D supplements to reduce the risk of corticosteroid-induced osteoporosis. Bisphosphonates, such as alendronate or residronate, which have a greater protective effect on bone may be used, but also have more side effects. Bone mineral density (DEXA) scanning offers a simple and effective way of monitoring bone loss, and should be repeated every 18–24 months in those on regular oral steroids.

Cytotoxic drugs

Cyclophosphamide

Cyclophosphamide (CYC) is an alkylating agent which is used in severe organ involvement in SLE; adequate evidence is lacking for its use in other organs except lupus nephritis.

The group from the National Institutes of Health (NIH) at Bethesda proposed that intravenous boluses of cyclophosphamide monthly for 6 months and subsequently every 3 months for 2 years compared to steroids alone, was the treatment of choice in patients with severe renal involvement and this was subsequently confirmed to be superior to pulse methylprednisolone alone in the long-term treatment of lupus nephritis.[4]

The problems of side effects with this drug in the long term—infertility or ovarian toxicity and increased risk of neoplasia—have made others more wary about its routine use, especially daily oral regimens. A shorter treatment protocol of six pulses of 500 mg cyclophosphamide fortnightly was compared to the standard NIH regime by the Euro-Lupus Nephritis Trial with a long-term follow-up of 10 years. Data from the trial suggest it may be as effective and safer than NIH regimen in controlling lupus nephritis though there is a high relapse rate, hence the need for maintenance therapy.[5]

In neuropsychiatric SLE there have been no adequate controlled trials of CYC though some believe it may be more effective than pulse corticosteroids especially in patients with seizures, optic neuritis, brainstem disease, and peripheral neuropathy.

Gonadotropin-releasing hormone analogue (GNRH-a) may help preserve ovarian function and is recommended especially in at-risk patients who are more than 30 years of age and receiving an average cumulative dose of more than 8 g.

Azathioprine

Azathioprine is a purine analogue; it is a prodrug that is metabolized into the active purine synthesis inhibitor 6-mercaptopurine, which affects T and B lymphocyte proliferation. Azathioprine is used in mucocutaneous, serositis and haematological manifestations of SLE for inducing disease remission. It may also be used as a steroid-sparing agent in cases where it proves difficult to reduce the dose of oral prednisolone without causing a flare. It is used widely as maintenance therapy after cyclophosphamide in lupus nephritis and other severe disease manifestations.

Thiopurines S-methyltransferase (TPMT) deactivates 6-mercaptopuirne into inactive metabolites; hence genetic polymorphisms of TPMT that reduce its activity can lead to excessive drug levels and toxicity. TPMT assays can be used to predict potential side effects which include reversible bone marrow suppression, hepatic toxicity and increase risk of infections.

Azathioprine should be used with caution in conjunction with other purine analogues such as allupurinol, if its use is inevitable, azathioprine dose should be reduced by 50–75%.

Methotrexate

There have been surprisingly few RCTs of methotrexate (MTX) in the treatment of SLE. Most have been retrospective, studying relatively few patients. There are some data to suggest that MTX may be useful for cutaneous lupus and be can used to treat anti-malarial resistant lupus arthritis and as a 'steroid sparer'.[6]

Some published small series report efficacy and improved prognosis in all neuropsychiatric SLE patients treated with intrathecal MTX and intrathecal dexamethasone refractory to conventional pulse methylprednisolone (MP).[7]

Mycophenolate mofetil

Mycophenolate mofetil (MMF) is a prodrug that is metabolized to mycophenolic acid which inhibits inosine-5-monophosphate dehydrogenase, inhibiting the de-novo pathway of purine synthesis and therefore B- and T-lymphocyte proliferation.

MMF is commonly used in cases of moderate to severe SLE that have proved resistant to other cytotoxic agents and there are case reports of its success in the treatment of patients with autoimmune haemolytic anaemia, thrombocytopenia, and anti-phospholipid syndrome. There is inadequate evidence for its use in refractory haematological and dermatological manifestations of SLE and its effectiveness in neuropsychiatric SLE is unproven.[8]

Experience in its use in solid organ transplantation suggested a better safety profile and tolerability than CYC, which had hitherto been the standard of care in the treatment of lupus nephritis. CYC has been dogged by concerns regarding its adverse effects, slow response, and failure to control lupus nephritis fully. A few clinical trials have suggested that MMF may be at least as effective or even superior to CYC in induction therapy and possibly safer. Results from the Aspreva Lupus Management Trial (ALMS), a large two-part RCT of 370 class III–V lupus nephritis patients designed to evaluate the superiority of MMF compared to CYC in a 24 month induction and subsequent maintenance therapy, however, failed to meet its primary endpoint of showing superiority of MMF to intravenous (IV) CYC as induction therapy. It had similar efficacy as CYC in short-term induction therapy in combination with corticosteroids with 56.2% response in the MMF group compared to 53.0% in I.V.CYC group. Secondary endpoints and adverse events were similar in both groups.[9] Intriguingly, the trial has shown statistically significant difference in response by different ethnic and racial groups to MMF vs CYC. Hispanic and black patients responded better to MMF compared to CYC, supporting findings from some earlier studies that in patients of African or Hispanic descent, IV CYC may be less effective for disease control. MMF was, however, effective in treating a wide variety of non-renal aspects of lupus in all racial and ethnic groups.[10]

The subsequent follow-up study has shown MMF to be better than azathioprine at maintaining patients in renal remission.[11] But invariably the question of the lower cost of azathioprine, and the relatively good response obtained from it, suggest it will continue to be used in patients with nephritis.

Beneficial results were obtained in the treatment of membranous glomerulonephritis (MGN) using moderate doses of MMF in combination with renoprotective and antiproteinuric therapy.

MMF may therefore be the treatment of choice in black and Hispanic populations, in patients who prefer the convenience of twice daily dosing vs monthly cyclophosphamide, and in women of childbearing age where there will be concerns about gonadal toxicity caused by IV CYC. Whatever immunosuppressive regime is chosen, a key element in managing renal lupus is controlling the blood pressure. Very often, in severe cases, a combination of anti-hypertensives (e.g. a diuretic, an angiotensin converting enzyme inhibitor, and a beta blocker) is required for adequate control.

For those patients in whom renal failure develops in spite of immunosuppressive therapy, dialysis and/or renal transplantation is required. There is equivalent patient and graft survival in SLE patients who receive renal transplantation compared to the general population, but recurrence of lupus nephritis appears to be frequent though not always tied with loss of the allograft and may present without clinical and serological confirmation of active disease.

Flow diagrams of the way we use drugs to treat the various aspects of lupus are shown in Figures 118.1 and 118.2.

Other 'standard' treatments

Leflunomide

Leflunomide is a synthetic isoxazol derivative known to inhibit the pyrimidine synthesis pathway, thus blocking RNA and DNA synthesis in T and B cells and inhibiting proliferation of these cells. It is well established in the treatment of rheumatoid and psoriatic arthritis and case reports suggest some level of efficacy in SLE arthropathy. Short-term studies of this drug in the treatment of SLE appeared to show it to be safe and reasonably efficacious in with significant reduction in Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) scores in mild to moderate SLE. There are also suggestions of its possible role in the treatment of lupus nephritis. However, large long-term RCTs are needed to prove its efficacy.

Plasma exchange

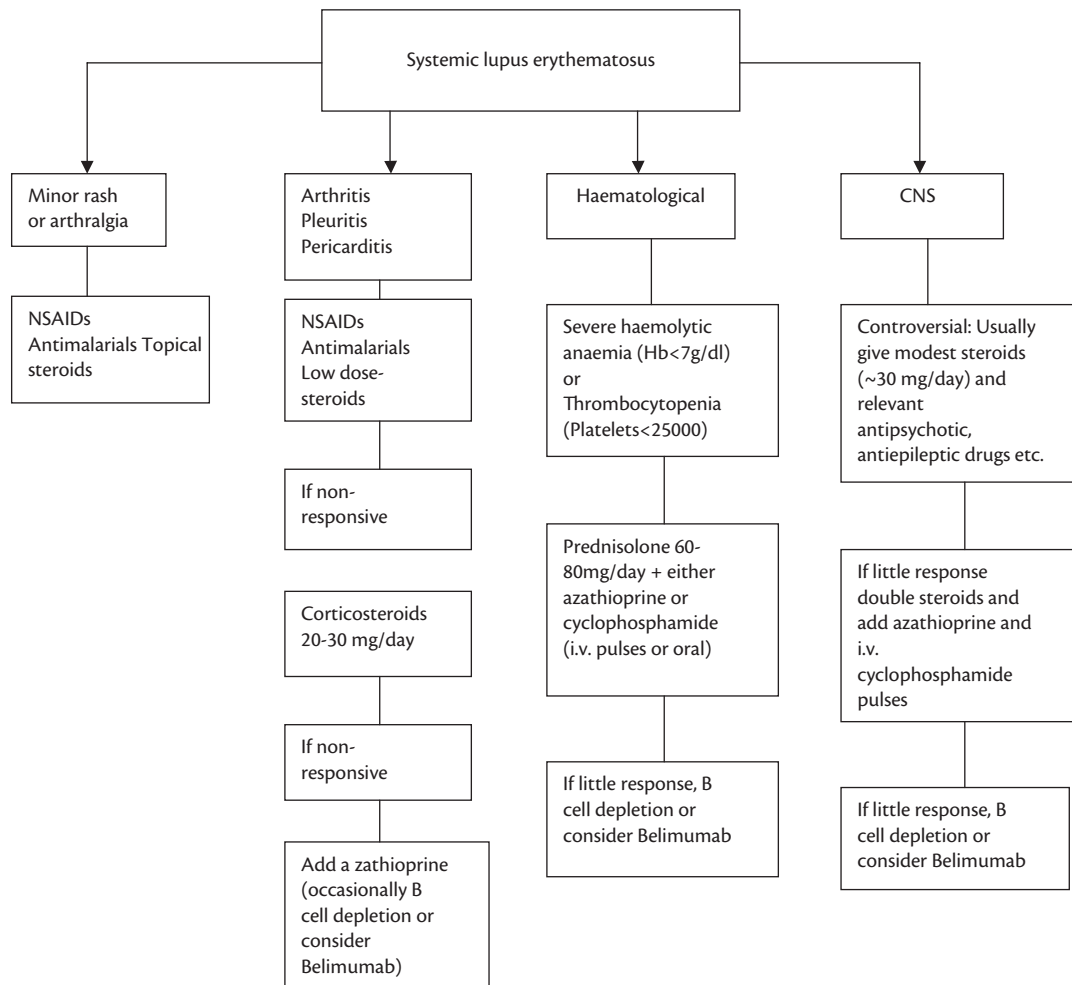
The effectiveness of plasma exchange is not supported by the few small, non-controlled, randomized and retrospective studies. The concept was that the removal of circulating, presumptively pathogenic, immune complexes offered a therapeutic advantage. In practice, it became evident that in some patients a 'rebound' phenomenon occurred in which patients' symptoms and signs dramatically improved but returned within a few days or weeks. It is mainly used in severe therapy-resistant or life threatening disease such as refractory renal disease, neuropsychiatric manifestations, thrombotic thrombocytopenic purpura, or catastrophic anti-phospholipid syndrome, though its efficacy is not supported in clinical trials. This form of treatment requires good venous access and much patience on the part of both physician and patient, and is extremely expensive. As reviewed elsewhere,[12] controlled studies failed to provide convincing evidence of real benefit. Even combining plasma exchange with subsequent pulse cyclophosphamide


Fig. 118.1 Flow diagram of the management of non-renal systemic lupus erythematosus that forms the basis of our practice.

Renal disease suspected

E.g. proteinuria> 500mg/day

Renal biopsy

ISN/RPS Classification system

I	II	III, IV, V*	VI
No specific action needed	Low doses of prednisolone and MMF/azathioprine, making sure the blood pressure is well controlled	MMF up to 3gm/day or low dose IV cyclophosphamide plus IV methyl prednisolone 500-750mg x 3, followed by oral prednisolone 0.5mg/kg/day for 4 weeks reducing to ≤ 10mg/day by 4 – 6 months.	End-stage renal disease will almost certainly require dialysis and eventually transplantation

+ Adjunctive therapy notably ACE-inhibitors
plus hydroxychloroquine, calcium and Vitamin D, +/- a statin,
+/- aspirin and consider anti-coagulation if serum albumin < 20g/L

| **Good Response Remission**

Maintain with low dose steroids and MMF or azathioprine. Treatment is likely to last several years. | **Inadequate Response**
Switch MMF and IV cyclophosphamide or introduce B cell depletion with Rituximab. If these measures do not work, end stage renal disease is likely to develop. |
|---|---|

**= 50% reduction in proteinuria and stability on improvement in GFR in 6 – 12 months.

Fig. 118.2 Flow diagram of the management of renal systemic lupus erythematosus based on our own practice.

did not provide additional clinical benefit compared to pulse cyclophosphamide alone.

Diet therapy

Supplementation of the diet by fish oils has been shown to be beneficial in a double-blind cross-over study in which all the lupus patients were put on to low-fat diets; those who were concurrently taking 10 g/day of fish oil were shown to have done significantly better over a 6 month period.[13] With the concomitant use of steroids and the association of the metabolic syndrome with SLE patients, general advice on modifiable risk factors such as reduced salt, reduced saturated fat, increased fruits and vegetables, and regular exercise is beneficial. It has become more important to monitor lipid levels over time. Anti-malarials have been shown to lower these levels, but if this is unsatisfactory statins may be needed.

Intravenous high-dose gammaglobulin

Intravenous high-dose gammaglobulin (IVIG) is not a first-line treatment in SLE, but may have a role in cases resistant to other treatment modalities, IVIG is a blood product prepared from plasma composing of plasma proteins secreted by plasma cells. Most of the evidence for its use in SLE is anecdotal or obtained from small clinical trials, case series, and case reports. It may be effective in the treatment of immune thrombocytopenic purpura, immune neutropenia, myositis, serositis, and recurrent pregnancy losses in SLE. Monthly IVIG may be a useful alternative to intravenous cyclophosphamide in the treatment of lupus nephritis.[14] However, in most cases rituximab is now used in preference to IVIG. Good-quality research is needed to inform for its effective and appropriate use in SLE.

Ciclosporin A/neoral therapy

Following the failure of original attempts to use ciclosporin (because the dose was too high and caused nephrotoxicity),[15] there was something of a moratorium on its use in patients with SLE. Recently, several investigators have shown that a dose of 2.5–5 mg/kg provides reasonable disease control and enables steroid reduction over long-term follow-up. However, hypertrichosis develops in the majority of patients; it is best avoided in the presence of significant renal disease with close monitoring of blood pressure.

Some controlled trials seem to suggest it may be used in the maintenance treatment of membranous lupus nephritis and it may be as effective as azathioprine for maintenance therapy for diffuse proliferative lupus nephritis.[16]

Sex hormone therapy

Given the marked predilection of lupus for females, it is not surprising that attempts have been made to treat the condition by manipulating the level of sex hormones. One drug, danazol, an androgen with reduced virilizing capacity, has been used by several groups; as is so often the case with new drugs, the initial optimism has given way to the view that it adds little to the treatment of lupus. Another androgen, dehydroepiandrosterone (DHEA), was shown to reduce the requirement for steroids in patients with SLE but had modest effects at best in mild SLE.

Newer forms of therapy

The management of rheumatologic conditions is moving from 'serendipity to (immunological) sense'. Advances in knowledge of immunological reactions including T-cell activation, T cell–B cell collaboration, anti-dsDNA antibody production, deposition of anti-dsDNA antibody complexes, and complement activation are leading to the development of more targeted treatments that are showing promise in the management of this complex disease.

B-cell-targeted therapies

Anti-CD20 (rituximab)

B-cell dysregulation is involved in the pathogenesis of SLE. Rituximab (RTX) is a chimeric mouse/human monoclonal antibody directed against peripheral blood B-cell-specific antigen anti-CD20, a surface marker expressed on the surface of developing B cells and minimally expressed on the plasma cells. Initially introduced for the treatment of low grade B-cell follicular non-Hodgkin's lymphoma (NHL), it has shown promise in the treatment of chronic immune thrombocytopenic purpura (ITP), rheumatoid arthritis (RA), Sjögren's syndrome, vasculitis, and dermatomyositis.

Currently it has found use as an alternative to conventional immunosuppressive agents in SLE patients with active or severe disease resistant to other forms of treatment. Many studies report its effectiveness in inducing complete remission in lupus patients with a wide variety of clinical features including refractory lupus nephritis. It has been used with steroids alone (to minimize allergic reactions) or in combination with cyclophosphamide with improvements clinically, histopathologically, and in serological parameters.[17] Studies also show a positive long-term safety profile, but long-term monitoring is necessary.[18]

Successful reports from studies of the use of rituximab in central nervous system (CNS) involvement refractory to standard therapy showed rapid improvement in manifestations such as acute confusional state, cognitive dysfunction, psychosis, seizures, transverse myelitis, and vasculitis of the CNS.[19]

Despite this favourable response from multiple non-randomized studies, rituximab failed to reach its primary endpoints in the EXPLORER (non-renal lupus) and LUNAR (renal lupus) studies, a result that has been attributed to poor trial design with inadequate power to detect a realistic effect, heterogeneous selection of SLE patients, and the concomitant use of high doses of other immunosuppressive therapies. Ideally, further controlled studies with improved designs are necessary to characterize the place of RTX in the management of SLE.

Anti-CD22

Epratuzumab is a fully humanized recombinant monoclonal antibody against CD22 expressed on the surface of maturing B cells but not plasma cells.

Phase 2b studies in 90 patients with moderate to severe lupus showed significant improvements to British Isles Lupus Assessment Group Scale (BILAG) C or better, most patients had symptom reduction and absence of active disease within specific body systems. Particularly prominent was cardiorespiratory and neuropsychiatric efficacy, with similar incidence of serious adverse events and infusion reactions as placebo. A multicentre phase 3 trial started in late 2010.

Ocrelizumab

A humanized monoclonal antibody to CD20 has shown efficacy and safety in RA patients. It was hoped it would avoid the development of human anti-chimaeric antibodies (HACA) responses seen in rituximab; however, ocrelizumab in combination with standard of care in extrarenal SLE (BEGIN) and lupus nephritis (BELONG) phase 3 trials have been terminated due to problems with development of severe and opportunistic infections in East Asian subjects.

B-cell survival factors

Belimumab

B-lymphocyte stimulation protein (BLyS), also known as B-cell activating factor (BAFF), is a cytokine of the tumour necrosis factor (TNF) superligand family. It plays an important role in proliferation and differentiation of B cells.

Belimumab (Benlysta) is a human monoclonal antibody developed to recognize and inhibit the biological activity of BLyS. It has been approved for the treatment of SLE, becoming the first specifically targeted biological therapy for SLE to have been developed in 50 years. Phase 2 and 3 trials confirmed its biological activity and tolerability. Serologically active patients responded better to belimumab plus standard of care than standard of care alone, with response of 57.6% and 43.2% for 10 mg/kg compared to 43.6% and 33.85 for placebo in the BLISS-52 and BLISS-76 studies.[20,21]

Questions remain to be answered about the optimal patient population for its use, however. As belimumab has not been used in renal or CNS lupus it is not known whether it would be effective in these groups of patients, the duration of treatment, long-term adverse effects, and its place in the standard treatment protocols.

Atacicept, a chimeric molecule formed by a receptor for BAFF and a proliferation-inducing ligand (APRIL) with immunoglobulin (Ig) is also undergoing a major clinical trial in SLE.

B-cell tolerization

LJP 394 (abetimus sodium)

LJP 394 is a drug that was developed specifically to inactivate B cells which produce anti-dsDNA antibodies. The drug consists of four oligonucleotides, each 20 bases in length, which are attached to an inert scaffold. When these nucleotides bind surface Ig anti-dsDNA molecules on B cells, they can cross-link those molecules.

This leads to anergy or deletion of the B cells rather than activation, because the drug molecule does not carry any T-cell epitopes and cannot recruit T-cell help.

Although some early studies showed promise (appearing to reduce the rate of renal flares), a large trial failed to show any benefit and this approach is no longer being used.

Anti-cytokine agents

Interleukin (IL)-10 levels are consistently elevated in the blood of patients with SLE, and monoclonal anti-IL-10 antibodies have been used to treat six patients with SLE for 21 days each.[22] These patients reported improvements of the skin and joints, which persisted for up to 6 months in the majority of cases. Surprisingly, this approach has not been further pursued.

Increased TNF concentrations are found in the sera of SLE patients with increased deposits in skin and renal tissues. Anti-TNFα drugs used in RA have been associated with the production of anti-dsDNA antibodies and, rarely, the development of a lupus-like syndrome.[23]

An open-label study suggests that TNF blockade in combination with azathioprine may be effective in SLE patients with arthritis and skin disease. Lupus nephritis patients showed reduction in proteinuria and, despite the induction of lupus-specific autoantibodies, it was not associated with disease flares; further controlled studies are warranted.[24]

Inhibition of costimulatory molecules

Anti-CD40 ligand antibody

The interaction between CD40, which is present on APCs, and CD40 ligand (L) expressed on T cells provides an important costimulus to the activation of T cells. This interaction also has significant effects on B cells, for example augmenting B-cell responses to cytokines and causing antibody isotype switching.[25]

In a double-blind placebo-controlled trial, a humanized monoclonal antibody against CD40L (IDEC-131) showed no statistically significant differences in SLEDAI and adverse events with placebo. Blockade of the CD40L pathway was successful but not safe with another antibody, BG9588, and there are fears about this approach causing major vascular events.[26]

CTLA4-Ig

CTLA4-Ig (abatacept) has been effective in the treatment of psoriatic arthritis and RA. In murine lupus models it has been found to be effective in combination with cyclophosphamide in treating lupus nephritis; however, a clinical trial involving over 150 patients did not meet its endpoints.

Autologous haematopoietic stem cell transplantation

In SLE some promising results of non-myeloablative and mesenchymal stem cell transplantation in reducing disease activity, improving serological markers, and stabilization of renal function has been shown.[27] [28] However, this treatment is very demanding of the patients and must only be undertaken at centres where the technique is performed regularly.

Questions plaguing future, clearly needed, studies include deciding which patient groups would do well or badly, and clinical, serological, and organ system involvement to use as markers for patient selection. Long-term outcomes remain unknown, as well as the selection of optimal remission and maintenance regimes.

Management in special situations

Pregnancy

Since most patients with SLE are women in their childbearing years, the question of managing pregnancy is a significant issue for many. It is important to recognize that around 25% of lupus patient pregnancies do not go to full term (i.e. well in excess of the figure of approximately 10% of pregnancies in healthy women). Those patients with anti-phospholipid antibodies are especially likely to suffer recurrent miscarriages. Those with anti-Ro or anti-La antibodies have a small (1:20) chance of having a child with the neonatal lupus syndrome or congenital heart block. Those patients with renal disease have to be watched very closely during pregnancy and on occasion it may be hard to distinguish a renal flare from pre-eclamptic toxaemia. We strongly recommend comanaging SLE patients with an interested obstetrician.

Contraindications to pregnancy include severe pulmonary hypertension (symptomatic or systolic pulmonary artery pressure>50 mmHg), chronic renal failure (Cr >2.8 g/dl), heart failure, restrictive lung disease, previous severe preeclampsia despite aspirin or heparin, stroke, or a severe lupus flare within the past 6 months.

Drugs safe to take in pregnancy include NSAIDs (avoid after week 32 to prevent premature closure of ductus arterosius), antimalarials, corticosteroids, ciclosporin, azathioprine, heparin, and low-dose aspirin. Try to keep prednisolone dose to 7.5 mg/day or less to prevent maternal adverse effects. NSAIDs, anti-malarials, corticosteroids, warfarin, heparin, and aspirin are safe for breastfeeding. Other immunosuppressive and biological drugs are contraindicated.[29]

In-vitro fertilization seems to be safe and successful, though there are reports of high maternal and complications in well-selected patients with SLE and anti-phospholipid syndrome (APS) though the evidence is mainly from case reports and small case series.

An overall guide to management is shown in Figure 118.3.

Coincident anti-phospholipid antibody syndrome

Perhaps 10% of patients with SLE also have APS and even more (around 25–35%) have anti-phospholipid antibodies. The 'balance of disease' may go in either direction and on occasion we have seen a patient deemed to have primary APS develop SLE over time. Mainly, however, in our experience SLE is diagnosed first.

Managing the APS component of those with both conditions is little different from patients who have primary APS. Problems may arise in particular when an overlap patient of this type presents with hypertension and mild proteinuria. Invariably a renal biopsy will be needed to ascertain to what extent the kidneys have been affected by multiple small thrombi and/or 'lupus' glomerulonephritis. In some patients, therapy with both immunosuppressive and long-term anticoagulants is needed.

Prognosis and survival

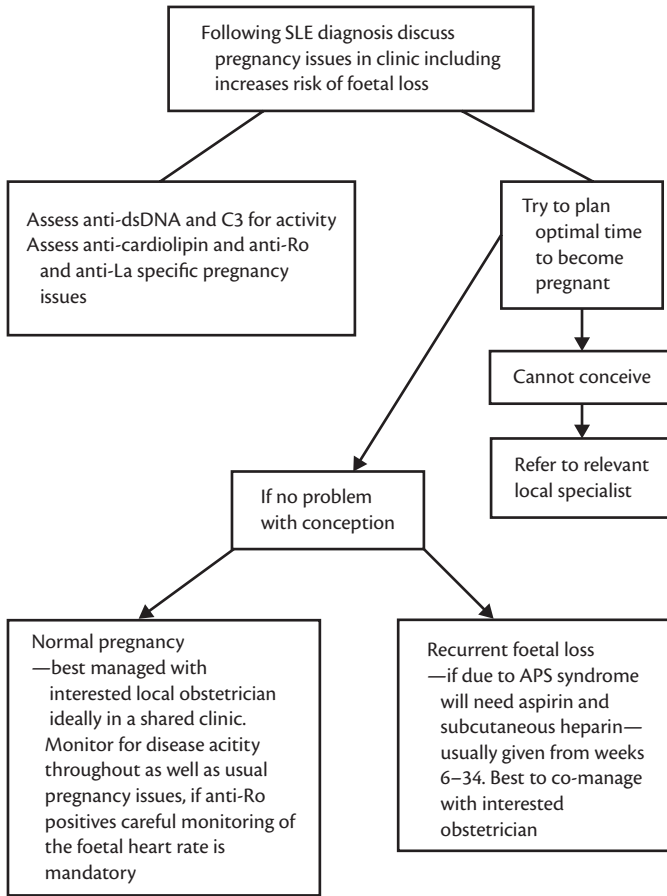
Studies on duration of disease and overall survival rates have frequently been confounded by the numbers of patients lost to follow-up and inadequate attention paid to the ethnic group, age of onset, and socio-economic status of individual patients. With these possible confounding factors in mind, and the division of lupus


Fig. 118.3 Flow diagram of the management of systemic lupus erythematosus in pregnancy.

patients into those with overt nephritis and those without, it is reasonable to state that the 5 year survival in lupus is presently 90% or greater, but at 15 years only 60% of those with nephritis will still be alive compared to around 85% of those without nephritis. In the United States, it has been claimed that black lupus patients, males, those from poorer socio-economic groups and possibly children, have poorer survival, especially if nephritis is present. It has also been suggested that there exists a bimodal mortality curve. Patients who die within 5 years usually have very active disease, with a requirement for substantial doses of steroids and other immunosuppressives. Those patients dying much later tend to do so from cardiovascular disease and possibly infection. Overall, most lupus patients die from sepsis, malignancy, cardiovascular disease, and active generalized disease.

One of the most important steps for monitoring progress has been the development of reliable activity tools like the BILAG, SLEDAI and the Systemic Lupus Erythematosus International Collaborating Clinics (SLICC) damage index.

SLE is a multisystem disease and the involvement of different medical subspecialties in management of patients is strongly encouraged to ensure the best outcome for patients.

Paediatric-onset systemic lupus erythematosus

Louise Watson and Michael W. Beresford

Introduction and epidemiology

Systemic lupus erythematous (SLE) is a rare, autoimmune, multisystem disorder. It is of unknown aetiology but it is characterized by the production of autoantibodies directed against nuclear antigens, including antinuclear antibodies (ANA), anti-extractable nuclear antibodies (ENA), and anti-double-stranded DNA antibodies (dsDNA).

SLE is rare in children, although around 20% of all cases of SLE will have an onset before adulthood.[1] The incidence of juvenile-onset SLE (JSLE) is reported to be 0.36–0.9 per 100 000 children per year.[2–7] In a similar manner to adult-onset disease, the incidence varies significantly according to racial background, with a higher incidence in patients of black African or Asian descent. Ethnicity may also influence disease phenotype, with an earlier disease onset and more nephritis seen in patients of black African or Asian origin.[8] Like most autoimmune conditions, SLE is more prevalent in females. However, the sex difference is less striking in JSLE than in adult-onset disease. In JSLE, the female to male ratio is around 5:1 in contrast to the 9:1 ratio seen in adult-onset SLE.[9]

Hormonal, environmental, and genetic factors play a contributory role in the development of JSLE. Hormonal influences, particularly oestrogen, contribute to disease activity, as illustrated in patients taking oral contraceptive medication or during pregnancy, both of which can trigger a flare of the disease. Men with Kleinfelter's syndrome (46XXY) are reported to have an increased risk of developing SLE.[10,11] Environmental factors including certain medications, UV exposure, and infectious stimuli such as the Epstein–Barr virus, all play a role.[12] Individuals with SLE have a genetic susceptibility to developing the disease, as the risk of autoimmunity in a first-degree relative is significantly higher than that of the general population.[13] Genetic contribution in JSLE may be more significant than that seen in adult-onset disease as the sex distribution is less striking, disease presents earlier and conditions, such as Aicardi–Goutiers syndrome with known genetic mutations present with a lupus phenotype in childhood.[14] Although genetic contribution is clearly very important in JSLE, it cannot be the entire cause as the concordance rate between monozygotic twins is only around 25%.[15]

JSLE also occurs in the context of rare inherited complement deficiencies, the most common of which is C1q deficiency. These deficiencies predispose patients to a high (>90%) chance of developing SLE over their lifetime and while C1q deficiency is phenotypically variable, children with C1q deficiency and SLE are often younger at disease onset, have a more severe disease course, and more cutaneous manifestations than patients with JSLE.[16]

Lupus-like disorders

Lupus-like features can present in children in a secondary form, either following the administration of certain drugs, so called 'drug-induced' lupus, or secondary to maternal lupus causing neonatal lupus in the newborn period. The medications with the highest risk of producing lupus-like features include the anti-hypertensive medication hydralazine, with features occurring in 5% of patients taking the medication, the anti-arrhythmic drug procainamide, and newer biologics including anti-TNFα therapy.[17] Drug-induced SLE is usually associated with transient autoantibodies and cutaneous manifestations, with occasional systemic features described mainly in neonatal lupus syndrome.[18] In infants of mothers with anti-Ro and/or anti-La antibodies congenital heart block can be seen and may lead to fetal death or in-utero cardiac failure. Once the infant is delivered they frequently require artificial cardiac pacing.[19] In both cases, symptoms typically resolve either with cessation of the offending medication or gradually over time.

Disease pathogenesis

An exaggerated immune response, characterized by an immune reaction directed against the nuclear components of one's own cells (thus autoantibody formation against nuclear material) underpins the pathophysiology of JSLE.

Adaptive immune system

Commonly observed nucleic autoantibodies include ANA, anti-ENA, and anti-dsDNA. Anti-ENAs include anti-Sm, -RNP, -Ro and -La antibodies. This response involves hyperactive immune cells and uncontrolled immune pathways with a reduced clearance of immune complexes and reduced tolerance to antigenic stimuli.

Increased and dysregulated apoptosis (programmed cell death) occurs in JSLE,[20] and defective clearance of the subsequent

apoptotic material is characteristic of mouse-models of lupus[21] and SLE.[22] Autoantigens typical of lupus cluster in surface blebs of apoptotic cells, increasing their immune exposure.[23] Saturation of the normal physiological processes to safely remove this apoptotic debris leads to amplification of autoantigen exposure and the immune cascade.[24] Autoantibodies produced as a result of plasma B-cell activity are a component of the adaptive immune system response, and form immune complexes. These immune complexes activate complement cascades and can deposit in tissues, resulting in specific features of SLE including cutaneous lupus and lupus nephritis.[25]

Although the adaptive immune system mounts a very specific antibody response to self-nucleic components, failure of its regulation, and its working relationship with the innate immune system, has more recently been recognized.

Innate immune system

Monocytes and macrophages secrete chemokines, cytokines, and growth factors, causing inflammation and damage to both healthy and target tissues. Interferon alpha (INF-α) is one of the most frequently found cytokines in SLE.[26,27] Recent research has identified Toll-like receptors (TLRs), present within certain cells including lymphocytes, having a specific early role in SLE.[28] TLRs, normally able to discriminate between self and foreign material, identify host nucleic acids as foreign invaders activating the innate immune system. Increased expression of TLRs capable of recognizing SLE-associated autoantigens, including TLR9, occurs in JSLE.[29] Apoptotic neutrophils trigger TLR activation through their presentation of autoantigens and trigger activation of the type 1 INF-α pathway.[29,30]

TLR activation produces a surge of inflammatory cytokines, interacting with signalling pathways, and influencing the release of downstream proinflammatory cytokines including tumour necrosis factor alpha (TNFα) and interleukins (IL). Other important cytokines seen in JSLE include B-cell activating factor (BAFF)/B lymphocyte stimulator (BlyS), IL-10, and monocyte chemo attractant protein 1 (MCP-1).[31] Inadequate production of the regulatory T and B cells occurs which results from abnormally low levels of IL-2 and transforming growth factor beta (TGFβ), from T and natural killer (NK) cells.

Other important antibodies

The presence of certain autoantibodies related to the coagulation system, such as lupus anticoagulant (LA), anti-phospholipid antibodies (APAs), and anti-cardiolipin antibodies (ACAs), are also seen. Over recent years, disease registries have demonstrated an increased association with childhood anti-phospholipid syndrome and autoimmune disease than in adults.[32–34]

Diagnosis and monitoring

Diagnosis

A combination of clinical features and laboratory markers are used to diagnose SLE. Classification criteria developed by the American College of Rheumatology (ACR) are generally used in forming the diagnosis (see Table 119.1). Four out of the 11 stated criteria are highly suggestive of SLE.[35–37]

The multisystemic nature of the condition means that JSLE may present to any one of a multitude of different specialists, including

Table 119.1 American College of Rheumatology classification criteria

Criterion	Definition
1. Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
2. Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
3. Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by physician
5. Non-erosive arthritis	Involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
6. Pleuritis or pericarditis	(1) Pleuritis—convincing history of pleuritic pain or rubbing heard by a physician or evidence of pleural effusion, *or* (2) Pericarditis—documented by ECG or rub or evidence of pericardial effusion
7. Renal disorder	(1) Persistent proteinuria >0.5 g/day or > 3+ if quantitation not performed, *or* (2) Cellular casts—may be red cell, haemoglobin, granular, tubular, or mixed
8. Neurological disorder	(1) Seizures—in the absence of offending drugs or known metabolic derangements e.g. uraemia, ketoacidosis, or electrolyte imbalance, *or* (2) Psychosis—in the absence of offending drugs or known metabolic derangements, e.g. uraemia, ketoacidosis, or electrolyte imbalance
9. Haematological disorder	(1) Haemolytic anaemia—with reticulocytosis, *or* (2) Leukopenia—<4000/mm³ on ≥2 occasions, *or* (3) Lymphopenia—<1500/mm³ on ≥2 occasions, *or* (4) Thrombocytopenia—<100 000/mm³ in the absence of offending drugs
10. Immunological disorder	(1) Anti-DNA—antibody to native DNA in abnormal titre, *or* (2) Anti-Sm—presence of antibody to Sm nuclear antigen, *or* (3) Positive finding of APA on: (a) an abnormal serum level of IgG or IgM anticardiolipin antibodies, (b) a positive test result for lupus anticoagulant using a standard method, or (c) a false-positive test result for at least 6 months confirmed by *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test
11. Positive ANA	An abnormal titre of ANA by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs

ANA, antinuclear antibody; APA, anti-phosphlipid antibodies.

psychiatrists, haematologists, or nephrologists. This may contribute to a delay in the initial diagnosis if they are unfamiliar with childhood lupus. Some children may have lupus or evolving lupus without formally meeting the ACR criteria. The opinion of an experienced paediatric rheumatologist with experience of paediatric connective tissue disorders should be sought.

Typically patients with JSLE present with non-specific constitutional symptoms, such as fever, lymphadenopathy, lethargy, and weight loss, which can make the diagnosis difficult. These may or may not accompany end-organ disease. Musculoskeletal, cutaneous, haematological, and renal system involvement are common features of JSLE at presentation and can occur in varying severity. Less frequent but important manifestations are neurological symptoms and signs, which occur in up to 10% of JSLE patients and can present with headaches, altered consciousness, seizures, and even psychosis. Liver, ophthalmic, and especially cardiac and pulmonary involvement are all rare manifestations in the paediatric form of SLE.

General points to ask in history taking are outlined in Box 119.1. Clinical signs of lupus can also be defined by system/organ involvement as shown in Box 119.2.

The main differential diagnoses of JSLE include other systemic autoimmune conditions, for example juvenile dermatomyositis or systemic juvenile idiopathic arthritis, bacterial or viral infections, immunodeficiency, or malignancy. Thorough evaluation, investigation, and experience of these conditions are required to distinguish JSLE from these differential diagnoses.

Disease monitoring

In view of the characteristic multisystem nature of SLE and the complexity of the clinical features of JSLE, a number of disease activity assessment tools have been developed. These endeavour to assess and summarize overall disease activity, especially at time of disease flare. In JSLE two main disease activity tools have been used. Both of these were originally designed for adult-onset SLE and have been modified for use in childhood disease; initial versions of these tools have subsequently been validated for use in JSLE.[38,39] The SLE Disease Activity Index (SLEDAI) scoring system[40] evaluates the presence of multiple features of SLE at the time of completion or in the previous 10 days. This tool has been demonstrated to differentiate mild and moderate from severe disease activity and generates an overall disease activity score. Another commonly used tool is the British Isles Lupus Assessment Group (BILAG) disease activity score.[41] Often used for clinical trials, it is able to separate disease activity into different organ systems and score accordingly. It takes into account the disease features experienced by a patient in the past 4 weeks and is designed to reflect a clinician's intention to alter treatment.

Disease flares are defined as a measurable increase in disease activity in one or more organ systems involving new or worse clinical signs and symptoms and/or laboratory measurements. It must be considered clinically significant by the assessor and usually there would be at least consideration of a change or an increase in treatment.[42]

Investigations

Investigations assist clinicians in forming a diagnosis of JSLE, monitoring activity and assessing organ damage. Children with lupus often present with haematological involvement affecting any of the blood cell lines together with evidence of autoantibodies. Lymphopenia is almost universally seen, with neutropenia, thrombocytopenia, and haemolytic anaemia common. Over 90% will be ANA positive; however, the presence, or precise levels, of particular antibodies are poor indicators of disease activity and, as

with adults, may occur as an isolated finding in healthy individuals. Useful laboratory tests and the common findings in JSLE are shown in Table 119.2.

To formulate a diagnosis and discover the extent of systemic involvement, a detailed multisystem work-up of patients is critical. Exclusion of other potential differential diagnoses, which include malignancy and infectious diseases, is important. Repeated

Box 119.1 Signs and symptoms in the diagnosis of juvenile-onset systemic lupus erythematosus

Constitutional symptoms
- Pyrexia
- Weight loss
- Lymphadenopathy
- Fatigue/lethargy
- Anorexia

Mucocutaneous
- Malar erythema
- Discoid lesions
- Mucosal ulceration
- Alopecia
- Photosensitive skin

Neurological
- Headache
- Cognitive dysfunction
- Seizures
- Hallucinations

Cardiovascular and respiratory
- Dyspnoea
- Chest pain

Vasculitis
- Thromboembolism
- Cutaneous changes ± ulceration
- Raynaud's

Renal
- Oedema
- Haematuria

Gastrointestinal
- Colitis
- Pancreatitis
- Cholecystitis

Ophthalmic
- Proptosis

Box 119.2 System/organ involvement in juvenile-onset systemic lupus erythematosus

General assessment

◆ Weight, height centiles

◆ Systolic and diastolic blood pressure and centiles

◆ Lymphadenopathy

◆ Hepatosplenomegaly

Mucocutaneous

◆ Skin rashes (discoid lesions, malar erythema)

◆ Alopecia

◆ Periungal erythema

◆ Mucosal ulceration

Neurological

◆ Altered consciousness

◆ Acute delirium or psychosis

◆ Meningitis

◆ Demyelitis

◆ Peripheral or cranial neuropathy

Cardiovascular and respiratory

◆ Cardiac failure

◆ Pericardial or pleural effusion

Musculoskeletal

◆ Myositis

◆ Arthritis (poly or mono)

◆ Tendonitis

Vasculitis

◆ Cutaneous ulceration/phlebitis

◆ Raynaud's phenomenon

◆ Livido reticularis

◆ Thromboembolism

Renal

◆ Oedema (nephritic syndrome)

Gastrointestinal

◆ Ascites

◆ Jaundice

◆ Abdominal pain

Ophthalmic

◆ Uveitis, keratitis, episcleritis

◆ Optic neuritis

Table 119.2 Laboratory investigations and common findings in juvenile-onset systemic lupus erythematosus

Investigation	Features with JSLE
FBC, blood film	Anaemia, leucopenia (especially lymphopenia), thrombocytopenia
Direct Coombs' test	Haemolytic anaemia
U&E	Abnormal renal function
LFTs, bone profile	Hypoalbuminaemia (nephritic syndrome); elevated transaminases (hepatitis)
Creatinine kinase	May be elevated (myositis)
LDH	May be elevated (myositis)
CRP	Often low or normal, unless concurrent infection
ESR	Usually elevated
Complement (C3, C4)	Often reduced, particularly in renal lupus
Coagulation, INR, lupus anticoagulant	May be deranged, lupus anticoagulant positive
Ferritin	Often elevated due to inflammation
Immunoglobulins G,A,M	May get hypogammaglobulinaemia
ANA	Positive
Anti-dsDNA	Often positive, may reflect renal lupus
Anti- ENA (includes anti-Sm, -RNP, -Ro, -La)	May be present
Anticardiolipin antibodies IgG, IgM	May be present
Complement C1q levels and anti-C1q antibodies	May be C1q deficient or have C1q antibodies, especially seen in renal lupus
ANCA	Often normal (useful for differential diagnosis)
TFTs	
Urinalysis	
Urine albumin:creatinine ratio	

ANA, antinuclear antibodies; ANCA, anti?neutrophil cytoplasmic antibody; CRP, C-reactive protein; dsDNA, double-stranded DNA; ENA, extractable nuclear antibodies; ESR, erythrocyte sedimentation rate; FBC, full blood count; INR, international normalization ratio; LADH, lactate dehydrogenase; LFTs, liver function tests; TFTs, thyroid function tests; U&E, urea and electrolytes.

evaluation is crucial at times of disease flare to assess the extent of disease involvement, and over time to assess disease related damage.

Appropriate investigations need to be considered carefully and tailored to the individual patient, balancing the invasiveness of each procedure with the ability to establish a diagnosis and determine the extent of the disease process. Where appropriate, investigations may include: electrocardiograph, chest radiograph, echocardiography, bone marrow aspiration, lumbar puncture, MRI, angiography, tissue histology (skin, lymph nodes) and renal biopsy (if significant proteinuria, haematuria, altered renal function, or hypertension). Many of these procedures will require sedation, even the use of

general anaesthesia, to perform the procedure safely and protect the young patient from painful experiences.

Management

The management of JSLE requires comprehensive and holistic multidisciplinary team (MDT) input to achieve optimal disease control and quality of life for children and young people with lupus. Key challenges include preventing disease progression, controlling symptoms, and minimizing adverse consequences of treatment while supporting the patient and their families through the enormous impact the diagnosis of JSLE may have upon them.

The multidisciplinary team

Because of the complexity of the disease, the care of a patient with JSLE requires involvement of multiple specialists preferably coordinated by a paediatric rheumatologist with experience of JSLE.[43] Nurse specialists have an essential role in liaison with the patient/family and can be useful in educating the patient about the disease and medication and liaising with schools. Paediatric specialists such as dermatologists, nephrologists, and haematologists may assist with the initial diagnosis, management of disease flares, and long-term disease monitoring. Physiotherapists, occupational therapists, and play specialists can assist the patient with adapting and coping with the disease and have a role in rehabilitation following disease activity flares.

JSLE can have significant and debilitating neuropsychiatric manifestations, and significant psychosocial consequences can occur secondary to chronic disease in childhood. The MDT should therefore include paediatric psychologists who can assist the patients through such difficulties. The family general practitioner should be kept informed about medication regimens and any monitoring required in the primary care setting including the special circumstances surrounding vaccination (see Chapter 95 and section 'Vaccination schedule'). Clinical medical teams working closely with clinical research teams will have a positive impact on the patient and facilitate recruitment to studies to further our understanding of this condition.

Medical management

JSLE is generally more aggressive than the adult-onset form and frequently requires higher doses of corticosteroid treatment as well as more intensive immunosuppressive treatment. Optimum disease control requires repeated and regular review to optimize management. Undertreatment can be associated with increased symptoms, worsening growth, and poor educational abilities, and can hasten disease progression and tissue damage. On the other hand, overtreatment poses more drug toxicity and potentially more frequent, severe opportunistic infections.

The overall aim of treatment is to achieve symptomatic resolution, disease control, and improved quality of life by reducing disease progression and preventing further tissue damage. This is balanced against the potential side effects of immunosuppressive therapy, which bring an increased risk of infection and a long-term risk of malignancy.

In JSLE, corticosteroids still have a crucial role in disease control. Immunosuppressive treatment regimens usually consist of a period of intensive induction of remission therapy over 6–12 months to achieve disease quiescence followed by a period of long-term maintenance therapy to control disease and prevent disease flares. Disease flares are proactively screened for and aggressively treated.

Induction therapies

Induction treatment options include intravenous corticosteroids (e.g. intravenous methylprednisolone 30 mg/kg per day for 3 days, up to maximum 1 g/day) and long-term high-dose oral corticosteroids (e.g. 1–2 mg/kg per day, followed by gradual weaning regime) combined with a disease-modifying agent. Traditionally, intravenous cyclophosphamide has been used for major organ involvement in JSLE,[44] with azathioprine or methotrexate used for milder or moderate disease. More recently, mycophenolate mofetil (MMF) has offered an alternative therapeutic option, depending on the type of organ manifestation. For example, in cases of severe lupus nephritis, identified by the International Society of Nephrology/Renal Pathology Society (ISN/RPS)[45] as class III (focal) and IV (diffuse), cyclophosphamide and MMF have been shown to be equally effective in adult-onset SLE [46] and may be more effective in those of black African ethnicity.[47] However, in cases of other major organ involvement, or where there is concurrent severe systemic vasculitis, intravenous cyclophosphamide along with corticosteroids remains the preferred induction therapy. In circumstances of rapidly progressive life-threatening disease (typically involving the neurological or renal systems) plasma exchange and intravenous immunoglobulin can be effective short-term treatment options while awaiting response to cytotoxic and corticosteroid treatment.

Maintenance therapies

All patients should receive hydroxychloroquine (HCQ), unless contraindicated, as in cases of glucose-6-phospate dehydrogenase (G6PD) deficiency. Adult studies indicate that HCQ[48,49] has a disease-modifying role, reduces long-term risk of flares, and has a steroid-sparing and lipid-lowering effect. It can be particularly useful for skin and joint disease; indeed, occasionally some patients with mild disease can be managed with HCQ alone or with addition of low-dose corticosteroids only.

Maintenance therapy of JSLE usually involves the use of either azathioprine (AZA) or MMF as immunosuppressive therapy, with reports suggesting that MMF is equally efficacious, if not slightly superior to AZA.[50,51] These disease-modifying drugs are steroid sparing and usually initially administered in combination with oral prednisolone, which is gradually withdrawn as the disease permits. Maintenance therapy should be continued for several years to achieve ongoing disease remission, particularly during critical stages of childhood development and educational milestones. For disease manifesting predominantly in the musculoskeletal system, methotrexate can achieve a good clinical response.

Second-line treatments

Second-line therapies include some of the newer biological therapies including monoclonal B-cell antibodies (rituximab), which may be used in unresponsive disease.[52] Other therapies that can be used for recalcitrant, complex disease, not controlled by the above

options, include ciclosporin and monoclonal antibodies against TNFα or newer biologic therapies outlined below. Thalidomide has been used effectively in patients with severe unremitting skin involvement, but clinicians have a duty to counsel patients appropriately about its teratogenic consequences and ensure adequate contraception in sexually active patients. The medications frequently prescribed, along with the most common side effects seen in children, are summarized in Table 119.3.

Treatment of relapses

Disease relapses require thorough investigation followed by treatment according to the severity of organ involvement. Disease activity tools can categorize flares into mild, moderate, and severe.[53] Milder flares may respond to a dose increase of their maintenance therapy or a short-term increase in oral corticosteroids. Moderate to severe disease flares are likely to need intravenous corticosteroid therapy to achieve remission and may need further cytotoxic treatment. Prompt recognition, intervention, and appropriate treatment of disease flares are important as disease damage can occur during periods of poor control. During each disease exacerbation and at each annual review a meticulous calculation of the cumulative cyclophosphamide dose exposure is essential.

New drug therapies

Newer biological therapies are usually derived from drug trials in adult SLE patients, which then become adapted for use in an unlicensed manner in children with SLE. The exact side effects likely to be experienced by children on these medications is therefore not known, and specific parental consent and education regarding the risks and benefits of new therapies is required.

Biological therapies currently under investigation primarily target B-cell function, although targets to several other parts of the immune system are beginning to emerge.

- **Belimumab** is a new drug that has shown promising results in adult SLE trials (e.g. BLISS-52 and BLISS-76[54]). Belimumab is a human monoclonal antibody that inhibits the survival and differentiation of B cells and immunoglobulin class switching by inhibiting BLyS/BAFF.

- **Epratuzumab** is a CD22 monoclonal antibody that inhibits B cells and is currently undergoing clinical trials in adult-onset SLE (http://clinicaltrials.gov/ct2/home).

- **Atacicept** has reached phase 2 trials and is a receptor analogue, inhibiting BAFF as well as APRIL, both of which are members of the TNF family; they reduce B-cell activity and immunoglobulin formation.

- **Tocilizumab**, a human monoclonal antibody, acts against IL-6 and has been tested in phase 1 studies of SLE with promising reduction in laboratory markers and a good safety profile.[55]

- **Ocrelizumab**, like rituximab, targets CD20+ B cells but is fully humanized and avoids the problem associated with chimeric products of human antibodies directed against the treatment.

- **Abatacept**, used in rheumatoid arthritis, tested in a double-blind randomized controlled trial (RCT) for adult SLE failed to show a significant reduction in new flares.[56] Abatacept modulates CD80/CD86:CD28, which is a costimulatory molecule that acts as an interface between regulatory and target T cells, resulting in the production of inhibitory factors such as IL-10.

Table 119.3 Frequently prescribed medications and common side effects seen in children

Medication	Indications	Common side effects
Corticosteroids	Induction and maintenance therapy	Adrenal suppression
	All moderate to severe cases; may be required for mild unremitting disease	Striae
		Obesity
		Mood alterations
		Growth failure
		Osteoporosis
Cyclophosphamide	Induction therapy, usually intravenous	Infertility
	Moderate to severe disease with organ involvement	Hair loss
		Increased risk of infection
		Nausea and vomiting
		Long-term increased risk of malignancy
Mycophenolate mofetil	Induction and maintenance therapy	Abdominal discomfort
	Moderate to severe cases	Diarrhoea
		Liver inflammation
		Increased risk of infection
		Teratogenic in pregnancy
Azathioprine	Maintenance treatment	Increased risk of infection
	Mild, moderate, or severe disease	Bone marrow suppression
Methotrexate	Maintenance treatment	Bone marrow suppression
		Musculoskeletal symptoms
		Liver inflammation
Hydroxychloroquine	All patients	Haemolytic anaemia in patients with G6PD
Rituximab	Second-line induction therapy in moderate to severe disease	Infusion reactions
		Increased risk of infection
		Potential malignancy risk
		Long-term data in children not available

- **Abetimus** is a synthetic immunomodulator, shown in phase 3 trials to reduce anti-dsDNA levels after inducing tolerance in B cells.[57]

- **Rigeromid** is a newer agent requiring long-term testing and acts via recognition by CD4+ T cells. Clinical trials in TLR inhibition are also under way (http://clinicaltrials.gov/ct2/home).

Growth and development

Patients with JSLE require particular consideration to their growth and development, with measurements and comparison to growth centile charts recommended every 3 months. Body mass index and pubertal assessment is also important during monitoring. Faltering growth and pubertal delay may be seen due to chronic disease or may occur secondary to treatment side effects.

Psychosocial well-being

Health consideration in terms of physical well-being is essential, but equally important is the acknowledgment of the patient's educational, emotional, and psychosocial needs.

Long-term consequences

The patients and their families need to be aware of the long-term consequences of JSLE secondary to both disease and treatment, including reduced fertility, long-term cardiovascular complications and the risk of future malignancy, particularly in cases requiring toxic immunosuppressant treatment or newer biologic therapies. The long-term consequences of the disease are very important in childhood disease as these patients have a lifetime of disease and treatment burden.

Research in JSLE

There is a great need to find more effective treatments in JSLE with fewer, more tolerable side effects. Achieving this in children requires international collaboration to produce large multicentre treatment trials. All patients with JSLE should be provided with an opportunity to take part in research to further the care and understanding of their condition. Paediatric-specific drug trials would allow a more accurate awareness of the childhood specific risks associated with new treatments and would assess the acceptability of administrating such medications to a childhood population.

The Paediatric Rheumatology International Trials Organization (PRINTO) is currently attempting to standardize definitions and management for SLE and have worked to define core sets of outcome measures for disease activity and disease damage assessment and definitions of improvement, to be used in clinical trials and outcome assessment studies in children with JSLE.[58] The overall goal of the PRINTO project is to have a standardized approach for the outcome evaluation of children with JSLE, allowing international trials.

Other management options

Bone marrow or stem cell transplant is considered in the rare cases of poorly controlled JSLE. It is reserved for severe cases and requires consensus from external expert reviewers, as it is associated with a significant mortality.

In cases of severe end-organ involvement other interventions may be required, for example renal transplant for advanced glomerulonephritis. These will not affect the systemic disease course and inflammation can reoccur in the transplanted organ, although surprisingly this is rare, perhaps because systemic immunosuppression is required to prevent organ rejection.

Topical immunosuppressive treatments can be used for isolated skin manifestations and laser therapy has been used to treat striae associated with corticosteroid use.

Compliance to treatment

As with many lifelong chronic conditions, poor compliance in JSLE can be an important factor contributing to worsening or poorly controlled disease. At every opportunity concordance with management should be explored in a sensitive way and may influence treatment options to suit the individual patient. A supportive partnership with the patient, family members and the MDT may assist with resolving compliance issues, which are frequently seen during adolescent years.

Vaccination schedule

Serological evaluation of viral status in relation to differential diagnosis is important, as well as determining immunity in relation to varicella and measles, as vaccination prior to immunosuppressive treatment is recommended where clinically possible.

All vaccines are strongly recommended except for live vaccines such as the measles, mumps, and rubella (MMR) vaccine, which are contraindicated while the patient is on immunosuppressive agents including corticosteroids. Live vaccines can only be given once the patient has been off treatment for greater than 3 months. In addition to scheduled vaccinations, which include the human papillomavirus (HPV) vaccine, the annual flu vaccine and pneumococcal vaccination are recommended. Patients who are not immune to measles and who come into contact with the condition should receive intravenous immunoglobulin. In response to contact with varicella, a non-immune patient should receive varicella zoster immunoglobulin and if symptoms develop intravenous aciclovir should be administered.

Prognosis

Long-term morbidity of JSLE is significant, related to both disease damage and treatment toxicity. The 10-year mortality rate remains around 10%, with the greatest improvement in mortality seen during the introduction and routine use of immunosuppressive medication and corticosteroid treatment. Children with SLE have a lower life expectancy than the general population, mainly due to an increased cardiovascular morbidity, with evidence of premature atherosclerosis when begins forming in childhood.[59,60]

More severe and active disease is associated with a worse life expectancy and JSLE has a higher risk of death than adult-onset SLE. Disease damage in JSLE should be monitored annually using the damage index Systemic Lupus International Collaborating Clinics/American College of Rheumatology (SLICC/ACR) Damage Index.[61] Designed and validated for use in adults, it provides a useful comparative tool for assessing the frequency and distribution of end-organ damage although a paediatric-specific damage index is required.

Conclusion

JSLE is a complex multisystemic disease requiring specialist assessment and careful monitoring. The disease shares many similarities to adult-onset SLE but an awareness of the differences is crucial. An experienced paediatric rheumatologist, working closely with a dedicated MDT, should lead the management of these patients. Children with this lifelong condition may have disease- and treatment-associated morbidity and a reduced life expectancy. Research into the pathophysiology of JSLE will provide important insight into childhood disease, which may be translational to adults and is crucial for developing more effective treatments to improve outcomes. Clinical trials in JSLE are urgently required to establish the optimum treatment regimens.

CHAPTER 120

Anti-phospholipid antibody syndrome

Munther A. Khamashta, Graham R. V. Hughes, and Guillermo Ruiz-Irastorza

Introduction

In 1983, few rheumatologists would have predicted the interest that the introduction of the anti-cardiolipin test would generate.[1] New autoantibodies turn up frequently in patients with systemic lupus erythematosus (SLE) and there may have seemed little reason why anti-cardiolipin antibodies should have merited any more than passing interest. However, their association with an unusual combination of clinical complications that included venous and arterial thrombosis, pregnancy loss, and thrombocytopenia attracted the attention of investigators from a variety of disciplines.[2] A chronology of the major developments in the unfolding of the anti-phospholipid syndrome (APS) story is listed in Box 120.1.

During the last three decades, considerable progress has been made in understanding anti-phospholipid antibodies (APA) and the disorder with which they are associated, but many questions remain unanswered, particularly those of pathogenesis and optimal treatment.[3]

Epidemiology

Efforts are being made in clinics throughout the world to assess the importance of APA in recurrent abortion, stroke, myocardial infarction, and epilepsy, among others. Prospective studies have shown an association between APA and the first episode of venous thrombosis,[4] the first myocardial infarction,[5] and the first ischaemic stroke.[6] A critical issue, therefore, is the identification of patients with APA who are at increased risk for a thrombotic event.

Many patients have laboratory evidence of APA without clinical consequence. APA, using standardized techniques, are detected in less than 1% of apparently normal individuals and in up to 3% of the elderly population without clinical manifestations of the APS. Among patients with SLE, the prevalence of APA is much higher, 30–40%.[7] For otherwise healthy control subjects, there are insufficient data to determine what percentage of those with APA will eventually have a thrombotic event or a complication of pregnancy consistent with the APS. In contrast, the APS may develop in

2006	Classification criteria updated

50–70% of patients with both SLE and APA after 10–20 years of follow-up.[8]

The specificities of APA probably differ in various disorders. Large retrospective studies of patients with thrombotic complications suggest that those with lupus anti-coagulant and/or high concentrations of IgG anti-cardiolipin antibodies appear to be at greatest risk for thrombosis, whereas the risk of clotting appears to be much lower in patients with infection-related or drug-induced APA.

Genetic analyses and modelling studies strongly support a genetic basis for disease in families with the APS and suggest an autosomal dominant model of inheritance.[9] HLA studies have suggested associations with DR7, DR4, DRw53, DQw7, and C4 null alleles.

Detection of anti-phospholipid antibodies

APA are detected by a variety of laboratory tests, the most useful for identifying patients with the APS being the lupus anti-coagulant and the anti-cardiolipin antibody tests. These antibodies are distinct and separable immunoglobulins present alone or in combination.[10]

The autoantibodies sometimes bind phospholipids utilized in the Venereal Disease Research Laboratories (VDRL) test; hence, some patients may have a false-positive test for syphilis. However, the VDRL test is not positive frequently enough to make it valuable in diagnosing the APS.

The lupus anti-coagulant is a functional assay measuring the ability of APA to prolong clotting via their inhibition of the conversion of prothrombin to thrombin or the activation of factor X (both reactions are catalysed by phospholipids). Tests for the lupus anti-coagulant have been difficult to standardize, and no single test appears to be adequate. The test begins with an attempt to demonstrate an abnormal coagulation screening test, such as a prolonged activated partial thromboplastin time (APTT) , dilute Russell viper venom time, or kaolin clotting time. If any of these is positive, the test is repeated, using a sample in which the patient's plasma has been mixed with normal plasma. If the patient's disorder is a clotting deficiency, the test should become normal. If, on the other hand, lupus anti-coagulant or some other clotting inhibitor is present, the clotting time will remain prolonged. The presence of lupus anti-coagulant is confirmed by the return to normal of the clotting test after addition of freeze-thawed platelets or excess phospholipids, either of which bind the antibodies. The lupus anti-coagulant test must be performed on platelet-poor plasma.[10]

The anti-cardiolipin antibody test was introduced in 1983 and extensively improved since that time.[11] This test uses enzyme-linked immunosorbent assay (ELISA) to determine antibody binding to solid plates coated with either cardiolipin or other phospholipids. Serum or plasma samples may be used for the anti-cardiolipin assay. The availability of reference sera which are isotype specific (IgG and IgM) has greatly improved interlaboratory testing and quantification of anti-cardiolipin antibodies. IgA anti-cardiolipin reference sera are also now available. Many laboratories currently measure all three isotypes and sensitive kits are commercially available.

In general, positive lupus anti-coagulant tests are more specific for the APS, whereas anti-cardiolipin antibodies are more sensitive. The specificity of anti-cardiolipin antibodies for APS increases with the titre and is higher for the IgG than for the IgM isotype. However, some patients may have only a positive IgM test, and a few are only IgA positive.[10]

The observation that many anti-cardiolipin antibodies are directed at an epitope on β2-glycoprotein I led to the development of anti-β2-glycoprotein I antibody immunoassays.[12] Their presence has been included in the 2006 updated criteria for the classification of the APS.[13] The main clinical utility of anti-β2-glycoprotein I antibodies is when they appear in combination with other APA, since those patients triple positive for lupus anti-coagulant, anti-cardiolipin, and anti-β2-glycoprotein I antibodies are at the highest risk of thrombosis.[14] However, in some patients with clinical features of APS, anti-β2-glycoprotein I antibodies are rarely the sole antibodies detected.[15] Thus, multiple APA tests should be used in seeking the diagnosis of APS.

The clinical utility of APA assays for autoantibodies to phospholipids other than cardiolipin and to phospholipid-binding proteins other than β2-glycoprotein I, such as prothrombin, remains unclear.[10] However, new refined tests are expected in the near future that could improve the correct identification of patients with APS.

Pathogenesis

There is now good evidence, mainly from animal models, that APA can be pathogenic rather than a simple serological marker for APS. Passive transfer and active immunization of BALB/c mice with human or mouse anti-cardiolipin monoclonal antibodies induced features of the APS.[16,17] Also, atherosclerosis in a susceptible mouse model (the LDL-receptor knockout mouse) was accelerated by immunization with human anti-cardiolipin antibodies from an APS patient, providing additional evidence for a causal pathogenic effect.[18]

Mechanisms of thrombosis

APA alone are apparently unable to induce thrombotic manifestations per se. In this regard, a two-hit hypothesis has been suggested: APA (first hit) increases the risk of thrombotic events that occur in the presence of another thrombophilic condition (second hit).[19]

Precisely how APA relate to thrombosis is unknown. Several mechanisms have been proposed to explain the prothrombotic nature of the APS. The range of possible mechanisms includes effects of APA on platelet membranes, on endothelial cells, and on clotting components such as antithrombin, protein C, and protein S (Box 120.2).[20]

Box 120.2 Proposed mechanisms of thrombosis mediated by anti-phospholipid antibody

- Increase of tissue factor expression on monocytes and on endothelial cells
- Increase of platelet activation and aggregation
- Decrease of prostacyclin production and/or release by endothelial cells
- Complement activation
- Decrease of function of annexin A5
- Decrease of protein C activation
- Decrease of free protein S levels
- Decrease of antithrombin activation
- Interference with thrombomodulin function on endothelial cells
- Interference with the function of plasma β2-glycoprotein I
- Inhibition of tissue factor pathway inhibitor
- Direct injury to endothelium
- Induction of apoptosis on vascular cells
- Vascular activation and release of von Willebrand factor multimer
- Increase of endothelin-1
- Increase of plasminogen activator inhibitor-1
- Cross-reactivity to oxidized LDL
- Inhibition of factor XII/prekallikrein-mediated fibrinolytic activity

It is now accepted that APA can react with endothelial cells, monocytes, and platelets, mainly through the binding to β2-glycoprotein I expressed on cell membranes. Exogenous β2-glycoprotein I can bind to endothelial cells at the putative phospholipid binding site located in the fifth domain of the molecule. Binding of APA induces activation of endothelial cells, monocytes, and platelets. Adhesion molecules such as intercellular cell adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), and E-selectin are expressed by activated endothelial cells. Both endothelial cells and monocytes upregulate the production of tissue factor (TF).[21] Activated platelets increase the expression of glycoprotein IIb–IIIa and the synthesis of thromboxane A2 (TXA2). Many of these processes are mediated by nuclear factor-κB (NFκB) and p-38 mitogen-activated protein kinase (p-38 MAPK).[22] Recent studies in mice also suggest an important role of complement activation in aPL-induced thrombosis.[23]

The activation of endothelial cells, monocytes, and platelets induces a procoagulant state that is mainly mediated by the increased synthesis of TF and TXA2. Activation of the complement cascade, in combination with a 'second hit', results in clinical thrombosis. Traditional cardiovascular risk factors, which are present in more than 50% of patients with the APS, frequently play an important role.[2] Additionally, interaction of APA with proteins implicated in clotting regulation, such as prothrombin, factor X, protein C, and plasmin, may interfere with the inactivation of procoagulant factors and fibrinolysis.

Mechanisms of pregnancy loss

The mechanism of pregnancy loss associated with APA remains uncertain. Progressive thrombosis of the microvasculature of the placenta and subsequent infarction resulting in placental insufficiency, fetal growth restriction, and, ultimately, fetal loss, is a plausible explanation. The disruption of the annexin A5 shield seems to play an important additional role in the pathogenesis of the obstetric manifestations of the APS. Annexin A5 is a potent vascular and placental anti-coagulant protein with high affinity for negatively charged phospholipids. It is highly expressed at the interface between the fetus and the placenta, with its anti-coagulant effect resulting from the capacity to crystallize over phospholipid bilayers, which blocks their availability for coagulation reactions. APA interfere with annexin A5 function.[24]

Not all placentas examined, however, have shown areas of thrombosis or infarction and other mechanisms may be operative in these patients. Recently, in-vitro studies showed that APA may impair trophoblastic invasion and hormone production, thereby promoting not only early miscarriages but also fetal loss and uteroplacental insufficiency.[25] These findings provide strong evidence for a defective placentation mediated directly by APA that is not necessarily associated with thrombotic phenomena.[26] Complement activation can also have a major role in APS-related pregnancy loss.[27]

Clinical features

The APS is a non-inflammatory autoimmune disease. The most critical pathologic process is thrombosis, which results in most of the clinical features suffered by these patients. Any organ can be affected in this disorder; thus, the range of clinical features is extremely wide (Box 120.3).

Box 120.3 Clinical features of the anti-phospholipid syndrome

Major features

◆ Venous thrombosis: deep venous thrombosis,

◆ Budd–Chiari syndrome, and pulmonary thromboembolism

◆ Arterial thrombosis: strokes, transient ischaemic attacks, multi-infarct dementia, and myocardial infarction

◆ Pregnancy complications: recurrent pregnancy loss, intrauterine growth restriction, pre-eclampsia, and abruption

Associated clinical features

◆ Thrombocytopenia

◆ Leg ulcers, livedo reticularis, thrombophlebitis, and Sneddon's syndrome

◆ Heart valve lesions

◆ Transverse myelitis, chorea, and epilepsy

◆ Haemolytic anaemia, Coombs' positivity, and Evans' syndrome

◆ Pulmonary hypertension

◆ Cognitive impairment

◆ Chronic headache

Others (less common)

◆ Splinter haemorrhages

◆ Labile hypertension and accelerated atherosclerosis

◆ Ischaemic necrosis of bone

◆ Bone marrow necrosis

◆ Addison's disease

◆ Guillain–Barré syndrome and pseudo-multiple sclerosis

◆ Aumaurosis fugax

◆ Sensorineural hearing loss

◆ Renal artery and vein thrombosis and microangiopathy

◆ Retinal artery and vein thrombosis

◆ Digital gangrene

Thrombosis

Arterial and venous thromboses are among the main features of the APS. In contrast, thromboses associated with congenital thrombophilias, such as protein C, protein S, or antithrombin deficiency, factor V Leiden and factor II 20210A mutations, are almost all only venous. Vessels of all sizes may be affected, and the vascular pathological appearance has consistently been of bland occlusion without inflammatory infiltrates.[28]

In the venous circulation, thrombosis of the deep veins of the lower extremities has been reported most frequently.[29] They are often recurrent and may be accompanied by pulmonary embolism. It has been estimated that up to 19% of patients with deep-vein thrombosis and/or pulmonary thromboembolism have APS.

Recurrent pulmonary emboli or pulmonary veno-occlusive disease may be cause of pulmonary hypertension. Other reported venous sites of thrombosis include the axillary, ocular, renal, hepatic and sagittal veins, and the inferior vena cava. The APS is now considered one of the most frequent causes of the Budd–Chiari syndrome.[30] APA have been implicated in the development of adrenal vein thrombosis leading to adrenal insufficiency. Venous events usually occur at single sites and they can recur at the same or different sites, months or years apart.

Arterial thromboses are a major feature of the APS. As with venous thrombosis, arterial events usually occur at single sites and can recur months or years later. Occlusion of the intracranial arteries has been reported most frequently, with the majority of patients presenting with stroke or transient ischaemic attacks. However, cerebral infarctions may be silent. MRI scans may show changes that vary from single lesions to multiple, widely scattered infarcts (Figure 120.1). In some patients, untreated recurrent cerebral thrombosis can lead to multi-infarct dementia and cognitive impairment has been prominent in the presentation of some patients with the APS.[31] APA are now recognized as an important aetiological factor and may be present in 7% of all patients who have suffered a stroke. They should be sought especially in young patients with strokes, where they may account for up to 18%. Since emboli from heart valve vegetations may be responsible for cerebral infarction, it is advisable to perform echocardiograms on patients with APS who present with transient ischaemic attacks or brain infarction. Other arterial thromboses are less frequent, involving the retina, coronary, mesenteric, and peripheral arteries.[29] The clinical presentation depends on the anatomic site occluded.
Renal involvement in APS was first described in 1992.[32] Glomerular thrombotic microangiopathy is the most characteristic finding in APS nephropathy, albeit not exclusive of this syndrome, usually presenting with the triad of hypertension, proteinuria, and renal failure. Other histological lesions include fibrous intimal hyperplasia, focal cortical atrophy, and arterial occlusions have also been described.[33] Refractory hypertension secondary to renal artery stenosis can be also found.[34]

Pregnancy complications

Recurrent spontaneous pregnancy losses are one of the most consistent complications of the APS. Losses can occur at any stage of pregnancy, although miscarriages associated with APA are strikingly frequent during the second and third trimester (about 50% of cases). This differs from the pattern of pregnancy loss in the normal population, which usually occurs during the first trimester and is most often due to non-immunological factors: that is, morphological or chromosomal abnormalities. The rate of miscarriage in patients positive for APA is still uncertain, although testing for this antibody is becoming a routine investigation in women with recurrent miscarriages. Fewer than 2% of apparently normal pregnant women have either anti-cardiolipin antibody or lupus anti-coagulant in any titre, and less than 0.2% have high titre antibody. Hence, screening normal pregnant women has little value. Previous pregnancy history is of importance in determining the significance of a positive laboratory test for APA. It has been estimated that if a patient with lupus has a positive lupus anti-coagulant or at least moderate levels of IgG anti-cardiolipin antibodies, the risk of spontaneous miscarriage during the first pregnancy is 30% and if she has a history of at least two spontaneous miscarriages, the risk is 70% during the following pregnancy.

The risk of fetal loss is directly related to the antibody type and titres. A recent meta-analysis including 25 studies showed that lupus anti-coagulant has the strongest association with recurrent fetal losses before 24 weeks of gestation—odds ratio (OR) 7.79, 95% confidence interval (CI) 2.30–26.45—although it was not possible to analyse its association with miscarriages before 13 weeks.[35] IgG anti-cardiolipin antibodies (aCL) were associated with both early (OR 3.56, 95% CI 1.48–8.59) and late recurrent fetal losses (OR 3.57, 95% CI 2.26–5.65), women with moderate to high titres showing increased risk (OR 4.68, 95% CI 2.96–7.40). IgM aCL were also associated with late recurrent fetal losses (OR 5.61, 95% CI 1.26–25.03). On the other hand, no relationship was found between anti-β2GP1 and recurrent miscarriages (OR 2.12, 95% CI 0.69–6.53).

Despite the clear relation between APA and obstetric morbidity, it is not possible to predict which women will develop complications in pregnancy. However, an adverse previous obstetric outcome, a history of thrombosis, and triple positivity for lupus anti-coagulant, anti-cardiolipin and anti-β2-glycoprotein I antibodies have been identified as high-risk predictors.[36,37] In pregnancies that do not end in miscarriage or fetal loss, there is still a high incidence of intrauterine growth restriction, placental abruption, and premature delivery.

Other manifestations

Thrombocytopenia is common in patients with APA, though rarely severe enough to cause haemorrhage. The platelet count often

Fig. 120.1 MRI scan showing cerebral infarctions.

remains stable for many years; then, for reasons that are often obscure, the count drops, sometimes catastrophically. Occasionally, patients with APS may present only with severe thrombocytopenia and later develop pregnancy loss or thrombosis. This form of presentation was observed in a very small number of our patients with the syndrome.[38] Some patients with APA and thrombocytopenia also develop haemolytic anaemia with positive direct Coombs' test, a combination known as Evans' syndrome.

Epilepsy and chorea are less frequent manifestations of the APS and have, intriguingly, been seen to improve in some patients treated with anti-coagulants. Transverse myelopathy, though rare, has been strongly associated with the presence of APA.[39] However, more recent studies put such association into question.[40] Occasionally, in some patients with bizarre, transient/recurrent neurological signs and cerebral lesions resembling multiple sclerosis, APA have been detected in the absence of other immunological abnormalities. Its recognition is important as anti-coagulation therapy may be effective in these patients.[41]

Migraine is a common finding in patients with the APS, and often predates the diagnosis by many years. However, several prospective studies have not demonstrated a significant statistical association between migraine headaches and the presence of APA.[38]

Heart valve disease is strikingly associated with APA.[42] In some cases, this is due to a combination of valvular thrombosis and degeneration. The mitral valve is the most frequently affected, followed by the aortic valve. Insufficiency is more common than stenosis. Most patients with heart valve disease associated with APA are asymptomatic, though severe valvular dysfunction requiring surgical valve replacement has been reported. Emboli from sterile valvular vegetations can cause multiple cerebral lesions.[43] Large intracardiac thrombosis associated with APA can mimic atrial myxoma.

One of the most striking physical signs in patients positive for APA is livedo reticularis (Figure 120.2), sometimes widespread, sometimes subtle, for example, confined to a small area on the back of the wrist. Many cases of Sneddon's syndrome, defined as the clinical triad of stroke, livedo reticularis, and hypertension, may represent undiagnosed APS. More dramatic skin manifestations associated with vascular thrombosis include widespread skin ulceration, notably in the lower extremities (Figure 120.3). Clinically, some patients with APA may develop nail splinter haemorrhages and clubbing,

Fig. 120.3 Skin ulceration associated with vascular thrombosis.

posing major diagnostic difficulties, in those with heart valve disease, in differentiating from bacterial endocarditis.

Avascular necrosis of bone is an uncommon complication in lupus patients and clearly associated with high steroid dosage. We have noted an increased risk of avascular necrosis in individuals positive for APA, possibly as a result of small arterial occlusions, notably of the head of the femur.

Many patients with APS seem to develop widespread arteriopathy. The systemic narrowing of major arteries is similar in many respects to the widespread endarterial disease seen in some patients after heart–lung transplantation. Thus, APA might be associated with accelerated vascular disease, including atherosclerosis.[18]

Definition and classification criteria

An international consensus statement on classification criteria for definite APS was first published after a workshop in Sapporo, Japan, in 1998.[44] These criteria have recently been updated.[13] At least one clinical manifestation such as vascular thrombosis or pregnancy morbidity, together with positive laboratory tests, including lupus anti-coagulant, anti-cardiolipin and anti-β2-glycoprotein I antibodies, detected at least twice 12 weeks apart, are necessary to fulfil the classification criteria (Box 120.4). Other features of APS such as thrombocytopenia, haemolytic anaemia, transient cerebral ischaemia, transverse myelopathy or myelitis, livedo reticularis, cardiac valve disease, multiple sclerosis-like syndrome, chorea, and migraine were felt by the workshop to not have as strong an association and were excluded as classification criteria. This should not deter the clinicians from making the diagnosis or administering therapy if other causes of such features have been excluded.

Many of the patients reported to have the syndrome have lupus and can be regarded as having secondary APS. Some patients do not have any underlying systemic disease. These patients may be regarded as having primary APS. For research and classification purposes, the term 'primary' is useful, although there appear to be few differences in complications related to APA or in antibody specificity in the presence or absence of SLE.[29] Although some patients with primary APS progress to SLE, most do not show such progression.

Fig. 120.2 Livedo reticularis.

Box 120.4 Criteria for the classification of definite anti-phospholipid syndrome

Clinical criteria

1. Vascular thrombosis

   One or more clinical episodes of arterial, venous, or small-vessel thrombosis, in any tissue or organ.
   Thrombosis must be confirmed by objective validated criteria (i.e. unequivocal findings of appropriate imaging studies or histopathology). For histopathological confirmation, thrombosis should be present without significant evidence of inflammation in the vessel wall.

2. Pregnancy morbidity

   (a) One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation, with normal fetal morphology documented by ultrasound or by direct examination of the fetus, *or*
   (b) One or more premature births of a morphologically normal neonate before the 34th week of gestation because of: (i) eclampsia or severe pre-eclampsia defined according to standard definitions or (ii) recognized features of placental failure, *or*
   (c) Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation, with maternal anatomic or hormonal abnormalities and paternal and maternal chromosomal causes excluded.
   In studies of populations of patients who have more than one type of pregnancy morbidity, investigators are strongly encouraged to stratify groups of subjects according to (a), (b), or (c) above

Laboratory criteria

1. Lupus anti-coagulant present in plasma, on 2 or more occasions at least 12 weeks apart, detected according to the guidelines of the International Society on Thrombosis and Hemostasis (Scientific Subcommittee on LA/phospholipid-dependent antibodies).

2. Anti-cardiolipin antibody of IgG and/or IgM isotype in serum or plasma, present in medium or high titres (i.e. >40 GPL or MPL, or greater than the 99th percentile), on 2 or more occasions, at least 12 weeks apart, measured by a standardized ELISA.

3. Anti-β2 glycoprotein I antibody of IgG and/or IgM isotype in serum or plasma (in titres greater than the 99th percentile), present on 2 or more occasions, at least 12 weeks apart, measured by a standardized ELISA, according to recommended procedures.

Note: Definite anti-phospholipid syndrome may be diagnosed if at least one of the clinical criteria and at least one of the laboratory criteria are met. Modified from Miyakis et al.[13]

A minority of patients with the APS present with an acute and devastating syndrome characterized by multiple simultaneous vascular occlusions throughout the body, often resulting in death. This syndrome, termed 'catastrophic APS', is defined by the clinical involvement of at least three different organ systems over a period of days or weeks with histopathological evidence of multiple occlusions of large or small vessels.[45] Although the same clinical manifestations seen with primary and secondary APS occur as part of catastrophic APS, there are important differences in prevalence and in the calibre of the vessels predominantly affected.

Ischaemia of the kidneys, bowels, lungs, heart and/or brain are most frequent, but rarely adrenal, testicular, splenic, pancreatic, or skin involvement have been described. Occlusion of small vessels (thrombotic microangiopathy) is characteristic, resulting in symptoms related to dysfunction of the affected organs. Depending on the organs involved, patients may present with hypertension and renal impairment, acute respiratory distress syndrome (ARDS), alveolar haemorrhage and capillaritis, confusion and disorientation, or abdominal pain and distension secondary to bowel infarction. Precipitating factors of catastrophic APS include infections, surgical procedures, withdrawal of anti-coagulant therapy, and the use of drugs such as oral contraceptives.

Differential diagnosis

Careful family and personal history and physical examination of patients with unexplained thromboses are of the utmost importance as thrombotic events and, notably, venous thromboses often have explanations other than APS. The occurrence of other features of APS, such as livedo reticularis or obstetric complications, should alert the clinician. Vascular risk factors are frequent in patients with APS and thrombosis, thus its presence should not be a reason for not pursuing the diagnosis.

One of the most striking features of APS is the frequent observation of life-threatening thrombosis in the setting of thrombocytopenia. A number of other conditions can result in thrombocytopenia and thrombosis, including heparin-induced thrombocytopenia and thrombotic thrombocytopenic purpura.

Heparin-induced thrombocytopenia develops in 1–5% of patients receiving standard heparin and less frequently in those who receive low-molecular-weight preparations. This is due to the presence of an antibody which binds to platelet factor 4 and heparin. Approximately 10–20% of patients with substantial heparin-induced thrombocytopenia have venous or arterial thrombosis, including pulmonary, cardiac, and cerebral thrombosis. Thrombocytopenia typically develops approximately a week after exposure in persons not previously treated with heparin and sooner in those with previous exposure.

Thrombotic thrombocytopenic purpura is associated with neurological syndromes, but it is chiefly a microvascular disorder and confusion, seizures, or changes in the level of consciousness are more frequent than isolated, cerebral, large-vessel thrombosis. Microangiopathic haemolysis with evidence of schistocytes in peripheral blood is usually a prominent finding. Elevation in the serum level of lactate dehydrogenase is found in nearly all cases and is a sensitive marker of the severity of the disorder.

APS has been identified as a cause of first, second, and third trimester pregnancy losses as well as intrauterine growth restriction and pre-eclampsia. One of the major advances in the field of thrombophilia in the last few years has been the recognition that other thrombophilic states, such as factor V Leiden mutation and prothrombin 20210A mutation, also predispose to second and third trimester losses, as well as intrauterine growth restriction and pre-eclampsia.[46] It is important when considering the late pregnancy morbidity associated with APA to check that the history concurs

with that of placental insufficiency. We have a number of women referred to our clinic with the diagnosis of APS on the basis of pregnancy loss where APA were an incidental finding. These women have proved to have pregnancy loss due to other causes such as premature labour secondary to an incompetent cervix.[26] Thus, history-taking and obtaining the post-mortem findings in previous pregnancy losses are very important.

Treatment

Given the diversity of clinical presentations and medical specialties involved, it is not surprising that treatment of APS has long been subject of intense debate. Fortunately, a consensus document has recently been agreed.[47] Some of these recommendations are supported by weak evidence and in others the consensus was not complete; however, these guidelines are a valuable tool for clinicians in order to decide therapy for individual patients with APS. A summary of recommendations is shown in Box 120.5.

Box 120.5 Recommendations for primary and secondary thromboprophylaxis in individuals with anti-phospholipid antibodies

General measures for anti-phospholipid antibody carriers

- A strict control of cardiovascular risk factors should be accomplished in all individuals with a high-risk antiphospholipid antibody profile,[a] irrespective of the presence of previous thrombosis, concomitant SLE or additional APS features
- All APA carriers should receive thromboprophylaxis with usual doses of LMWH in high-risk situations, such as surgery, prolonged immobilization, and puerperium

Primary thromboprophylaxis in SLE patients with anti-phospholipid antibodies

- In patients with SLE and positive lupus anti-coagulant or isolated persistent anti-cardiolipin antibodies at medium–high titres, primary thromboprophylaxis with hydroxychloroquine ± low-dose aspirin is recommended

Primary thromboprophylaxis in APA-positive individuals without SLE

- In non-SLE individuals with APA and no previous thrombosis, long-term primary thromboprophylaxis with low-dose aspirin is recommended in those with a high-risk APA profile, especially in the presence of other thrombotic risk factors

Secondary thromboprophylaxis

- Patients with either arterial or venous thrombosis and APA who do not fulfil criteria for APS should be managed in the same manner as APA-negative patients with similar thrombotic events
- Patients with definite APS and a first venous event should receive oral anti-coagulant therapy to a target INR 2.0–3.0
- Patients with definite APS and arterial thrombosis should be treated with warfarin at an INR >3.0 or combined anti-aggregant–anti-coagulant therapy (INR 2.0–3.0)

- The patient's bleeding risk should be estimated before prescribing high-intensity anti-coagulant or combined anti-aggregant–anti-coagulant therapy
- Non-SLE patients with a first non-cardioembolic cerebral arterial event, with a low-risk APA profile[b] and the presence of reversible trigger factors could individually be considered candidates for treatment with antiplatelet agents.

Duration of treatment

- Indefinite antithrombotic therapy is recommended in patients with definite APS and thrombosis
- In cases of first venous event, low-risk APA profile[b] and a known transient precipitating factor, anti-coagulation could be limited to 3–6 months.

Refractory and difficult cases

- In patients with difficult management due to recurrent thrombosis, fluctuating INR levels, major bleeding or at a high risk for major bleeding, alternative therapies could include long-term LMWH, hydroxychloroquine, or statins.

APA, anti-phospholipid antibody; APS, anti-phospholipid syndrome; INR, international normalized ratio; LMWH, low-molecular-weight heparin; SLE, systemic lupus erythematosus.
[a]High-risk APA profile: lupus anti-coagulant positivity, triple positivity (lupus anti-coagulant + anti-cardiolipin + anti-β2-glycoprotein I antibodies), isolated persistently positive anti-cardiolipin antibodies at medium–high titres.
[b]Low-risk APA profile: isolated, intermittently positive anti-cardiolipin or anti-β2-glycoprotein I at low-medium titres.
Modified from Ruiz-Irastorza et al.[47]

Primary thromboprophylaxis

Whether prophylactic treatment is indicated in patients with APA who have no history of thrombosis reminds an open question. No study has clearly demonstrated the benefit or harm of active therapy against placebo. General measures to control cardiovascular risk factors are recommended for all patients with APA. In fact, the most important prophylactic therapy may be the avoidance or reduction of smoking, obesity, high blood pressure, hypercholesterolaemia, and oestrogen-containing oral contraceptive pills or oestrogen replacement therapy.

SLE is considered by itself a risk factor for thrombosis. Thus, all patients with lupus and positive lupus anti-coagulant (alone or in combination with other APA) or with isolated persistent anti-cardiolipin antibodies at medium–high titres should be given primary thromboprophylaxis.[47] Hydroxychloroquine has shown protection against thrombosis in lupus patients, including those with APA.[48] Aspirin may also be effective in this setting.[49] However, no study has investigated whether combination therapy offers additional protection. Thus, given the general recommendation of hydroxychloroquine therapy in lupus patients, the addition of low-dose aspirin should be decided on an individual basis.

In asymptomatic carriers of APA without lupus, the decision regarding thromboprophylaxis should be best based on the APA profile. Aspirin thromboprophylaxis is suggested for those with a high-risk profile (lupus anti-coagulant, particularly triple-positive individuals), although the efficacy of this regime has not been

demonstrated.[14,50] The presence of concomitant vascular risk factors should count in favour of starting low-dose aspirin. On the contrary, previous obstetric manifestations are not definitely associated with a higher thrombotic risk.[47]

The addition of low intensity oral anti-coagulation (international normalized ratio, INR~1.5) to low-dose aspirin has been tested in a recent randomized controlled trial (RCT).[51] This regime has not been more effective and, on the contrary, is poorly tolerated by the patients.

Prevention of recurrent thrombosis

There is good evidence that APS patients with thrombosis will be subject to recurrences, and these can be prevented by long-term antithrombotic therapy.[52,53] However, two important questions arise in this setting: (1) Should patients with APS receive the same therapy as the general population with similar manifestations? and (2) Should arterial and venous events be treated differently?

Two RCTs have compared high (target INR 3.0–4.0) with standard (target INR 2.0–3.0) intensity of anti-coagulation for the secondary thromboprophylaxis in patients with APS.[54,55] None of them found significant differences in efficacy or side effects between both regimes. However, given the overrepresentation of patients with first venous thromboembolism in both trials, the recommendation of warfarin therapy to a target INR 2.0–3.0 can only be extended to that subgroup.

Regarding arterial events, recommendations are more disputed. The APA and Stroke Study (APASS) supported the view that patients with stroke and APA not fulfilling classification criteria should be best treated as the general population.[56] On the other hand, patients with definite APS having arterial and/or recurrent events are at a higher risk for recurrences, even when treated with oral anti-coagulation to a target INR 2.0–3.0. As a whole, recurrences are very infrequent among patients effectively receiving oral anti-coagulation to an INR 3.0–4.0.[57] A small Japanese RCT has shown that combined therapy warfarin (target INR 2.0–3.0) plus low-dose aspirin is more effective and as safe as warfarin in monotherapy.[58] The current consensus recommends that patients with APS and arterial disease be treated with warfarin to a target INR of more than 3.0 or combined anti-coagulant–anti-aggregant therapy.[57]

Concerns exist over the validity of the INR in the control of oral anti-coagulant dosing if lupus anti-coagulant is present. The inhibitor occasionally increases the prothrombin time (PT) and, in turn, the INR, which may thus not reflect the true degree of anti-coagulation. This phenomenon seems to be more likely when certain recombinant thromboplastin reagents are used and can usually be circumvented by careful selection of the thromboplastin to be used for the PT test.[59]

High-intensity oral anti-coagulation therapy carries an inevitable risk of serious haemorrhage. In APS, serious bleeding complications may occur, but their risk is not higher than that observed in other thrombotic conditions warranting oral anti-coagulation.[60]

The role of steroids and immunosuppressive drugs in treatment of patients with APA and thrombosis is uncertain. Such drugs have severe side effects when given for prolonged periods and APA are not always suppressed by these agents. The use of these drugs is probably justified only in patients with repeated episodes of thrombosis despite adequate anti-coagulant therapy, that is, catastrophic APS. In this rare but life-threatening condition, combination therapy with heparin, steroids, and immunoglobulins, or plasmapheresis is recommended.[45]

The use of intra-arterial fibrinolysis has been described to be of benefit in patients with acute myocardial infarction associated with APA. Prostacyclin analogues (Iloprost) were also successfully used in patients with severe ischaemic necrotic toes associated with APS. Elective pulmonary thromboendarterectomy can be very effective and life-saving in selected patients with chronic thromboembolic pulmonary hypertension.

Prevention of pregnancy loss

The management of pregnancy in women known to have APS is also the subject of much debate and, as yet, there have been few RCTs. Antithrombotic therapy is the preferred treatment. Glucocorticoids and immunoglobulins have not demonstrated additional benefit compared with aspirin/heparin. Moreover, glucocorticoids may cause serious pregnancy complications, such as prematurity and hypertension.[36]

For therapeutic purposes during pregnancy, women with APS may be categorized into one of three groups: (1) those with recurrent early miscarriage (pre-embryonic or embryonic); (2) those with one or more prior fetal deaths (>10 weeks' gestation) or prior early delivery (<34 weeks' gestation) due to severe pre-eclampsia or placental insufficiency; and (3) those with previous thrombosis. Proposed recommendations for each of these groups are shown in Box 120.6.

Three RCTs[61–63] and one trial with consecutive treatment assignment[64] have compared low-dose aspirin alone vs combination therapy with heparin in women with APS, many of them with predominantly recurrent early miscarriage. In two studies the proportion of successful pregnancies significantly improved on adding unfractionated heparin to low-dose aspirin,[61,64] while the two other randomized trials, both using low-molecular-weight heparin (LMWH), found no differences.[62,63] It is noteworthy that the heterogeneity in the results is attributable to outcomes in women receiving aspirin only, who did strikingly worse in the two former studies. Remarkably, several observational studies have reported 79–100% pregnancy success rates with low-dose aspirin alone in this subgroup of women.[36] Despite the general recommendation of combined therapy with aspirin and heparin for all women with

Box 120.6 Recommended treatment of anti-phospholipid syndrome in pregnancy

APS with poor obstetric outcomes

Recurrent early (pre-embryonic or embryonic) miscarriage

◆ Low-dose aspirin *alone, or plus*:

◆ LMWH at thromboprophylactic doses

Fetal death (>10 weeks' gestation) or prior early delivery (<34 weeks' gestation) due to severe pre-eclampsia or placental insufficiency

◆ Low-dose aspirin, *plus*:

◆ LMWH at thromboprophylactic doses

APS with thrombosis

◆ Low-dose aspirin, *plus*:

◆ LMWH

APS, anti-phospholipid syndrome; LMWH, low-molecular-weight heparin.

obstetric APS, we believe that the option of monotherapy with aspirin cannot be discarded beforehand in the subgroup of women with recurrent early miscarriages. The selection of therapy should be decided on an individual basis, with pros and cons being discussed with the patient in the preconceptional counselling visit.

Women with APS and fetal losses have been studied much less extensively. However, fetal loss being a more severe and specific manifestation of the APS, combination therapy with aspirin and heparin is recommended by most authors.[36] When used for obstetric purposes, aspirin is best started before conception. No differences have been found between unfractionated heparin and LMWH combined with aspirin, thus any of them can be given, starting once pregnancy has been confirmed. Many centres are now using LMWH, since it has increased bioavailability and a longer half-life and can therefore conveniently be given once daily.

Patients with APS who have suffered a previous thrombosis need a different approach. In this group, low-dose aspirin and therapeutic dose heparin or LMWH at anti-coagulant doses are recommended.[36] The change from warfarin to heparin should be achieved prior to 6 weeks gestation to avoid warfarin embryopathy. Heparin does not cross the placenta and is not known to cause any adverse fetal effects. However, long-term use of heparin in pregnancy has been associated with osteoporosis in the mother. LMWH seems safer in this setting.[65] Heparin should be continued intrapartum and postpartum until women are rewarfarinized. Both warfarin and subcutaneous heparin are compatible with breastfeeding.

Antithrombotic coverage of the postpartum period is recommended also in women with APA and no previous thrombosis. The current recommendation is for prophylactic-dose heparin or LMWH, although the extension is variable from 1 to 6 weeks depending on the presence of additional risk factors.[66]

Most authorities agree that one of the main reasons for the improving outcome of APS pregnancies is closer obstetric surveillance. Viable anti-phospholipid pregnancies have a high incidence of obstetric and fetal complications, including intrauterine growth restriction, prematurity, and pre-eclampsia; hence, close monitoring and timely delivery may improve fetal outcome in these women. Preconception counselling is essential in order to estimate the chance of both fetal and maternal problems and to provide the patient with reliable information regarding her specific risk for complications and the expected management plan. Despite the good prognosis achieved with correct management, patients must also know that there is an increased risk of serious complications (miscarriage, thrombosis, fetal death, prematurity, pre-eclampsia). A complete set of APA and autoantibodies should be available before planning pregnancy. Women who have recently had thrombotic events, particularly stroke, should be advised to delay pregnancy.

All women with APS should be managed in a combined high-risk medical–obstetric clinic throughout the whole pregnancy. The general schedule includes more frequent visits as pregnancy progresses. Regular monitoring of blood pressure and urine analysis and timely Doppler studies of the uteroplacental circulation are essential part of the optimal care of these women.

Management of other manifestations of anti-phospholipid syndrome

Mild thrombocytopenia with platelet counts between 100 000 and 150 000/mm^3 are common in patients with APA and usually does not require intervention. In a minority of cases it can be severe.

In these cases, corticosteroid therapy should be the treatment of choice. Several drugs have been used successfully to treat steroid-resistant thrombocytopenia in APS patients, including aspirin, intravenous gammaglobulin infusion, danazol, chloroquine, and dapsone. Splenectomy has been safely and successfully performed in some patients.[67]

Transverse myelitis and multiple sclerosis-like illnesses have been described in APS. Anecdotally, most clinicians dealing with APS or lupus with APS have seen patients initially labelled as 'probable multiple sclerosis'. Certainly the ischaemic changes produced by the APS in white matter may be indistinguishable on MRI from those of multiple sclerosis. Therefore, in some of these patients with multiple sclerosis-like illness, the importance of a treatable differential diagnosis—APS—cannot be underestimated.

There is a high prevalence of heart valve lesions in patients with APA. In some cases, valvular damage may result in significant haemodynamic compromise requiring surgery. Both biological and mechanical valves have been implanted with favourable results, although both bleeding and thrombotic complications have been reported in about one-half of the patients.[68]

It is important to distinguish the thrombotic microangiopathy found in some patients with APS from inflammatory forms of renal involvement. The physician will face this problem mainly in patients with SLE, and management with oral anti-coagulation or steroids will depend on the histological findings. The outcome of kidney transplantation in patients with SLEs and endstage renal failure appears to be similar to that of patients with renal failure from other causes. However, the presence of APA seems to be associated with a poorer prognosis. Post-transplant thromboembolic phenomena, recurrence of thrombotic microangiopathy in the graft despite anti-coagulation, and thrombosis of the graft's renal vein have all been reported.[69]

Prognosis

The long-term prognosis in patients with APS is primarily influenced by the risk of recurrent thrombosis. Although there are a number of studies of prognostic factors in SLE, only a few have addressed the possible role of APA. Lupus patients with APS are reported to accrue more damage and have higher mortality rates. Two studies have found that the prognosis of patients with primary APS is poor.[70,71] One-third of patients had organ damage and one-fifth were unable to perform everyday activities. A recent cohort study of 135 patients with APS, with concurrent systemic lupus in one-third of them, has shown that 29% of patients accrued damage and 5 died after a mean follow-up of 7.5 years. Arterial thrombosis and the presence of lupus were associated with an adverse prognosis.[72]

Anti-phospholipid syndrome in childhood

There have been relatively few reports of clinical associations of APA in children and the spectrum of clinical findings remains at present unknown. APA in childhood-onset SLE (see Chapter 119) have been described in several small clinical reports, occurring in one-third of the patients. The clinical manifestations are similar to those encountered in adults, particularly recurrent deep-vein thrombosis, strokes, and chorea. Devastating thrombotic complications of the APS in children have been reported, including digital

ischaemia and myocardial infarction. The risk of maternal transmission of APA to infants during pregnancy is unknown, though there have been several case reports of thrombotic events in neonates of mothers with the APS.[73]

There is general agreement that long-term anti-coagulation is needed in children who experienced an anti-phospholipid-related thrombosis to prevent recurrences, but there is no consensus about the duration and intensity of this therapy. Given that the risk of recurrence might be lower in anti-phospholipid-positive children compared with adults, and considering the higher risk of haemorrhage during play and sports, it was suggested that intermediate-intensity anti-coagulation therapy targeted at an INR of 2.0–2.5 be performed in paediatric patients who have experienced an anti-phospholipid-related thrombosis.[74]

Systemic sclerosis

Christopher P. Denton and Pia Moinzadeh

Introduction

'Scleroderma', a word meaning hard skin, is a part of many syndromes including localized and systemic scleroderma. Most of these disorders can occur at any stage of life, although the pattern of scleroderma occurring in childhood is different from that in the adult (see below). Scleroderma or systemic sclerosis has been confused with other diseases that have cutaneous features resembling it, for example scleromyxoedema, scleroedema, and primary amyloidosis (see Box 121.1). In this chapter we focus on systemic sclerosis (SSc) and localized scleroderma.

Systemic sclerosis

Systemic sclerosis (SSc) is a heterogeneous and rare, multisystem connective tissue disease, based on autoimmunological processes,

---

Box 121.1 Spectrum of scleroderma and scleroderma-like syndromes

- Systemic sclerosis
- Localized scleroderma (morphoea)
- Eosinophilic fasciitis
- Sclerodermatous genodermatoses (e.g. progeria, acrogeria, Werner's disease)
- Acrodermatitis chronic atrophicans
- Eosinophilia-myalgia syndrome
- Scleredoema adultorum Buschke
- Scleredoema diabeticorum
- Scleromyxeodema
- Sclerodoema amyloidosis
- Nephrogenic systemic fibrosis
- Porphyria cutanea tarda
- Sclerodermatous chronic graft-vs-host disease
- Scleroderma-like lesions in malignancies (paraneoplastic scleroderma)
- Lichen sclerosus et atrophicans

---

vascular endothelial cell damage and an extensive activation of fibroblasts, causing a massive production and accumulation of extracellular matrix proteins and collagen. It is characterized by a large individual variability in the extent of skin and organ involvement, as well as in disease progression and prognosis.

Epidemiology

Systemic sclerosis (SSc; scleroderma) is an uncommon disorder and virtually all of the descriptive epidemiology is derived from retrospective or prospective reviews of patients attending hospitals or institutions serving a defined denominator population. Variations in incidence and prevalence rates of SSc patients seem to appear due to differences in disease definition/characterization, geographic differences, and methods of individual case ascertainment. Also the fact that patients are nowadays identified earlier due to better interdisciplinary medical care, increased awareness by physicians, and also due to improved survival rates because of growing treatment options, has changed incidence and prevalence rates in SSc patients. A summary of salient epidemiological data is given in Table 121.1.

Published data about incidence rates reported variations from 0.1 to 4.3 patients per 100 000 inhabitants, which is also true for the prevalence rates, which have risen from 1.5 to 34 patients per

Table 121.1 Variations in prevalence and incidence rates depending on study and country

Study	Incidence (patients per 100 000 per year)	Prevalence (patients per 100 000)
North-west Greece 1981–20024	0.11	1.54
Pennsylvania 1978–198210	0.18	No data
Tokyo 19882	No data	2.1–5.3
South Australia 1993–20027	0.15	2.14
Britain 1985–19868–9	0.37	3.08
North-east England 200081	No data	8.80
Detroit, USA 1989–19911	1.9	27.6
North-west Spain 1988–20065	2.3	27.7
North Italy 1999–20076	4.3	34.0

100 000 inhabitants per year.[1–10] SSc seem to occur more frequently in the United States than in Europe (north–south gradient with lower rates in northern Europe), the United Kingdom, and Japan.[11] Currently the best estimate for United Kingdom prevalence overall is approximately 120 per million of the population. The formation of these geographical clusters may be due to genetic and/or environmental exposures, necessary for disease susceptibility, which occurs infrequently in the population. For example, clustering has been described close to two major international airports in the United Kingdom,[12] for a variety of autoimmune rheumatic diseases in the Republic of Georgia,[13] and there is a clearer cluster of systemic sclerosis in a region of Italy close to Rome.[14] In North America the highest prevalence has been observed among a population of Choctaw native Americans in Oklahoma.[15] The prevalence in these full-blooded Choctaws was 469 cases/100 000 (based on 14 cases) with a majority suffering from diffuse SSc and anti-topoisomerase antibodies.[15] There is growing evidence for a genetic basis for this high prevalence and ongoing studies are defining this in detail.[16] Scleroderma has a female excess (4F:1M overall, and in the childbearing years 15F:1M). Interestingly the peak of the female:male ratio in the major autoimmune connective tissue diseases, including SSc, is between the late teens and forties and some reports hypothesized that this is the time with the greatest changes in hormone levels.[17] Finally, again in contrast to other autoimmune rheumatic diseases, a growing number of environmental agents have been implicated in SSc.

Aetiopathogenesis

SSc is almost certainly multifactorial, involving genetic and environmental factors, and it is clear that a combination of genetic or environmental factors is responsible for the susceptibility to develop the disease.[18] SSc occurs mostly in females and gender may be one of the strongest genetic markers. There are several lines of evidence indicating familial or genetic predisposition to SSc. Besides gender, racial variations are also reported with a higher and also a more severe form of this disease in the black population. Furthermore, 50% of black women with scleroderma have the diffuse form, compared to only 25% of white women with SSc.[19]

Genetic factors

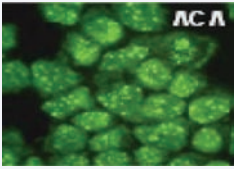
Studies of families with a member suffering from SSc have shown that another SSc case occur more frequently in these SSc-positive families (1.6%) in comparison to the general population (0.026%)[20] with a 13–14-fold increased relative risk for a first-degree relative.[20–21] Some authors have hypothesized that the clustering of SSc within families may also be associated with shared environmental factors, shared genes, or interactions between them (Table 121.2).[22]

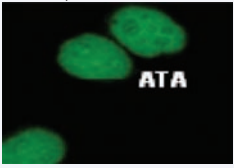
Many centres worldwide have observed abnormal frequencies of the major histocompatibility complex (MHC) antigens associated with SSc. As one of the primary roles of MHC class II molecules is the presentation of processed antigen to the T-cell receptor (TCTR) on helper T lymphocytes resulting in an antigen-specific immune response, autoantibody subsets in scleroderma might be expected to show correlations with class II MHC polymorphism and indeed they do, although again they appear to be complex. Haplotypes of *DRB1*11-DQB1*0301* seem to be associated with

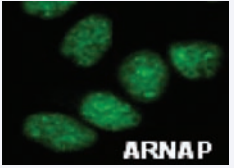
anti-topoisomerase antibodies in white Europeans.[23–24] Anti-centromere antibody was reported to be associated with *HLA DRB1*01*, *DQB1*0501*, and *DQB1 26 epi*,[22,25] while anti-RNA polymerase antibodies has been reported to be associated with *DRB1*0404*, *DRB1*11*, and *DQB1*03*.[23] Several studies suggest an association of *HLA DRB1*1302*, *DQB1*0604/0605* haplotypes with anti-fibrillarin positive patients,[26] while *HLA SRB1*0301* occurs in patients with anti-Pm-Scl antibodies.[27]

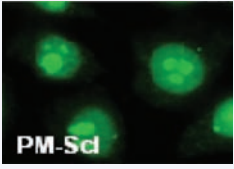
Studies coping with the whole-genome microarray expression studies of skin biopsies and circulating blood cells support the involvement of multiple and complex pathways in the development of SSc.[21]

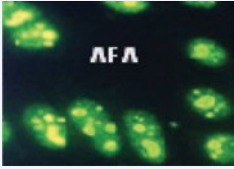
These studies identified several genes involved in immune function, such as *IRF5* (interferon regulatory factor 5),[28] *CTGF*, [29] *BANK1*,[30] and *STAT4* (signal transducer and activator of transcription 4), *CD247*, *PTPN22* (protein tyrosine phosphatase non-receptor type 22), which are all associated with an increased susceptibility to SSc (see Table 121.3).[31–33] Candidate gene studies have confirmed these findings by identifying single nucleotide polymorphisms (SNPs), again associated with susceptibility to SSc.

Increasingly, gene expression profiling in SSc plays a major role in detecting and confirming genetic alterations, analysing skin biopsies as well as peripheral blood of SSc patients in comparison to healthy controls. After clustering the gene expression signatures depending on their expression pattern, Milano et al. found distinct subgroups of signatures which arranged patients into four different groups with a more inflammatory pattern, with a fibroproliferative signature for limited and diffuse forms, and a group of healthy controls and some SSc patients classified with a normal-like signature.[34]










Environmental factors

SSc and scleroderma-like syndromes have been reported in association with numerous different environmental toxins and drugs, including solvents (vinyl chloride, benzene, toluene, epoxy resins), drugs (bleomycin, cardiopa, pentazocine, cocaine, docetaxel, metaphenylenediamine), and other miscellaneous substances.[35] Furthermore, scleroderma was reported to occur especially in men who worked underground as coal and gold miners. In male patients with silicosis who are older than 40 years of age, the likelihood of developing SSc is approximately 190 times greater than in males who were never exposed to silica, and 50 times higher than in males without silicosis but exposed to silica dust.[36] Whether silicone gel implants and other silicone products may play a role in the development of scleroderma has also been discussed, but a recent meta-analysis showed no evidence that they trigger SSc.[37] However, most epidemiological studies have failed to show a significant association. There is still a lack of large epidemiological studies that might reveal a significant role for toxins and drugs in the development of scleroderma.

Immune events

An increasing number of immune abnormalities are being reported in SSc and the designation of SSc as an autoimmune disease now has widespread support. Some of the clinical features of scleroderma bear similarities to other autoimmune disorders such as systemic lupus erythematosus (SLE), dermatomyositis, and rheumatoid arthritis (RA), and there are also patients who have overlap syndromes or who have sequential development of more

Table 121.2 Autoantibodies and clinical associations

Autoantibodies	Characteristics
Anti-centromere antibodies	◆ ACA antibodies together with Raynaud phenomenon has been reported to be predictive for the development of SSc ◆ Associated with the limited form of SSc, vasculopathy, and calcinosis cutis ◆ In later stages patients have a higher risk of developing an isolated pulmonary arterial hypertension ◆ In 20–30% overall, very specific for scleroderma, frequency varies depending on ethnic background ◆ In IIF pattern on HEp-2 cells show punctuate spots (speckled pattern) in the nucleolus ◆ Solid-phase ELISA used for routine diagnostics in the clinic
Anti-topoisomerase antibodies	◆ Associated with the diffuse form of SSc, as well as a higher risk for lung fibrosis, renal crisis, severe heart involvement and digital ulcers ◆ In approximately 40% in overall, frequency varies depending on ethnic background (28–70%) ◆ <10% of patients with lSSc carry this kind of autoantibody ◆ In IIF it shows a homogenous and nucleolar pattern ◆ Solid-phase ELISA used for routine diagnostics in the clinic
Anti-RNA polymerase antibodies	◆ Highly specific for SSc ◆ Anti-RNAP I and III coexist, while anti-RNAP II is very rare ◆ Associated with the diffuse form of SSc, as well as a higher risk for renal crisis ◆ Survival rates are better than in those patients with anti-topoisomerase antibodies ◆ Fine speckled and nucleolar pattern in IIF ◆ Solid-phase ELISA used for routine diagnostics in the clinic
Anti-PmScl antibodies	◆ In approximately 4–11% overall, frequency varies depending on ethnic background ◆ In approximately 25% of SSc patients with myositis overlap, but just in 2% with SSc alone ◆ Associated with the limited form of SSc, usually with no severe internal organ manifestations ◆ In IIF) it shows a homogenous and nucleolar pattern
Anti-fibrillarin antibodies	◆ In approximately 4–10% patients with SSc ◆ More frequently found in African-American patients ◆ These patients usually have a diffuse form of SSc with peripheral vasculopathy, pulmonary hypertension, and myositis ◆ Nucleolar pattern (clumpy) in IIF

ELISA, enzyme-linked immunosorbent assay; IIF indirect immunofluorescence; SSc, system sclerosis.
Reviewed by Hamaguchi.[82]

than one autoimmune rheumatic disease. There is considerable evidence that abnormalities in both humoral and cell-mediated immunity occur in SSc, although the precise importance of these immunological events in the pathogenesis remains uncertain. The lack of a generalized immune dysfunction in SSc suggests that the derangement of immune-cell dysfunction may be specific to certain antigens or cells.[38–39] The association of SSc with particular major HLA antigens and the close association of certain HLA alleles with scleroderma-specific antibodies is indirect evidence for T-cell involvement in SSc. There is considerable evidence for T-cell activation in SSc, including an increased ratio of circulating CD4+:CD8+ cells,[40–41] reflecting an increased number of CD4+ and/or a reduced number of CD8+ lymphocytes. Consequently increased serum levels of T-cell derived cytokines, i.e. interleukins IL-2, IL-4, IL-10, IL-13, and IL-17, have been observed in scleroderma patients.[42–43] It is known that T cells provide major stimuli for collagen synthesis in fibroblasts but depending on the type of T cells they have distinct roles in their influence on collagen production. The Th1 cells produce cytokines which are associated with the cellular immune response, including interferon-gamma (IFNγ), tumour necrosis factor alpha (TNFα), IL-1, IL-2, and IL-12, while the Th2 lymphocytes synthesize cytokines which are involved in the inflammatory processes of SSc, such as IL-4, IL-13, IL-5, IL-6, and IL-10. Another group of lymphocytes, namely the Th17 cells, produce cytokines (IL-17, IL-21, IL-22) which are involved in the inflammation but also regulation of processes[44–45] that are more frequently found in early stages of SSc, enhancing the production and deposition of extracellular matrix (ECM); see Table 121.4. Especially in SSc patients a predominance of Th2-polarized T cells have been found. Besides T cells, B cells are also found in involved skin. Several studies suggest that B cells are able to induce ECM production through secretion of IL-6 and tissue growth factor beta (TGFβ) and are involved in the production of autoantibodies (Figure 121.1, Table 121.4).

Table 121.3 Major non-HLA-associated systemic sclerosis susceptibility genes

Genes	Chromosome variant	Function
Innate immunity		
IRF5 *(Interferon regulatory factor 5)*	**7q32** rs2004640 rs2280714	◆ Central mediator of innate immunity ◆ Already found in several autoimmune diseases, such as SLE, Sjögren's syndrome, pernicious anaemia, RA as well as SSc ◆ Transcription factor with important role in the TLR signalling pathway ◆ Important in the activation of type I IFN genes ◆ Identified as potential risk factor for SSc; preferentially found in SSc patients suffering from the diffuse form with ATA positivity
T-cell differentiation and activation		
PTPN 22 *(Protein tyrosine phosphatase non-receptor type 22)*	**1p13.2** rs2476601	◆ Expressed in hematopoietic cells ◆ Acts as inhibitor of TCR signal transduction ◆ Reported to be associated with type I diabetes[83] as well as with RA, JIA, SLE, myasthenia gravis, generalized vitiligo, alopecia areata, and SSc (reviewed in[22]) ◆ Patients carrying the *620W* allele showed a significant correlation with ATA positive
STAT4 *(Signal transducer and activator of transcription 4)*	**2q32.3** rs7574865	◆ Relevant for directing Th cells to the proinflammatory Th1 and Th17 lineages, induced by IL-12, IL-23, and type 1 IFN, leading to production of IFN-γ and IL-17[84] ◆ rs7574865 T allele seem to be a risk factor for SSc susceptibility, especially for patients with ACA positivity
Immune signalling		
BANK1 *(B-cell scaffold protein with ankryn repeats)*	**4q24** rs3733197 rs10516487	◆ *BANK1* gene encodes a B-cell-specific scaffold protein with ankyrin repeats ◆ Acts as a substrate for LYN tyrosine kinase[85] ◆ Both SNPs (rs3733197 and rs10516487) were found to be connected with the diffuse form of SSc[32]
BLK/C8orf13 *(B lymphocyte kinase)*	**8p23–22** rs13277113	◆ B-cell specific gene ◆ Close association to ACA positivity
CD247	**1q22–23** rs2056626	◆ Encodes the TCRζ subunit (component of the TCR-CD3 complex) involved in receptor signalling ◆ Associations found for SSc and SLE[85] (new susceptibility locus for SSc)[33]

ACA, anti-centromere antibodies; ATA, anti-topoisomerase-1; IFN, interferon; JIA, juvenile idiopathic arthritis; RA, rheumatoid arthritis; SLE systemic lupus erythematosus; SNP, single-nucleotide polymorphism; SSc, systemic sclerosis; TCR, T-cell receptor; TLR, Toll-like receptor.
Reviewed by Dieude et al.[22]

An increased number of lymphokine-activated killer and natural killer (NK) cells[46] have been reported in blood samples from patients with SSc.

Humoral abnormalities in SSc are most clearly reflected by the presence of autoantibodies with well-defined target epitopes; mapping of the precise binding sites for some of these is currently being undertaken in several centres.[47] About 97% of SSc patients have detectable anti-nuclear antibodies when HEp-2 lines are used as the detection tissue. Characteristic staining patterns for anti-nuclear antibodies within the nuclear and subnuclear structures are relatively specific,[48] and can be confirmed by more sophisticated tests.

The pathogenesis of SSc is still uncertain; it is likely that the development of both the fibrous and the vascular lesion is complicated and a the result of a number of key events.

Fibrosis

Fibrosis is a hallmark of a number of diseases including scleroderma, pulmonary fibrosis, atherosclerosis, liver cirrhosis, and keloids. Excess deposition of collagen and ECM protein in the skin and internal organs of patients with SSc was first demonstrated histopathologically many years ago, and this was confirmed by physical and biochemical means. Subsequently, techniques for culturing fibroblasts have provided valuable insight into the mechanisms involved in the synthesis of ECM components.

The observation that skin fibroblasts from scleroderma, or at least a subset of them, synthesize increased quantities of fibronectin, fibrillins, proteoglycan core proteins, and particularly collagens types I and III and to a lesser degree IV and VI was inferred from ex-vivo studies of skin biopsies, but the intriguing finding that this phenotype of matrix overproduction persists in tissue culture and could be passed on at cell division has provided a paradigm for the mechanisms underlying the development of fibrosis secondary to vascular and immunological perturbation.[49] Overproduction of type I collagen is a reflection of increased transcriptional activation of the two pro(I)collagen genes and of increased transcript stability. Transcriptional regulation of collagen genes has itself been a major area of biological study and a number of important cis-acting regulatory regions and factors interacting with these regions have been

Table 121.4 T cells and cytokines involved in pathogenesis of systemic sclerosis[44]

Cytokines	Function
Th1 lymphocytes	
IFN-γ	◆ Produced by Th1 cells, memory T CD8+ cells, dendritic and NK cells ◆ Responsible for Th1 differentiation, the activation of B cells to produce immunoglobulins as well as the Th2 cytokine inhibition via IL-4 and IL-10 repression
TNFα	◆ Mainly produced by macrophages, APC, skin mast cells and keratinocytes ◆ Important for neutrophil/lymphocyte recruitment ◆ Proinflammatory and proapoptotic
IL-1	◆ Produced by Th1 cells, monocytes, macrophages, dendritic and endothelial cells ◆ Important role for Th1 (together with IL-1β, IL-23) and Th17 (together with IL-1β, IL-6, and IL-23) differentiation ◆ Proinflammatory
IL-2	◆ Produced by T lymphocytes ◆ Stimulates NK and T CD8+ cells ◆ Important for lymphocyte proliferation and differentiation to Th1 cells in the presence of IL-12 and IFN-ν as well as Th2 cells together with IL-4 ◆ Important for anti-inflammatory response associated with Th17 inhibition and Treg activation
IL-12	◆ Produced by monocytes, macrophages, dendritic cells as well as B lymphocytes ◆ Important for Th1 differentiation, while inhibiting Th17 differentiation ◆ Proinflammatory
Th2 lymphocytes	
IL-4	◆ Produced by Th2 cells, macrophages, mast cells and NK cells ◆ Important for Th2 differentiation, Th1 cytokine inhibition as well as Treg differentiation
IL-5	◆ Produced by Th2 cells, as well as by mast cells and eosinophils ◆ Important for B-cell differentaition
IL-6	◆ Produced by Th2 cells, macrophages, B lymphocytes as well as epithelial cells and fibroblasts ◆ Important for Th2 differentiation, Th17 differentiation (together with TGFβ and IL-21), stimulation of inflammation due to inhibition of Treg differentiation and triggering of fibrosis due to stimulation of collagen production and inhibition of collagenase production
IL-13	◆ Produced by Th2, NK, and mast cells ◆ Important for B-cell proliferation and differentiation as well as anti-inflammatory response and fibrosis
Th17 lymphocytes	
IL-17	◆ Produced by Th17 cells and NK cells ◆ Proinflammatory and profibrotic
IL-21	◆ Produced by Th17 cells and NK cells ◆ Important for Th17 response expansion
IL-22	◆ Produced by mature Th17 cells and Th2 cells and NK cells ◆ Proinflammatory

APC, antigen-presenting cells; IFN, interferon; IL, interleukin; TGF, tissue growth factor; Th, T helper cell; TNF, tumour necrosis factor; Treg, regulatory T cell.

identified. More recent studies have implicated several ubiquitous transcription factors in collagen gene activation in SSc fibroblasts including the heterotrimeric factor CBF, the GC-sequence binding protein Sp1, and most recently Smad proteins and their coactivators. It seems likely that upstream regulators of these factors are disturbed in SSc and that this leads to greater levels or more active phosphorylated forms of the transcription factors. Another possibility is that genetic differences in these factors or their regulation contribute to severity or susceptibility to scleroderma, as part of the polygenic background to this disease.

Profibrotic cytokines and chemokines, such as TGFβ, CTGF, PDGF, endothelin-1, interleukins, and monocyte chemoattractant proteins (MCP-1 and -3), are involved in the initiation of fibrosis in scleroderma, and constitutive alterations in the production of some growth factors or responsiveness to their actions has been observed in scleroderma fibroblasts. One of the most potent of these is connective tissue growth factor and there is a body of evidence now suggesting that this could be an important autocrine factor in the maintenance of the scleroderma fibroblast phenotype. Several studies have shown that a lot of serum markers in SSc patients correlate positively with the extent of skin fibrosis in SSc patients (reviewed by Moinzadeh et al.[50]).

Vasculopathy

The most prevalent clinical manifestation of vascular abnormality is Raynaud's phenomenon, which is present in over 95% of SSc
Fig. 121.1 Immunological mechanisms resulting in fibrosis.

patients. In addition, nailfold capillaroscopy is generally altered in SSc at the time of diagnosis. Indeed, the combination of Raynaud's phenomenon and characteristic nailfold capillary dilatation or drop-out offers one of the earliest opportunities to diagnose patients as they develop SSc and it has been proposed that these patients, especially when they also carry a hallmark autoantibody reactivity such as anti-centromere or anti-topoisomerase-1 reactivity, comprise a specific pre-scleroderma clinical subset of the disease.[51] It has also prompted reclassification of some of these cases as limited SSc.[52]

The pathological features of vascular damage, immune-cell activation, and fibrosis are believed to be closely linked in scleroderma.[53] In both localized and generalized disease many histological features are often shared, but the remainder of this discussion focuses on SSc. Detailed studies suggest that in both the skin and internal organs one of the earliest features is endothelial cell injury, initially at the ultrastructural level,[54] and that this is temporally and spatially associated with activation of perivascular fibroblasts and subsequent deposition of increased amounts of structurally normal ECM components. Inflammation is associated with early lesions leading to tissue oedema and leucocytic infiltration. Mononuclear cells predominate, with monocytes/macrophages amongst the

earliest cells within lesional tissue[55] followed later by lymphocytes, mainly carrying phenotypic markers of activated T lymphocytes and including a significant proportion of Ro+ 'memory' cells.

The precise role of vascular pathology in the pathogenesis of SSc remains uncertain. There is considerable evidence that endothelial cell activation and damage are early events in lesional and prelesional tissues but their importance in initiating or sustaining abnormalities in other cell types remains uncertain.

Data suggest that angiogenesis might be altered in scleroderma. The classical telangiectatic lesions of limited cutaneous disease, which are also common especially at later stages of diffuse cutaneous SSc, are consistent with local disruption of angiogenesis. The established fibrotic skin of scleroderma is relatively avascular and it is an attractive hypothesis that perhaps angiogenesis in scleroderma may be inadequate and perturbed. Elevated circulating levels of inhibitors of angiogenesis have been reported although tissue expression of angiogenic factors has not been shown to be consistently altered.

Clinical features

As discussed earlier, SSs is a very heterogeneous condition occurring at any age and including skin and internal organ manifestations.

Within each subtype the rate of progression and extent of damage varies.

Classification of different SSc subsets

The heterogeneity of SSc is caused by the range of disease manifestations that vary in extent and severity of organ involvement between each individual patient. However, Raynaud's phenomenon and skin sclerosis are almost always present. The extent of skin thickening helps to define patients into the two major SSc subsets, i.e. the limited and diffuse forms.

In 1980 the American College of Rheumatology (ACR) reported preliminary SSc classification criteria, for patients with definite disease.[56] The criteria are satisfied, and therefore the diagnosis is established, if either one major criterion (scleroderma proximal to the metacarpophalangeal or metatarsophalangeal joints) or at least two or more minor criteria (sclerodactyly, digital ulcerations and/or pitting digital scars and bibasilary pulmonary fibrosis) are found.

In 1988 LeRoy published a descriptive subclassification of limited vs diffuse SSc,[57] primarily just according to the extent of cutaneous involvement, but later, in 2001, LeRoy and Medsger[29] published amendments, which included the additional presence of autoantibodies and nailfold capillaroscopic alterations to identify also patients with early onset of SSc and just minimal skin sclerosis. To fulfil these criteria, it is essential that patients with early (limited) SSc have evidence of Raynaud's phenomenon plus scleroderma-specific autoantibodies and/or nailfold capillaroscopic manifestations.[58–59]

Patients with the diffuse form of SSc are defined by an early onset of Raynaud's phenomenon, usually within 1 year of onset of skin thickening. This subset is characterized by a very progressive course with skin involvement of trunk, face, upper arms, and thighs, within 1 year. These patients very frequently show anti-Scl 70 (anti-topoisomerase-I) or anti-RNAPIII antibodies,[57] with a higher risk of developing pulmonary fibrosis, cardiac involvement, and scleroderma renal crisis.

Limited cutaneous SSc is characterized by a long pre-existing history of Raynaud's phenomenon, usually several years before the appearance of the first skin changes in the extremities distal to the knee and elbow joints, and including facial skin.[57] This variant of SSc subset often (50–70%) shows anti-centromere antibodies (ACA) and is frequently associated with an isolated pulmonary arterial hypertension. The traditional acronym CREST (defining patients with calcinosis, Raynaud's phenomenon, oesophageal dysmotility, sclerodactyly, and teleangiectasias) is no longer used and all patients with these symptoms are assigned to the limited form of SSc.

Patients are said to have an overlap syndrome if they have the clinical features of SSc (according to the ACR criteria) or main symptoms of SSc simultaneously with those of other connective tissue diseases or other autoimmune diseases such as dermatomyositis, Sjögren's syndrome, SLE, vasculitis, or polyarthritis. These patients mostly have high titres of anti-U1-RNP, anti-nRNP, anti-fibrillarin, or anti-PM Scl antibodies.[60]

Patients classified as having early SSc, also known as undifferentiated SSc, show a positive Raynaud's phenomenon and at least one further aspect of SSc (positive nailfold capillary alterations, puffy fingers, pulmonary hypertension) and/or detectable scleroderma-associated autoantibodies without fulfilling the ACR criteria.[61]

Patients suffering from SSc without scleroderma are very rare and present with virtually no skin thickening, but with Raynaud's phenomenon, pulmonary hypertension, or other scleroderma features as well as ACA or other scleroderma-associated autoantibodies.[62]

Organ manifestation

Vasculopathy

Raynaud's phenomenon was first described by Maurice Raynaud in 1862 as episodic digital ischaemia provoked by cold and emotion, and appears in more than 90% of scleroderma patients. It is classically manifest by episodic pallor of the digits followed by cyanosis, suffusion, and/or pain and tingling (Figure 121.2). The blanching reflects digital arterial vasospasm, the cyanosis the deoxygenation of static venous blood, and the redness reactive hyperaemia following the return of blood flow (triphasic Raynaud's). Diagnostic procedures and therapeutic strategies are summarized in Table 121.5.

Important clues to secondary Raynaud's phenomenon on clinical evaluation are: the development of Raynaud's phenomenon either in very young children or after the age of 45 years; severe symptoms occurring all year round; digital ulcerations, which rarely, if ever occur in primary Raynaud's phenomenon; asymmetry of symptoms; and the recurrence of chilblains in an adult. Two simple, inexpensive, non-invasive procedures have high predictive power for detecting patients in the Raynaud's group who will have SSc in the future, namely patients with positive serum autoantibodies and alterations seen in the nailfold capillaroscopy. Nailfold capillaroscopy is a non-invasive and very useful tool to distinguish between patients with primary and secondary Raynaud's phenomenon and to visualize changes which are typical for early, active and late stages of SSc (Figure 121.3). In addition, laser Doppler perfusion imaging (LDPI), a non-invasive microvascular imaging technique, provides maps of the cutaneous blood flow.[63]

Some SSc patients are troubled by digital ulcerations which are associated with vasculopathy. This is the major external feature of structural vessel disease, probably due to thickened intima and luminal occlusions of vessels. Tender and painful pitting scars are observable and may progress to very painful ulcers, which have a major impact on quality of life with regard to activities of daily living—dressing, eating, etc. These ulcers occur on the tips of the fingers or toes, but may also be found over the extensor surfaces of the joints due to microtrauma or in association with calcinosis cutis. Further possible complications are critical digital ischaemia, paronychia, infections, gangrene, osteomyelitis, and finger pulp loss or amputation.

Cutaneous involvement

The changes in the skin usually proceed through three phases: early, established, and late. The early stage can be difficult to diagnose and a high level of suspicion is needed in the oedematous phase when the only feature may be puffiness of the hands and feet, most marked in the mornings. Oedema may be dependent and can lead to symptoms of neural compression including carpal tunnel syndrome. The face may feel slightly taut at this stage and Raynaud's phenomenon may be present. On examination there is a non-pitting oedema with intact epidermal and dermal appendages. The subsequent, often sudden, development of firm, taut, hidebound skin proximal to the metacarpophalangeal joints, adherent to deeper structures such as tendons and joints, causing limitation of their movement and subsequent contractures,

Fig. 121.2 Typical clinical features in the hands of patients with systemic sclerosis.

permits a definitive diagnosis in over 90% of patients. The epidermis thins, hair growth ceases, sweating is impaired, hypo- and hyperpigmentations (salt and pepper phenomenon) appear, and skin creases disappear.

Sclerotic changes limited to the fingers alone (sclerodactyly) do not have the same implications. The classical changes, once fully developed, can remain static for many years. Depending on the region of skin sclerosis, restricted mobility of joints with contractures and/or restricted chest excursion may appear. Typical facial features include teleangiectasiases, a beak-shaped nose as well as

reduced mouth aperture (microstomy) with a typical physiognomy of SSc patients (radial furrowing around the mouth, an expressionless stiff and mask-like facial appearance, and sclerosis of the frenulum). Besides cosmetic/aesthetic problems, in some cases skin sclerosis may also cause difficulties for eating and oral hygiene. The cutaneous or subcutaneous deposition of calcium (calcinosis cutis) usually occurs over pressure points (acral, joints) and is known as Thieberge–Weissenbach syndrome, if it appears extended next to joints. Diagnostic procedures and therapeutic strategies are summarized in Table 121.6.

Table 121.5 Diagnostic procedures and therapeutic strategies, including disease-modifying treatment options for the vascular system

Clinical feature	Diagnostic procedure	Therapeutic strategies
Vascular system		
RP	◆ RP provocation ◆ Nailfold capillaroscopy ◆ Serology	◆ General recommendations: avoid coldness, keep body warm, paraffin bath, heatable soles and gloves ◆ Vitamins and supplements: fish oil capsules, antioxidant vitamins, ginko biloba **Oral treatments** ◆ Calcium channel blockers: nifedipin (10–20 mg, three times daily); amlodipin or felodipin (10 mg once daily) ◆ Angiotensin-II-receptor 1 blocker: losartan (25–50 mg once daily) ◆ Serotonin reuptake inhibitors: luoxetin (20 mg once daily) ◆ Phosphodiesterase type 5 inhibitor: sildenafil (not licensed, trial in severe cases) **Topical treatment** ◆ GTN patches (1/2 of the patch located at the wrist, next to the vessels for 12 hours) **Intravenous treatment** ◆ Prostacyclin infusion: iloprost (0.5–2 ng/kg per minute over 6 h on 5 consecutive days) **Surgical treatment** ◆ Lumbar sympathectomy ◆ Radical microaretriolysis
Digital ulceration	◆ Clinical assessment for infection, necrosis, etc. ◆ Radiograph or MRI to exclude osteomyelitis	**Intravenous treatment** ◆ Prostacyclin infusion: iloprost (0.5–2 ng/kg per minute over 6 h on 5 consecutive days) **Oral treatments** ◆ Phosphodiesterase type 5 inhibitor: sildenafil (not licensed, trial in severe cases) ◆ Dual ET receptor antagonist: bosentan (reduce the frequency of new DUs in the future) ◆ Pain reliever ◆ Antibiotic treatment in case of infection **Topical treatment** ◆ Hydrocolloid wound dressing ◆ Hydrofibre dressing ◆ Vitamin E gel **Surgical treatment** ◆ Lumbar sympathectomy ◆ Radical microaretriolysis ◆ Amputation, debridement

RP, Raynaud's phenomenon.

Careful mapping of the degree and extent of skin involvement is the single best clinical technique for detecting the patient at risk for life-threatening involvement of internal organs. A number of scoring systems to quantify skin sclerosis have been developed. The most widely used is a modification of that proposed by Rodnan, consisting of a 0 to 3 grading at 17 skin sites (maximum score 51). The sites assessed in the modified skin score are summarized in Figure 121.4. The interobserver variability in the use of the modified Rodnan skin score in studies from the United Kingdom and United States is similar.[64]

Furthermore, new techniques for skin thickening scoring have been evaluated, such as 20 MHz ultrasound,[65] durometry,[66] cutometry,[67] elastometry,[68] and plicometry.[69] The evaluation of collagen bundles and inflammatory infiltrates is still only possible by taking skin biopsies with histological evaluation of the dermal skin thickness (see Table 121.6).

The natural history of skin involvement in SSc emphasizes that after 2–3 years plateauing of skin score and/or improvement even without effective treatment is often observable. Also, its use as a surrogate for outcome is supported by secondary analyses confirming that skin score at presentation reflects disease outcome at later time points.

Systemic features of disease

The patient with SSc must cope with a complex set of symptoms that range from features common to chronic diseases through to complaints attributable to specific visceral involvement. Fatigue and lethargy are common throughout the illness, although usually more pronounced in its early phases. Weight loss is almost universal in the diffuse cutaneous form but less common in the limited variety.

Gastrointestinal tract

The gastrointestinal tract is probably the most commonly involved internal organ system in SSc. More than 90% of patients with limited cutaneous and diffuse cutaneous SSc have oesophageal hypomotility and serious gastrointestinal disease has been estimated to occur in 50% of patients with limited cutaneous SSc.

Fig. 121.3 Nailfold capillaroscopy with early, active, and late patterns of systemic sclerosis:[86]
(a) Normal capillaries (9–11 capillaries/mm with a regular order of capillary loops).
(b) Earlysystemic sclerosis pattern (few enlarged/ecstatic capillaries and a few haemorrhages, but normal density of capillaries). (c) Active pattern (multiple giant and enlarged/ecstatic capillaries with haemorrhages and also disordered capillaries due to development of capillary loss).
(d) Late pattern (completely disturbed architecture with multiple losses of capillaries and bushy capillaries (neovascularization); giant capillaries, and haemorrhages just occasionally visible).

Table 121.6 Diagnostic procedures and therapeutic strategies, including disease-modifying treatment options for the skin

Clinical feature	Diagnostic procedure	Therapeutic strategies
Skin thickening	◆ Clinical assessment ◆ mRSS ◆ Durometer ◆ 20 Mhz ultrasound ◆ Biopsy	General recommendations: skin care with moisturizing cream or ointments **Physical treatments** ◆ Lymphatic drainage/physiotherapy: for skin fibrosis, sclerodactyly, microstomia, dermatogenous contractures, puffy fingers ◆ Phototherapy: skin hardening, itchiness **Topical treatment** ◆ Steroids or calcineurin inhibitors: early stage of skin hardening with inflammation and itchiness **Systemic treatments** ◆ Steroids (just short dated due to side effects and risk of renal crisis) ◆ Ciclosporin (small studies showed improvement of skin score[87] ◆ Methotrexate (improvement in skin score reported)[88–90] ◆ Cyclophosphamide (trials have shown significant improvement in mRSS)[91–92]
Calcinosis cutis	◆ Clinical assessment ◆ Imaging (X-ray, MRI, CT)	**Caution: side effects have to be balanced** ◆ General recommendations: improve blood flow and keep hands warm ◆ Local corticosteroid injections ◆ Laser therapy ◆ Surgery ◆ Minocycline ◆ Bisphosphonate (oral)
Teleangiectases	◆ Clinical assessment	◆ Laser therapy ◆ Camouflage

mRSS, Modified Rodnan skin score.

Site	Maximum score		
Face	3		
Anterior chest	3		
Abdomen	3		
Subtotal	**9**		
		Right	**Left**
Upper arm		3	3
Forearm		3	3
Hand		3	3
Fingers		3	3
Thigh		3	3
Leg		3	3
Foot		3	3
		21	21
Maximum	**51**		
Scoring of each skin region determined by skin thickness and tethering:

0 = normal

1 = possible thickening

2 = definite thickening but mobile

3 = skin more thickened and fixed to deeper tissues "hide-bound"

Scoring system assessing 17 sites (omitting neck and back) with maximum of 54 is also widely used to avoid these sites which are often hard to accurately score.

Fig. 121.4 Standardized assessment of skin involvement in systemic sclerosis using a modified Rodnan skin score.

The earliest clinical symptoms may be quite subtle. Patients may experience difficulties in swallowing (dysphagia), retrosternal discomfort or even overt pain, which can be nocturnal, due to reflux and oesophagitis. Measurement of lower oesophageal pressure is frequently unacceptable to the patient and therefore in clinical practice the oesophageal transit time (quantitative oesophageal scintigraphy) is usually the preferred screening test. In those who have an abnormal scan and those who have severe dysphagia and/ or heartburn, direct oesophago-/gastroscopy may be required to identify structural divisions such as hiatus hernia and oesophageal strictures as well as to identify Barrett's metaplasia at an early stage. Proton pump inhibitors are the drugs of first choice. Diagnostic procedures and therapeutic strategies are summarized in Table 121.7.

Small-bowel disease with hypomotility is a major problem in scleroderma and can lead to weight loss, cachexia, and malabsorption. The classical symptoms are of a change in bowel pattern, with loose, frequent, floating, foul-smelling stools, and abdominal distension. Once the disease is established, bacterial overgrowth with its associated malabsorption is a recurring problem, often punctuated by abrupt episodes of distension and adynamic ileus (pseudo-obstruction). Management of such patients is difficult and includes the rotational use of antibiotics, attempts to stimulate the bowel directly with prokinetics including erythomycin or domperidone, and on occasion total parenteral nutrition. Atony and hypomotility of the rectum and sigmoid colon is frequent and occurs early. Constipation is usually manageable with the use of dietary manipulation and stool volume expanders.

Surgery to the large bowel or any other part of the gastrointestinal tract must be viewed with great caution because it is not without risk and not always successful. As the gastrointestinal manifestations of SSc are frequent, and debilitating if not life-threatening, the goal in this area must be early detection, support, and control, thus permitting as active a life as possible.

Cardiopulmonary involvement

It is likely that cardiac involvement from scleroderma, although important and potentially life-threatening, is underdiagnosed. The cardiopulmonary system may be affected different ways, most often by fibrosis and pulmonary arterial hypertension (PAH). PAH is defined as a mean pulmonary pressure (mPAP) of at least 25 mmHg at rest combined with a pulmonary capillary wedge pressure of less than 15 mmHg, determined by right heart catheterization.[70]

Due to similar, overlapping clinical features, such as dyspnoea, non-productive cough, disturbed diffusion capacity, and cyanoses, it can sometimes be a challenge to distinguish between cardiac and pulmonary factors. PAH is the most common cause of disease-related death in SSc, replacing scleroderma renal crisis. PAH occurs in patients with limited and diffuse SSc, although the most typical cases are those of lSSc associated with isolated PAH, but there are also some patients with late-stage extensive interstitial lung fibrosis in SSc who develop a secondary PAH. In addition the heart can also be affected due to diffuse interstitial myocardial fibrosis, which leads to diastolic dysfunctions as well as restricted contractibility of the myocardium. These patients typically present symptoms such as cardiac arrhythmia, paroxysmal tachycardia, incomplete or complete right-heart blocks, and heart insufficiency.

All patients with SSc should be followed up at least annually with lung function tests and echocardiography. Further investigation such as the 6 minute walk test or high-resolution CT (HRCT) may

Table 121.7 Diagnostic procedures and therapeutic strategies, including disease-modifying treatment options for the gastrointestinal system and the kidneys

Clinical feature	Diagnostic procedure	Therapeutic strategies
Gastrointestinal involvement		
Reflux	◆ Gastro-oesophageal endcoscopy	◆ General recommendations: bed head elevated during the night, small meals **Oral treatments** ◆ Proton pump inhibitors: lansoprazole, omeprazole, etc. ◆ Procinetics: domperidone ◆ H$_2$ receptor antagonists: ranitidine
Dysphagia	◆ Oesophageal szintigraphy	◆ General recommendations: change of eating habits, small meals **Oral treatments** ◆ Prokinetics: domperidone, metoclopramide
GAVE	◆ Endoscopy	◆ Argon plasma coagulation
Diarrhoea Constipation	◆ Coloscopy	◆ General recommendations: change of eating habits **Oral treatments** ◆ Prokinetics: domperidone ◆ Antibiotics ◆ Laxative
Faecal incontinence	◆ Coloscopy ◆ Rectal manometry	◆ Solidifying liquid stools ◆ Biofeedback therapy ◆ Sacral nerve stimulation
Rectal prolapse	◆ Clinical assessment	◆ Surgery

help to determine possible cardiopulmonary involvement. Lung function testing is useful to give early signs for both lung fibrosis and PAH, in the form of impaired diffusion capacity (DL$_{CO}$ ≤75%). To determine the presence of interstitial lung involvement, HRCT and/or chest radiograph should be used and these tests are generally performed at diagnosis, especially if there is any breathlessness or impaired lung function. Regular follow-up looking for cardiac involvement should also include transthoracic Doppler echocardiography, which can indicate a hypertrophy with or without enlargement of the right ventricle, paradoxical motion of the interventricular septum, tricuspid valve insufficiency, and pericardial effusion. In case of suspected PAH, right heart catheterization is still the gold standard, but it is an invasive diagnostic procedure.

Fibrotic changes in the myocardium in scleroderma have been demonstrated in biopsy specimens and at necropsy. Noninvasive imaging techniques such as MRI or spiral CT scanning may allow this to be determined more precisely. Indirect clues to cardiac involvement may be deduced from ECG or echocardiographic studies. Conduction defects are the most frequently observed disturbances. Typical features include QTc prolongation on 12-lead ECG. Later, conduction tissue fibrosis may lead to varying degrees of heart block including first- or second-degree block or complete heart block necessitating pacemaker implantation. Also the use of N-terminal brain natriuretic peptide (NTproBNP) in the patient's serum is helpful to detect right ventricular impairment.

The treatment of the cardiac manifestations of SSc is primarily supportive, empirical, and of moderate value. Diagnostic procedures and therapeutic strategies are summarized in Table 121.8.

Kidney involvement

This remains one of the most important complications of scleroderma and is amenable to treatment, although the prognosis is much better if appropriate management is instituted early. As with PAH, renal scleroderma is mainly a vascular disease. Both post- and antemortem studies suggest that epithelial and endothelial renal lesions occur before there is clinical evidence of renal disease in SSc,[71] and certainly precede any histological evidence of fibrosis. This supports the view that epithelial, and particularly endothelial, damage are important early events in the pathogenesis of scleroderma.[72] The best-characterized pattern of renal involvement in SSc is an acute or subacute renal hypertensive crisis. This generally occurs in patients with diffuse SSc within 5 years of disease onset. The overall incidence of scleroderma renal crisis is uncertain, with differences in the reported frequency even in series from the same unit. This variation probably reflects differences in incidence in the various subsets of SSc. Traub et al. proposed the following criteria to diagnose scleroderma renal crisis: abrupt onset of arterial hypertension greater than 160/90 mmHg, hypertensive retinopathy of at least grade III severity, rapid deterioration of renal function, and elevated plasma renin activity.[73] Other typical features include the presence of a microangiopathic haemolytic blood film and hypertensive encephalopathy, often complicated by generalized

Clinical feature	Diagnostic procedure	Therapeutic strategies
Respiratory system		
Lung fibrosis	◆ Lung function test ◆ Imaging (X-ray/HRCT) ◆ Bronchioalveolar lavage	**Systemic treatments** ◆ Cyclophosphamide orally or IV ◆ Glucocorticosteroids (short dated) ◆ Azathioprine orally ◆ Mycophenolate mofetil orally vOxygen (if needed)
Cardiac system		
PAH	◆ Lung function test ◆ Electrocardiography ◆ Echocardiography ◆ 24 h blood pressure control ◆ Right heart catheterization	**Systemic treatments** ◆ Bosentan orally ◆ Sildenafil orally ◆ Epoprostenol orally ◆ Oxygen (if needed)
Cardiac myopathy	◆ Electrocardiography ◆ Echocardiography ◆ 24 h blood pressure control ◆ MRI	**Systemic treatments** ◆ Cyclophosphamide orally or intravenous ◆ Glucocorticosteroids (short dated) ◆ Azathioprine orally ◆ Mycophenolate mofetil orally ◆ Pacemaker (if needed)
Renal system		
Scleroderma renal crisis	◆ Regular blood pressure controls ◆ Ultrasound ◆ Serological renal profile ◆ Proteinuria analysis	**Systemic treatments** ◆ ACE inhibitors (high-dose) under blood pressure monitoring ◆ Iloprost intravenous

convulsions. It is generally considered important to perform a renal biopsy, once hypertension has been adequately controlled, especially if renal replacement therapy is being contemplated. This allows histological confirmation of the diagnosis and the exclusion of other causes for renal failure of abrupt onset, such as glomerulonephritis or the haemolytic uraemic syndrome.

Musculoskeletal system

Skeletal muscle is often involved in scleroderma. In many instances the weakness, pain, and atrophy results from disuse secondary to joint contractures or chronic disease. However, about 20% of patients have a chronic myopathy, characterized by mild weakness and atrophy of muscles, minimal elevation of creatine phosphokinase, few or no changes on electromyography, and subtle histological features showing focal replacement of myofibrils with collagen and perimysial and epimysial fibrosis without inflammatory change. A minority of patients exhibit an inflammatory myositis, usually categorized as an SSc–polymyositis overlap syndrome, sometimes indistinguishable from polymyositis; caution is required if this occurs in the context of early diffuse disease, when treatment with high-dose steroids might precipitate renal failure, and an alternative treatment should be considered.

A symmetrical polyarthritis, usually seronegative, anodular and non-erosive, is the presenting feature in a small number of patients destined ultimately to develop SSc. By 2 years, frequently much earlier, the synovitis has subsided and classic cutaneous SSc is present, often developing abruptly over 1–3 months.

Management of systemic sclerosis

There have been major advances in treating many of the organ-specific complications of SSc. Critical ischaemia and severe Raynaud's phenomenon are improved by parenteral prostacyclin analogues; the management and outcome of scleroderma renal crisis has been transformed by use of angiotensin converting enzyme (ACE) inhibitors, and the morbidity from oesophagitis has been drastically cut by use of proton pump inhibitors. Added to this are the exciting developments in treating PAH and several encouraging retrospective studies suggesting that immunosuppression using cyclophosphamide may be effective in slowing the progression of SSc-associated fibrosing alveolitis (all symptomatic and disease-modifying treatments for SSc are listed in Tables 121.5–121.8). In addition to these developments, there is now a much clearer understanding of the heterogeneity and natural history of the major subsets of SSc and an appreciation of risk stratification, the use of serological markers, and proactive regular screening of patients for early signs of complications. Together, these factors make SSc a much more manageable disease.

The choice and evaluation of any treatment regimen are not easy because the disease is complex and the pathogenesis poorly

understood; the disorder is heterogeneous and its extent, severity, and rate of progression are highly variable. Therapy must therefore be closely tailored to the individual patient involved. There is a tendency towards spontaneous stabilization and/or regression after a few years, particularly within the more benign and numerically larger subset of limited cutaneous SSc; and there is a paucity of both clinical and laboratory features for ascertaining improvement (or deterioration) in the disease, especially with respect to visceral change. Ultimately it is hoped that a better understanding of the pathogenesis of SSc, especially in its aggressive diffuse form, will identify key factors, pathways, or processes that can be targeted therapeutically. It is possible that targets will be stage- or subset-specific. There are already examples of pilot studies of anti-cytokine therapies using neutralizing antibodies or soluble receptors. Ultimately, small molecules that inhibit key pathways are likely to be the most successful form of treatment but these are presently a long way off.

It is generally considered that immunosuppressive strategies are most likely to be effective in the early stages of SSc when inflammatory features are prominent. A large number of agents have been tried but none has been shown in clinical trials to be definitely effective.

Localized scleroderma

This is distinguished from SSc not only by the absence of vasospasm, structural vascular damage, and involvement of internal organs, but also by the distribution of the dermal lesions, which may, depending on the subtype, follow a dermatomal pattern. It can appear in children and adults and depending on the subtype of localized scleroderma; children more frequently develop the linear form of SSc, while adults suffer commonly from the limited localized scleroderma form. The incidence varies between 0.4 and 2.7 per 100 000 inhabitants and it is also predominantly a female condition.[8,74–75] The pathogenesis of this disease is also still not fully understood, but some authors have reported that trauma, autoimmunity, drugs, radiation, and also infections might be triggers for this kind of disease.

Classification

The varied clinical features have led to the separation of four main varieties of localized scleroderma: limited and generalized forms of morphoea, and linear and frontal ('en coup de sabre') forms of localized scleroderma (see Figure 121.5 and Table 121.9).[76]
Fig. 121.5 Variants of localized scleroderma: (a) limited forms of morphoea (plaque type); (b) linear forms of morphoea (linear type, en coup de sabre, Parry–Romberg syndrome); (c) generalized forms of morphoea (generalized disabling form of morphoea).

Table 121.9 Classification of localized scleroderma[76]

Localized scleroderma	Subtypes	Clinical characteristics
Limited type	Morphoea (plaque type)	At least one lesion (>1cm), in one or two anatomic regions, such as back, abdomen, limbs, buttock, and/or neck. The lesions are usually initially erythematous, afterwards changing into indurated and central thickened plaques. The typical lilac ring can be used as an activity sign
	Guttata morphoea	Characterized by at least one lesion (<1cm), which are commonly visible at the trunk
	Atrophoderma of Pasini and Pierini	Hyperpigmented/erythematous atrophic patches, which are commonly located at the trunk. Interestingly, these lesions show no sclerotic process
Generalized type	Generalized localized scleroderma	The plaques of this form show a tendency to confluence at more than two anatomic areas into huge plaques
	Disabling pansclerotic morphoea	Generalized, diffuse sclerosis, involving the whole body of the patients and usually sparing only the extremities of the patients. It can be complicated by very painful and resistant ulcerations
	Eosinophilic fasciitis	Severe fibrosis of the deep fascia, characterized by symmetric skin sclerosis, oedema, and eosinophilia around the lower extremities
Linear type	Linear localized scleroderma	This type shows band-like lesions of sclerotic skin with possibly deep atrophy of the soft tissue. Patients develop this condition usually in the first or second decade of their life
	'en coup de sabre' type	Linear skin sclerosis and atrophy of subcutaneous tissue localized at the forehead. Typically children develop this form of linear scleroderma
	Progressive facial hemiatrophy@ (Parry–Romberg syndrome)	This is the more severe form of the linear variant with an involvement of one-half of the face defined by atrophy of subcutaneous tissue
Deep type	Deep morphoea	This form primarily involves the panniculus or fascia and therefore forms deep and bound down skin lesions

Morphoea

The **limited form** of morphoea includes plaque-type morphoea, guttata morphoea, and the atrophoderma of Pasini and Pierini. This form is characterized by changes that often begin with small, violaceous or erythematous skin lesions, which enlarge and progress to firm 'hidebound' skin with variable degrees of hypo- or hyperpigmentation. These lesions eventually settle into a waxy, white appearance with subsequent atrophy. Pruritus is often a problem with the early lesion. Lesions vary in diameter between 1 and 10 cm. The condition generally resolves within 3–5 years, although sometimes a patch may persist for more than 25 years.

The **generalized form** of morphoea includes generalized localized scleroderma and the disabling pansclerotic morphoea as well as eosinophilic fasciitis. These forms are characterized by the development of many patches covering a large surface area. The acral parts are usually spared, but the trunk and legs are often involved. Generalized morphea can be disfiguring and may continue to extend, resulting in contractures, disability, and troublesome ulceration that may occasionally become malignant. In guttate morphea there are multiple small, hypopigmented and pigmented papules 2–10 mm in diameter, with minimal sclerosis, and the lesions closely resemble those of lichen sclerosus et atrophicus. These lesions usually localize to the neck, shoulders, and anterior chest wall.

Linear form of localized scleroderma

The linear form of localized scleroderma includes the normal linear morphoea, en coup de sabre, and the Parry–Romberg syndrome. These patients are defined by sclerotic areas occurring in a linear, band-like pattern, often in a dermatome distribution. These areas often cross joint lines, and are associated with atrophy of the soft tissue, muscle, periosteum, bone, and occasionally synovium; they can lead to extensive growth defects in a limb or a part thereof, which can be extremely disfiguring. Fixed valgus or various deformities also occur, and scoliotic changes in the spine can develop as a result of inequalities in limb length. If the toes or fingers are involved, 'hammer toes' or 'claw hand' may develop. All of these changes are much more noticeable in a growing child and most cases of linear SSc tend to occur in childhood, as do most cases of en coup de sabre, a specialized form of linear disease. Lesions generally predominate on one side of the body although some degree of contralateral involvement is often present at later stages, suggesting that there may be a systemic process operating.

Frontal linear scleroderma ('en coup de sabre')

This gets its name because the lesion was originally considered to be reminiscent of the scar from a sabre wound so it was termed 'en coup de sabre'. It is a form of linear scleroderma occurring on the face or scalp; the linear lesion may assume a depressed, ivory appearance and is often associated with hemiatrophy of the face on the same side. It may also be associated with vascular abnormalities of the brain and also with morphoea lesions elsewhere. There is clinical overlap between this form of linear scleroderma and specific localized growth defects such as idiopathic hemifacial atrophy (Parry–Romberg syndrome). In the latter the overlying skin may be texturally normal or there may be skin changes resembling those of scleroderma. It is not uncommon for patients to present with morphea and then later develop linear lesions. This evolution should be anticipated extremely carefully,

as the linear lesions tend to have much greater morbidity than the circumscribed patches of morphoea. The linear lesions may be quietly progressive for a long period, and lengthy follow-up is important.

Other forms

In addition, a small group of children has been described with morphoea and/or linear lesions who also have a synovitis, which can be demonstrated by infrared thermography. These patients have a raised erythrocyte sedimentation rate (ESR), rheumatoid factor (RF), and circulating autoantibodies. Such cases are unusual, but they have an accelerated course with rapid development of contractures. At the time of presentation, there may only be a small area of localized or linear scleroderma, distant from the joint symptoms. The ESR and RF are usually normal, but autoantibodies are often present. There is both a clinical and a biochemical association, the nature of which is unclear, between localized scleroderma and eosinophilic fasciitis, in which large sclerotic patches may also occur.

Evaluation

Evaluation of all forms of scleroderma is difficult. In the localized forms, charting of the involved areas is often cumbersome and imprecise. However, the size of the lesion can be recorded, leg length, limb circumferences, and posture can be monitored, and muscle function and neurological status assessed. Charting of new lesions is also essential. In addition, thermography can be used to assess the activity of localized disease,[77] and high-frequency ultrasound or MRI have also been used to determine the depth of localized scleroderma lesions. CT scans and MRI investigations are also useful to identify extracutaneous manifestations, such as subcortical calcifications, brain atrophy, and muscular, bone, and subcutaneous tissue involvement.

Different variants of skin scoring techniques are now used in patients with morphoea to assess the development over years and to see whether there are still signs for activity and progression. The Localized Scleroderma Clinical and Ultrasound group (LOCUS)[78] has validated a morphoea-specific skin scoring system which is used at 18 different body areas, classifying skin erythema, skin hardening, and new lesions. Laser Doppler flowmetry,[79] durometry,[80] elastometry, and cutometry[68] have also been used in clinical practice as well as in clinical trials to evaluate the progression of the skin hardening, as in patients with SSc.

Different therapy strategies can be used in morphoea patients depending on the type and the severity/extension, as listed in Table 121.10.

In addition to localized scleroderma and the more severe SSc, there are many other scleroderma-mimicking diseases, which have to be excluded and also considered as differential diagnoses. These disorders are briefly summarized in Box 121.1.

Table 121.10 Morphoea: treatment recommendations

Treatment	Comments
Topical treatments	
Topical steroids	Can be helpful in active stages of superficial morphoea subtypes
Topical calcipotriol	Can be beneficial for plaque-type superficial types of morphoea
Topical tacrolimus	Can improve skin lesions, especially in the erythematous, active stage of superficial morphoea types
Phototherapy	Initial UV dosage has to be adjusted after determining the individual MED for UVA1 and MPD for bath PUVA
UVA$_1$ phototherapy	◆ Phototherapy is known to have an anti-inflammatory and also an anti-fibrotic effect on sclerotic skin lesions ◆ **Caution**: especially in light-skinned patients, long-term consequences should be discussed in detail
Bath PUVA	◆ Phototherapy is known to have an anti-inflammatory and also an anti-fibrotic effect on sclerotic skin lesions ◆ Bath PUVA can be effective in early inflammatory stages of morphoea ◆ **Caution**: especially in light-skinned patients, long-term consequences should be discussed in detail
Systemic treatments	
Oral steroids	◆ Helpful in early acute stage of severe morphoea types and eosinophilic fasciitis ◆ **Caution**: side effects should be considered
Methotrexate	◆ Used in patients with generalized types of morphoea and active linear morphoea ◆ Can be used orally or subcutaneously, once per week
Physical treatments	
Physiotherapy	It is important to combine all systemic or topical treatments with physiotherapy, especially in patients with linear localized morphoea, to reduce skin contractures and defective positions of extremities **Caution**: physiotherapy should not be used in inflammatory active stages
Lymphatic drainage	Again the combination of physical and medicinal treatments is important in patients with linear localized morphoea **Caution**: lymphatic drainage should not be used in inflammatory active stages

MED, minimal erythema dose; MPD, minimal phototoxic dose; PUVA, psoralen ultraviolet A.

CHAPTER 122

Paediatric scleroderma and related disorders

Francesco Zulian

Juvenile systemic sclerosis

Introduction

Juvenile systemic sclerosis (JSSc) is a chronic, multisystem connective tissue disease characterized by sclerodermatous skin changes and widespread abnormalities of the viscera.

According to 1980 classification criteria of the American College of Rheumatology (ACR),[1] definite SSc requires the presence either of the major criterion (fibrosis/induration involving areas proximal to the metacarpophalangeal (MCP) or metatarsophalangeal (MTP) joints) or of two minor criteria (sclerodactyly, digital pitting scars, bibasilar pulmonary fibrosis). Subsequently, the widespread use of nailfold capillary microscopy, the discovery of SSc-specific autoantibodies and the early detection of Raynaud's phenomenon in patients who, years later, developed SSc, have raised the need for a more comprehensive classification.

Recently, an ad-hoc International Committee on Classification Criteria for Juvenile Systemic Sclerosis, following an evidence-dased and consensus-based methodology, developed new classification criteria for this rare paediatric disease.[2] According to these criteria, a patient aged less than 16 years, is classified as having JSSc if the one major (presence of skin sclerosis/induration proximal to MCP or MTP joint) and at least two of the 20 minor criteria listed in Box 122.1 are present.

Epidemiology

Onset of SSc in childhood is uncommon. A recent study from the United Kingdom reported an annual incidence rate of 0.27 per million children under the age of 16 years.[3] It has been estimated that approximately 3% of all patients had onset in childhood, and patients aged 10–20 years account for only 1.2–9% of all cases.[4]

JSSc occurs with equal frequency in boys and girls younger than 8 years old, whereas girls outnumber boys 3 to 1 when disease onset occurs in children who are older than 8 years.[5]

Aetiology and pathogenesis

The cause of diffuse SSc is unknown, despite significant advances in understanding of potential pathogenetic mechanisms. The disease can be represented as a tripartite process in which dysfunction of the immune system, endothelium, and fibroblasts gives rise to a heterogeneous phenotype that is characterized prominently by fibrosis. Since both aetiology and pathogenesis are similar to the more common adult disease the reader is referred to Chapter 121 for a detailed description.

Genetic background

The familial occurrence of JSSc is very rare, as confirmed by few case reports in which first-degree relatives of the same family were affected.[6] Just one report described JSSc monozygotic twins.[7]

Microchimerism, defined as the presence within one individual of cells derived from a different individual, was postulated as a possible cause of scleroderma. Microchimerism occurs in women who had previous pregnancies, individuals who have had blood transfusions, and children with cells from the mother or a twin. Maternal cells can persist in an immunocompetent offspring even in adult life, and fetus-derived haemopoietic cells may persist in the maternal circulation for many years postpartum. In scleroderma, circulating chimeric cells are increased in number[8] and have been described also in sclerodermatous skin.[9] These findings support the hypothesis that fetal anti-maternal graft-vs-host reactions might be involved in the pathogenesis of SSc,[10] but cannot explain the occurrence of scleroderma in men or in women who have never had children.

Clinical manifestations

Early signs and symptoms

Onset of the disease is usually insidious and the course prolonged. Generally, in children SSc may have two possible evolutions: a few children have a rapid development of internal organ failure leading to severe disability and eventually to death, whereas other patients experience a slow, insidious course of the disease with lower mortality.[11] The onset is often characterized by the development of isolated Raynaud's phenomenon which is usually associated with positive antinuclear antigens (ANA) and capillariscopy changes. Months or years later, tightening of the skin, especially of fingers and face, appearance of cutaneous telangiectases and symptoms related to internal organs involvement gradually develop.[5] Because of the subtle nature of this presentation, there is often a diagnostic delay of years.

The main signs and symptoms of JSSc are summarized in Table 122.1.

Box 122.1 PRES/ACR/EULAR provisional classification criteria for juvenile systemic sclerosis

Major criterion

Proximal sclerosis/induration of the skin

Minor criteria

Skin

◆ Sclerodactyly

Vascular

◆ Raynaud's phenomenon
◆ Nailfold capillary abnormalities
◆ Digital tip ulcers

Gastrointestinal

◆ Dysphagia
◆ Gastro-oesophageal reflux

Renal

● Renal crisis
◆ New-onset arterial hypertension

Cardiac

◆ Arrhythmias
◆ Heart failure

Respiratory

◆ Pulmonary fibrosis (HRCT/chest radiograph)
◆ DL_{CO}
◆ Pulmonary hypertension

Muskuloskeletal

◆ Tendon friction rubs

Skin disease

Cutaneous changes characteristically evolve in a sequence beginning with oedema, followed by induration resulting in marked tightening and contractures, and eventually atrophy.

During the sclerotic phase, the skin develops a waxy texture and becomes tight and bound to subcutaneous structures. This is particularly noticeable in skin of the dorsal surface of the digits, so-called sclerodactyly (Figure 122.1), and face; the characteristic expressionless, unwrinkled appearance of the skin may be the first clue to the diagnosis (Figure 122.2). These superficial abnormalities result in a shiny appearance of the skin accompanied by areas of hypo- or hyperpigmentation.

Telangiectases of the periungual nailfold is often the early location, and examination with an ophthalmoscope demonstrates capillary dropout, tortuous dilated loops, and occasionally distorted capillary architecture. Digital pitting, sometimes with ulceration and gangrene, occurs in the pulp of the fingertips as a result of ischaemia (Figure 122.3). Subcutaneous calcification, especially over the elbows, MCP joints, and knees, may occur, sometimes with ulceration of surrounding skin.

Fig. 122.1 Sclerodactyly in juvenile scleroderma.

Fig. 122.2 Unwrinkled facial skin in early juvenile scleroderma.

Fig. 122.3 Typical digital pits indicating ischaemia in scleroderma.

As already stated, Raynaud's phenomenon represents the first manifestation of the disease in 70% of children with JSSc preceding other manifestations, in some instances, by years.[12] During the overall course of the disease, Raynaud's phenomenon is also the most frequently reported symptom being present in 90% of children. In 10% it is complicated by digital infarcts.[5,12]

Musculoskeletal disease

Musculoskeletal symptoms characteristically occur at or near onset of the disease in one-third of children with JSS.[5] Morning stiffness, arthralgias, and arthritis are often the initial manifestations of the disease.

Joint contractures of insidious onset and limitation of motion are most common at the proximal interphalangeal (PIP) joints and elbows, but other joints can be affected. Muscle inflammation characterized by pain and tenderness occurs in up to one-fifth of children.

Gastrointestinal disease

Symptomatic gastrointestinal involvement affects around one-third of the patients but is much more frequent if the diagnosis is made instrumentally (barium swallow, scintigraphy, etc.).[5,12] Lesions of the mouth include mucosal telangiectases, reduced maxima mouth opening caused by skin thickening and tightness and, rarely, parotitis as part of the sicca syndrome. Although the oesophagus is involved, often quite early in the disease, many patients are asymptomatic and rarely present as heartburn with postural aggravation or dysphagia. Small-bowel involvement usually develops in association with oesophageal or colonic disease. Malabsorptive diarrhoea and delayed colonic transit, when present, reflect long-standing disease. Large-bowel disease is also often asymptomatic but may sometimes cause severe constipation, bloating, or diarrhoea.

Cardiopulmonary disease

The involvement of the cardiopulmonary system is the leading cause of morbidity and mortality.[11,13] Pericardial effusions are usually small and asymptomatic, although fever and retrosternal pain may accompany acute disease. Severe cardiomyopathy is rare, although it can be one of the causes of early death and require prompt and aggressive immunosuppressive treatment.[13]

Cardiac ischaemia may result from the equivalent of Raynaud's phenomenon of the coronary arteries and is a potential precursor of myocardial fibrosis.

Pulmonary disease is initially asymptomatic but later on it may be revealed by dry, hacking cough or dyspnoea on exertion and by rales or pleural friction rubs on physical examination. Pulmonary artery hypertension occurs in 7% of JSSc patients and, as in adults, may be an isolated vascular complication or consequence of pulmonary fibrosis.[5,12]

Renal disease

The kidney is rarely involved in JSSc. In the Padua database, 5% of the patients had renal involvement as increased urinary protein secretion or raised creatinine level, and only one patient developed renal crisis.[5] Since in adult patients the presence of anti-topoisomerase I antibody, rapidly progressing skin involvement, and high-dose steroids are predictors of early and often severe renal and cardiac involvement,[14] close monitoring of blood pressure and renal function in patients treated with steroids is recommended.

Neurological involvement

The rare neurological involvement consists of cranial neuropathy, especially of the sensory branch of the trigeminal nerve, or peripheral neuropathies.[5,15] Involvement of the central nervous system (CNS), as hypertensive encephalopathy, is usually a reflection of renal or pulmonary disease.

Differences from adult disease

As compared with adults, at diagnosis, children show a significantly less frequent involvement of all organs, except for the prevalence of arthritis which is equally frequent.[5,12,16] Differences from adults become less evident during follow-up with the exception of interstitial lung involvement, gastroesophageal dysmotility, and renal involvement which are significantly much more common in adults. Arthritis and muscle inflammation are slightly more common in children.[7] The limited cutaneous form, which is by far the most frequent in adults, is rare in children. It is possible that this subset may be underdiagnosed because young children with just isolated Raynaud's phenomenon and capillaroscopy changes are diagnosed during adolescence or early adulthood when the other typical features appear.

Differential diagnosis

Because JSSc usually involves internal organs, muscles, and skin, the differential diagnosis includes many disorders such as juvenile dermatomyositis mixed connective tissue disease, and other undifferentiated connective tissue diseases. In the following section the most common non-rheumatological conditions which enter into the differential diagnosis with JSSc are described.

Chronic graft-vs-host disease

Chronic graft-vs-host disease (GVHD) is a complication of allogeneic bone marrow transplantation for the treatment of marrow aplasia, leukaemia, or malignant diseases. GVHD results from the interaction between immunocompetent T lymphocytes from the donor and host cells bearing histocompatibility antigens that are recognized as foreign. The resulting scleroderma-like disease may follow acute GVHD or occur de novo up to 100 days after transplantation. It is characterized by dermatitis, usually beginning with erythema of the face, palms, soles and followed by hyper- or hypopigmentation. A hidebound skin and extreme tightening of the tendons and periarticular structures may severely limit motion. The histology in GVHD and SSc is similar but not identical.[17] Recent modifications of the chemotherapeutic preparation of the graft recipient have reduced the incidence of this complication.

Chemically induced scleroderma-like disease

Several chemicals have been implicated in the induction of scleroderma.[18] Bleomycin, an antineoplastic agent, causes skin changes resembling scleroderma and pulmonary fibrosis. This syndrome is not accompanied by Raynaud's phenomenon and may improve on cessation of the drug. Pentazocine, a non-narcotic analgesic drug, has been reported to cause cutaneous sclerosis with or without ulceration.[18]

The toxic oil syndrome, caused by ingestion of rapeseed cooking oil that contained unidentified contaminants, occurred in epidemic proportions in Spain in the early 1980s, and indications are that complications have been less severe in children.[19] The onset of the disease was characterized by fever, eosinophilia, dyspnoea caused by pulmonary oedema, a pruritic rash, and malaise. Scleroderma-like changes, involving both skin and internal organs, evolved over a period of months.

Phenylketonuria

A minority of children with phenylketonuria develop sclerodermatous skin lesions.[20] These lesions, which usually appear within the first year of life, are symmetric, poorly demarcated, and occur most frequently on the lower extremities and trunk. After the introduction of newborn metabolic screening in many countries, this complication has almost completely disappeared.

Syndromes of premature ageing

Two rare autosomal recessive disorders accompanied by dwarfing, premature ageing, and early death from atherosclerotic heart disease are associated with sclerodermatous skin changes. In **progeria**, the cutaneous changes usually develop before 1 year of age and are characterized by thickened, bound-down skin on the abdomen, flanks, proximal thighs, and upper buttocks (Figure 122.4).[21] During the second year of life, the skin becomes thinner, subcutaneous vascularization is more evident, and alopecia and nail dystrophy develop. **Werner's syndrome** most often presents in adolescence with generalized atrophy of muscle and subcutaneous tissue, greying of the hair, baldness, and scleroderma-like skin changes and ulcers involving the extremities.[22]

Fig. 122.4 Generalized trunkal sceroderma.

Scleroedema

Scleroedema is characterized by edematous induration of the face, neck, shoulders, thorax, and proximal extremities, but not the hands.[23] It usually follows β-haemolytic streptococcal infection with insidious onset and spontaneous resolution after 6–12 months. Dysphagia may be present, but Raynaud's phenomenon and telangiectases are not. Histologically, the dermis is thickened; there are multiple fenestrations between swollen collagen bundles, a scant perivascular lymphocytic infiltrate, and minimal deposits of acid mucopolysaccharides.

Autoantibodies

High-titre ANA are frequently present from the disease onset. The predominant patterns on HEp-2 cell substrate are speckled and nucleolar. ANA seropositivity in two large paediatric series was 81–97%, which is slightly lower than that reported in adults.[5,12] Anti-topoisomerase I (anti-Scl-70) autoantibodies are present in 28–34% of patients, while the prevalence of anti-centromere antibodies is lower in children than in adults (7% vs 23%).[5,16]

Anti-PM-Scl and anti-U1RNP antibodies correlate with scleroderma in overlap syndromes with muskuloskeletal involvement. Anti-RNA-polymerase III antibody is very unusual, in parallel with the rarity of renal involvement in JSSc.[12]

The frequency of rheumatoid factor (RF) and anti-cardiolipin antibodies (aCL) is similar in adults and children with SSc (RF17% vs 23%; aCL14.8% vs 10%).[5,16]

Clinical assessment and monitoring

Assessment of disease activity and severity in JSSc is difficult. For organ-based complications such as cardiac abnormalities, pulmonary fibrosis, pulmonary hypertension, or renal involvement, objective assessment is possible.

Electrocardiographic abnormalities include first-degree heart block, right and left bundle branch block, premature atrial and ventricular contractions, and non-specific T-wave changes. The most frequent cardiac arrhythmias in children are supraventricular, whereas ventricular arrhythmias do not occur very often.[24] Echocardiographic abnormalities in addition to pericardial effusions include thickening of the left ventricular wall and decreased left ventricular compliance. The two-dimensional echocardiogram is important in confirming early pulmonary hypertension by documentation of a dilated right ventricle with thickening of the ventricular wall and straightening of the septum. Right heart catheterization provides definitive confirmation but is often unnecessary.

Characteristic findings of respiratory tract involvement include a decrease in timed vital capacity (FVC) and forced expiratory flow (FEV), and decrease in CO diffusion (DL_{CO}).[25] Radiographic changes on chest radiograph correlate poorly with pulmonary function. High-resolution CT (HRCT) may confirm pulmonary disease despite a normal chest radiograph. In children, the most frequent HRCT findings are ground-glass opacification, subpleural micronodules, linear opacities, and honeycombing.[26]

Gastrointestinal involvement can be assessed by cine-oesophagogram that may document decreased or absent peristalsis in the lower part of the oesophagus with distal dilatation and, frequently, stricture and shortening of the oesophagus. Oesophageal motility studies by manometry and pH probe monitoring of the distal oesophagus for 12–24 hours provide more sensitive indicators of diminished lower sphincter tone and the presence of reflux.[27]

Skin involvement can be quantified by the modified Rodnan skin score (MRSS). The role of capillaroscopy in children is similar to that of adults and is discussed further elsewhere (Chapter 121).

A multidimensional severity score, named "J4S", an acronym which stays for Juvenile Systemic Sclerosis Severity Score, including growth parameters, skin and internal organs involvement has been recently reported[28] This is a simple instrument to assess disease severity in JSSc which includes nine clinical categories, scored from 0 to 8, weighting various organ involvements on the basis of their clinical importance. J4S may have several applications for the pediatric age group since it can be used, in daily clinical practice, to guide decision-making, to compare study populations and to identify potentially reversible aspects of the disease.

Treatment

The pharmacological management of patients with JSSc is challenging since no drug has been shown to be of unequivocal benefit in either children or adults with systemic sclerosis (Figure 122.5). Recently, an European League Against Rheumatism (EULAR) task force, including paediatric rheumatologists, has proposed some recommendations for the management of SSc.[29] As first-line therapy for Raynaud's phenomenon, calcium channel blockers, such as nifedipine or nicardipine, should be considered. For severe Raynaud's phenomenon with ischaemic digits or digital ulcers, iloprost, or other available intravenously delivered prostanoids, should be used.[30,31] Cyclophosphamide represents the drug of choice for the treatment of interstitial lung disease and, according to the experience in juvenile systemic lupus erythematosus (SLE), it should be administered as intravenous pulse therapy at a dosage of 0.5–1 g/m² every 4 weeks for at least 6 months.[32] To prevent cystitis, adequate hydration and frequent voiding must be emphasized.

Glucocorticoids, preferably prednisone at a dosage of 0.3–0.5 mg/kg per day, should be reserved for the treatment of myositis, arthritis, and tenosynovitis. Since several studies suggest that steroids are associated with a higher risk of scleroderma renal crisis, blood pressure and renal function should be carefully monitored. Methotrexate has been shown to improves skin score in early diffuse SSc in adults.[33] Accordingly, methotrexate should be the treatment of choice for the skin manifestations also for JSSc, especially in the early phase. With the same indication, mycophenolate mofetil may be a good alternative to methotrexate, especially in refractory disease or in case of intolerance[34].

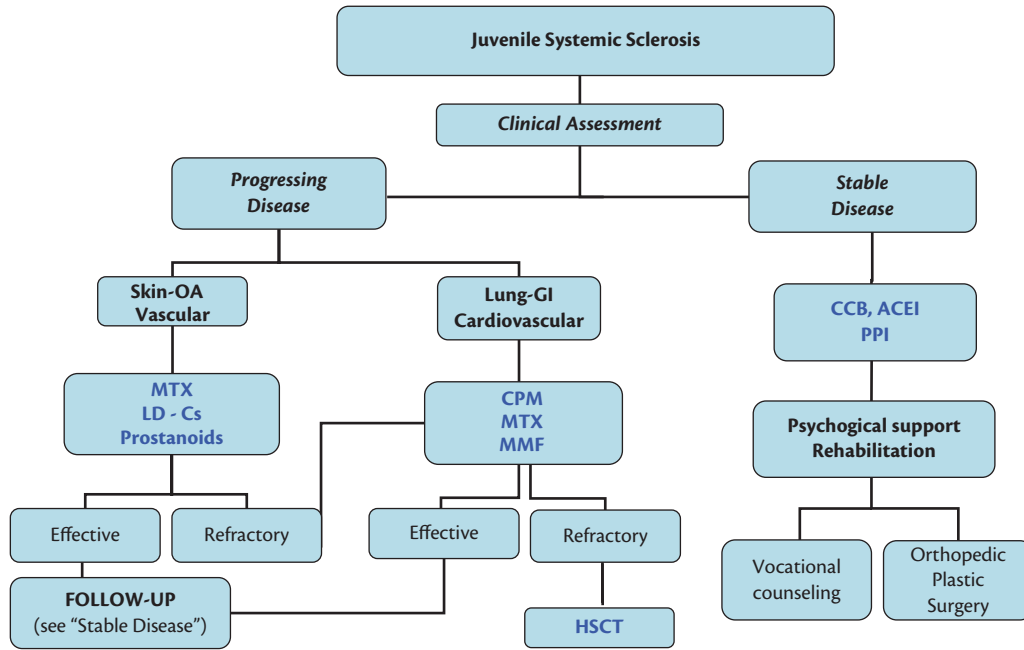
Symptomatic treatments are essentially based on the principle of good clinical practice and include the use of proton pump inhibitors, such as omeprazole and lansoprazole, for prevention of gastroesophageal reflux disease and oesophageal ulcers; the use of prokinetic drugs, such as domperidone, for the management of symptomatic motility disturbances; and rotating antibiotics, such as metronidazole, ciprofloxacin, and doxycycline, to treat malabsorption due to bacterial overgrowth. Angiotensin converting enzyme (ACE) inhibitors (e.g. captopril, losartan) are effective for the long-term control of blood pressure and stabilization of renal function of scleroderma renal crisis.[35] With regard to new experimental drugs, such as bosentan and sildenafil for pulmonary arterial hypertension and digital ulcers, the paediatric experience is encouraging although still anecdotal.[36,37]


Fig. 122.5 Proposed flowchart for the management of juvenile systemic sclerosis.

One of the most innovative although aggressive approaches to therapy is immunoablation followed by reconstitution with autologous haemopoietic stem cell transplantation (HSCT). The rationale for this therapy is the ablation of self-reactive lymphocyte clones to block the autoimmune process. Recent studies reported that HSCT improved the skin score for 69% of patients, did not affect lung function, but halted pulmonary hypertension.[38] However, disease progression occurred in 19%, and 17% died of complications related to the procedure.[38] Because of this high mortality rate, HSCT should be carefully considered for paediatric patients, and it may only be a rational therapy early in the disease course before irreversible damage has resulted.

Course of the disease and prognosis

The ultimate prognosis of the child with JSSc depends primarily on the extent of visceral involvement. Skin tightness and joint contractures inevitably lead to severe disability. Cardiac arrhythmias may result from myocardial fibrosis and congestive heart failure is often a terminal event. Pulmonary interstitial disease and vascular lesions are probably universal, even if not clinically evident. Renal failure or acute hypertensive encephalopathy supervenes as a potentially fatal outcome in a few children. Nevertheless, the overall prognosis of SSc in children appears better than in adults. The survival of childhood-onset SSc at 5, 10, 15 and 20 years after diagnosis is 89%, 80–87.4%, 74–87.4%, and 69–82.5%, respectively—significantly higher than in adult-onset disease.[11,39] Death in JSSc is usually related to the involvement of cardiac, renal, and pulmonary systems.[11] Cardiomyopathy early in the disease course is rare and usually associated with diffuse cutaneous disease and features of polymyositis. An aggressive immunosuppressive treatment has been shown to be effective on muscle, skin, and lung involvement but hardly impairs progression of myocardial dysfunction.[11,13]

Localized sclerodermas

Localized sclerodermas are a group of disorders whose manifestations are confined to the skin and subdermal tissues and, with some exceptions, do not affect internal organs. There is no accepted uniform terminology; dermatologists typically use the term 'morphoea' and rheumatologists tend to use the term 'localized scleroderma' to refer to the same group of conditions.

Definition and classification

Localized scleroderma (LS) includes a number of conditions that are often grouped together. The classification used most widely currently includes five subtypes: circumscribed morphoea, linear scleroderma, generalized morphoea, pansclerotic morphoea, and the new mixed subtype where a combination of two or more of the previous subtypes is present (Table 122.2).[40]

- **Circumscribed morphoea** (CM) is characterized by oval or round circumscribed areas of induration with a central waxy, ivory colour surrounded by a violaceous halo (Figure 122.6). The superficial variety is usually confined to the dermis. Very rarely lesions are small, less than 1 cm in diameter (guttate). In the deep variety the entire skin feels thickened, taut, and bound down, and the primary site of involvement is the panniculus or subcutaneous tissue. CM lesions occur most frequently on the trunk and less often on the extremities or face.

- **Generalized morphoea**: This term is used when four or more individual plaques larger than 3 cm become confluent, involving at least two out of seven anatomical sites (head–neck, right upper extremity, left upper extremity, right lower extremity, left lower extremity, anterior trunk, posterior trunk) (Figure 122.7).

- **Linear scleroderma** is the most common subtype in children and adolescents.[41] It is characterized by one or more linear

Table 122.2 Preliminary classification of juvenile localized scleroderma

Type	Subtype	Features
1. Circumscribed morphea	(a) Superficial	Oval or round circumscribed areas of induration limited to epidermis and dermis, often with altered pigmentation and violaceous, erythematous halo (lilac ring). The lesions can be single or multiple
	(b) Deep	Oval or round circumscribed deep induration of the skin involving subcutaneous tissue extending to fascia and underlying muscle. The lesions can be single or multiple
		Sometimes the primary site of involvement is in the subcutaneous tissue without involvement of the skin
2. Linear scleroderma	(a) Trunk/limbs	Linear induration involving dermis, subcutaneous tissue and, sometimes, muscle and underlying bone and affecting the limbs and/or the trunk
	(b) Head	*En coup de sabre* (ECDS)—linear induration of the skin that affects the face and/or the scalp and sometimes involves muscle and underlying bone
		Parry–Romberg or progressive hemifacial athrophy—loss of tissue on one side of the face that may involve dermis, subcutaneous tissue, muscle. and bone. The skin is unaffected and mobile
3. Generalized morphoea		Induration of the skin starting as individual plaques (4 or more, >3 cm) that become confluent and involve at least two anatomical sites
4. Pansclerotic morphoea		Circumferential involvement of limb(s) affecting the skin, subcutaneous tissue, muscle and bone. The lesion may also involve other areas of the body without internal organ involvement
5. Mixed morphoea		Combination of two or more of the previous subtypes. The order of the concomitant subtypes, specified in brackets, follows their predominant representation in the individual patient, e.g. 'mixed (linear-circumscribed)'

Adapted from Laxer and Zulian.[40]

Fig. 122.6 Circumscribed morphoea.

Fig. 122.7 Generalized morphoea.

streaks that typically involve an upper or lower extremity. With time, the streaks become progressively more indurated and can extend through the dermis, subcutaneous tissue, and muscle to the underlying bone (Figure 122.8). The lesions frequently follow a dermatomal distribution or Blaschko's lines[42] and are unilateral in 85–95% of cases.[41]

– The face or scalp may also be involved, as in the **en coup de sabre** (ECDS) variety. This term was applied historically because the lesion was reminiscent of the depression caused by a sword wound (Figure 122.9).

– The **Parry–Romberg syndrome** (PRS), characterized by a progressive hemifacial atrophy of the skin and tissue below the forehead, with mild or absent involvement of the superficial skin, is considered the severe end of the spectrum of ECDS

and for this reason included in the linear head subtype.[40,43] Evidence for this close relationship is the presence of associated disorders, including seizures and dental and ocular abnormalities, reported with similar prevalence in both conditions.[43]

In both circumscribed and linear morphoea subtypes, deep variants where the entire skin feels thickened, taut, and bound down can be present.[40]

◆ **Pansclerotic morphoea** is an extremely rare but severe disorder characterized by generalized full-thickness involvement of the skin of the trunk, extremities, face, and scalp with the sparing of the fingertips and toes (Figure 122.10).[44] The involvement of the entire body without internal organ involvement helps differentiate this from SSc. Recent reports have raised awareness of the possible evolution of chronic ulcers, frequently complicating

Fig. 122.8 Linear scleroderma.

Fig. 122.9 Linear scleroderma 'en coup de sabre'.

panensclerotic morphoea, to squamous cell carcinoma, a threatening complication already reported in SSc.[45,46]

- The **mixed subtype** results from a combination of two or more of the previous subtypes. The order of the concomitant subtypes, specified in brackets, follows their predominant representation in the individual patient, e.g. 'mixed (linear-circumscribed)'.[40]

Associated conditions

Other disorders not included in the more recent classification of LS can precede, follow, or be concomitant with LS.

- **Lichen sclerosus et atrophicus** is characterized by shiny white plaques often preceded by violaceous discoloration with some predilection for the anogenital area, wrists, and ankles. The superficial layers of the skin are usually involved.

- **Atrophoderma of Pasini and Pierini** is characterized by asymptomatic hyperpigmented atrophic patches usually on the trunk with well-demarcated borders. These lesions usually represent the end stage of LS.

Fig. 122.10 Pansclerotic morphoea.

- **Bullous morphoea** is a very rare subtype characterized by bullous lesions possibly resulting from a localized trauma or related to lymphatic obstruction from the sclerodermatous process.[47]

- In **eosinophilic fasciitis** the fascia is the predominant site of involvement.[48] The lesions typically involve the extremities, spare the hands and feet, and have an appearance that is described as 'peau d'orange'. Hypergammaglobulinemia and eosinophilia are often present.

Epidemiology

LS is more frequent than SSc but still a rare condition. In the general population the incidence of LS is 2.7 cases per 100 000,[49] and in children under the age of 16 years there are 3.4 cases per million per year.[3] In a population-based study of LS,[49] CM accounted for 56%, generalized morphoea for 13%, linear morphoea for 20%, and deep morphoea for 11%. The female-to-male ratio of LS is 2.4:1, the mean age at onset is approximately 7.3 years,[4] and there are no differences in the various LS subtypes.[41] The disease can start as early as at birth.[50] It can be misdiagnosed as skin infection, naevus, or salmon patch and this may lead to a consistent delay in diagnosis.

Aetiology and pathogenesis

The cause and pathogenesis of LS are unknown. Abnormalities of the immune system, regulation of fibroblasts, and production of collagen represent the most important points investigated

by experimental studies. Multiple studies have demonstrated increased levels of cytokines and other molecules that influence fibroblasts and collagen synthesis.[51] Autoimmunity, environmental factors, infection, and trauma have all been associated with localized disease. It seems certain that autoimmunity plays an important role because of the multiplicity of abnormal serum antibodies that occurs in patients with LS and because of the association of similar cutaneous abnormalities in patients with chronic GVHD.[52]

The clinical and histopathological similarities of LS to chronic GVHD have suggested that non-self cells or chimerism may be involved in the pathogenesis of the disease.[53] A large number of chimeric infiltrating cells, mainly epithelial or dendritic cells, have been found in biopsies of LS patients.

Some drugs and environmental toxins have resulted in scleroderma-like reactions, including bleomycin, ergot, bromocriptine, pentazocine, carbidopa, and vitamin K_1.[54]

A few studies have examined a putative association of LS and *Borrelia burgdorferi*, the spirochete that causes Lyme disease. Many studies have documented evidence of infection with *B. burgdorferi* in patients with morphoea who live in areas endemic for Lyme disease, or have a history of tick bites.[55] This was not confirmed in patients with morphoea who do not live in endemic areas.[56] Trauma has been implicated in the initiation of lesions and particularly with the onset of eosinophilic fasciitis.[41,57]

Extracutaneous manifestations

One-fifth of patients with LS present extracutaneous manifestations and 4% of them may have multiple features.[58] Extracutaneous findings are more frequent in patients with linear scleroderma and consist essentially of arthritis (19%), neurological findings (4%), or other autoimmune conditions (3%). In these patients, organ impairment is milder and not life-threatening compared to SSc.

Articular involvement is the most frequent extracutaneous feature, and is more common in patients with linear scleroderma. The joint involved may be completely unrelated to the site of the skin lesion. Children with LS who develop arthritis often have a positive RF,[41] and sometimes an elevated erythrocyte sedimentation rate (ESR).

The most frequent neurological conditions are seizures and headaches, although behavioural changes and learning disabilities also have been described.[58,59] Abnormalities seen on MRI, such as calcifications, white matter changes, vascular malformations, and changes consistent with CNS vasculitis, also have been reported.[60] Gastro-oesophageal reflux is the only gastrointestinal complication reported so far.[61] In a cohort of 14 consecutive patients, oesophageal involvement was found in 8 (57%), 7 had pathological pH test findings, and in 4 of them, concomitant oesophageal dysmotility was also present.[61]

Ocular involvement has been reported in 3.2% of patients affected by LS.[62] As expected, two-thirds of patients with ocular manifestations have the ECDS subtype but, interestingly, the other third have no facial skin lesion. The most frequent lesions (42%) are on eyelids and eyelashes; one-third consists of anterior segment inflammation, such as anterior uveitis or episcleritis, the remaining are mainly CNS-related abnormalities. Although extracutaneous manifestations should be considered on every patient with LS, routine screening for internal organ manifestations (other than uveitis in linear scleroderma of the face) is generally not recommended.

Differential diagnosis

LS should be differentiated from systemic disease. In the most common form, linear scleroderma, the lesions are discrete, limited to a single extremity, and easily differentiated from SSc. The more difficult diagnostic challenge is to differentiate SSc from the diffuse and deep forms, such as pansclerotic morphoea. These patients, in contrast to those with SSc, rarely have Raynaud's phenomenon and do not develop symptomatic evidence of internal organ involvement. Occasionally, the deep forms of LS may be confused with juvenile idiopathic arthritis in that they can manifest with contractures of the hands, arthralgias, and sometimes synovitis and may have a positive RF test result. In cases such as these, further testing may document the presence of anti-histone antibodies, hypergammaglobulinaemia, and eosinophilia typical of the deep varieties of LS.

Laboratory findings

The diagnosis of LS is established on clinical grounds; no laboratory abnormality is diagnostic. Routine laboratory tests such as a complete blood cell count, blood chemistries, and urinalysis are normal. The acute-phase reactants, ESR and C-reactive protein (CRP), are usually within the normal ranges with the exception of the deep subtypes in which eosinophilia and hypergammaglobulinaemia may be found.[41,63]

RF is present in 25–40% of patients[41,58] and is often related to the presence of articular involvement.[4]

Autoantibodies are found in many patients with LS. ANA can be present in any subtype, with a frequency ranging from 23% to 73%.[41,63] Anti-histone antibodies (AHA) have been detected in 47% of patients with LS with a different prevalence in the various subtypes—higher in generalized morphoea, lower in CM.[64]

Anti-topoisomerase I antibodies (anti-Scl 70), a marker of SSc in adults, were found to be positive in 2–3% of children with LS but not in adults with LS.[41,64] Conversely, anti-centromere antibodies (ACA) were found in 12% of adults with LS but only in 1.7% of children.[41,65] Anti-DNA topoisomerase IIα antibodies (anti-topo IIα) were detected in 76% of patients with LS and in 85% of those with generalized morphoea.[66] Immunoblotting showed no cross-reactivity of anti-topo IIα with anti-topo I autoantibodies, which are almost exclusively detected in SSc. Anti-topo IIα, however, is not completely specific for LS, being present also in patients with SSc (14%), in those with SLE (8%), and even in dermatomyositis (10%). Anti-cardiolipin antibodies (aCL) have been found in 46% of the patients with LS and lupus anticoagulant (LAC) in 24% while β2-glycoproteinI (β2GPI) antibodies were absent.[67] In children aCL were found in 12.6% of patients.[41]

Serum concentrations of soluble interleukin(IL)-2 receptor have been increased in cases of LS and may differentiate active from inactive disease,[68] although this finding is not supported by all studies.[57]

Disease monitoring

Various methods for the clinical monitoring of LS have been developed but none has been validated in large cohort of patients.

A semiquantitative scoring method, the Localized Scleroderma Severity Index (LoSSI), is based on the evaluation of three parameters: lesion extension, intensity of inflammation, and new lesion development or existing lesion extension.[69] The extension score is based on the evaluation of 14 cutaneous anatomic sites, each

divided into 3 segments; the intensity score is related to the degree of erythema of the lesion's edge and/or skin thickness by palpation. The last parameter is calculated on the basis of the appearance of new lesions or enlargement of the existing ones. The overall composite score ranges between 0 and 168. The limitation of this method is that it is quite subjective and does not evaluate the real size of the lesions.

A computerized skin score (CSS) method for the measurement of circumscribed lesions allows a more precise evaluation of the extension of each lesion.[70] It involves demarcating the indurate borders of the scleroderma lesions on an adhesive transparent film, transferring them to a card, scanning, and recording the data in a computer. Calculation of the affected area, performed by computer software, takes into account the child's growth and in this way allows the longitudinal monitoring of the lesions.

Infrared thermography (IT) has been shown to be of value in the detection of active LS lesions in children with high sensitivity (92%) but low specificity (68%).[71] The false-positive results are related to the fact that old lesions lead to a marked atrophy of skin, subcutaneous fat, and muscle, with increased heat conduction from deeper tissues. Laser doppler flowmetry (LDF) is another non-invasive method for the measurement of cutaneous microcirculation for the evaluation of scleroderma lesions.[72] LDF can detect the increase of blood flow in clinically active lesions. It represents a complementary tools in evaluating LS in the sense that while IT can quantitate thermographic changes of visible lesions and may reveal hidden active lesions, LDF can confirm the presence of active lesion and exclude activity in atrophic lesions. High-frequency ultrasound can detect several abnormalities of LS lesions such as increased blood flow, increased echogenicity due to fibrosis. and loss of subcutaneous fat[73]. The main limits of this tool are its operator dependency and the lack of standardization.

The use of MRI is indicated when CNS or orbital involvement are suspected,[74] and to demonstrate the depth of soft tissue lesions in the deep subtypes of LS.[75]

Treatment

Over the years, many treatments have tried for LS.[76] Management decisions must be based on the particular subtype of disease and the fact that these disorders may spontaneously enter remission after 3–5 years (Figure 122.6).

CM is generally of cosmetic concern only, and treatments with potentially significant toxicity are not justified., Treatment should therefore be directed towards topical therapies such as moisturizing agents, topical glucocorticoids, or calcipotriene.[76]

Phototherapy with ultraviolet (UV) represents another possible therapeutic choice for LS.[77] The use of UV light therapy, with or without chemical agents such as psoralen, has been reported to be beneficial for localized or superficial lesions in a number of studies. Limitations for the use of UV phototherapy in children are the need for prolonged maintenance therapy, leading to a high cumulative dosage of irradiation, and the increased risk for potential long-term effects such as skin ageing and carcinogenesis.[78]

The use of vitamin D or its analogues (topically and systemically) has been reported in several case series,[76] but in the only controlled trial, results did not show efficacy higher than placebo.[79]

When there is a significant risk for disability, such as in progressive linear scleroderma crossing joint lines and generalized or pansclerotic morphoea, systemic treatment, particularly with methotrexate, should be considered.[76] A weekly regimen of methotrexate of 10–15 mg/m^2 as a single oral or subcutaneous dose per week is recommended. During the first 3 months of therapy, a course of glucocorticoids should be used as adjunctive 'bridge therapy'. Recently, a randomized trial comparing a 12 month course of oral methotrexate (15 mg/m^2) for 12 months with a 3 month course of oral prednisone (1 mg/kg per day, maximum dose 50 mg) showed that methotrexate was effective and well tolerated in more than two-thirds of patients with JLS.[80] New lesions appeared in only 6.5% of methotrexate-treated patients compared with 16.7% of the prednisone group. Patients who do not respond to this treatment may be treated with mycophenolate mofetil at a dose of 500–1000 mg/m^2.[81] There are, to date, no published trials of biologics or combination treatments. Surgical reconstruction may be required if the disease has not been adequately controlled. Surgery should only be performed after the active phase of the disease has abated and when the child's growth is complete. Facial recontouring is a surgical treatment option that may improve quality of life in adolescents with facial asymmetry due to scleroderma ECDS.[82]

Course of the disease and prognosis

Unlike SSc, the prognosis with regard to survival for LS is usually benign. The course is characterized by an early inflammatory phase, with progression to multiple or extensive lesions, then stabilization, and finally improvement with softening of the skin and increased pigmentation around the lesions. In a population-based study of LS,[49] 50% of patients had documented skin softening of 50% or more or had disease resolution by 3.8 years after the diagnosis. A small number of patients had active disease for more than 20 years. One-fourth of patients with linear scleroderma and 44% of those with deep morphoea developed significant disability. Progression to systemic sclerosis occurs rarely in children.[83]

Nephrogenic systemic fibrosis

Cate H. Orteu

Introduction

The first cases of nephrogenic systemic fibrosis (NSF) were identified in 1997 and published by Cowper in 2000.[1] He described a scleromyxoedema-like cutaneous fibrotic disease in patients with renal impairment. The common features of renal insufficiency and cutaneous fibrosis initially prompted the name nephrogenic fibrosing dermopathy (NFD).[2] When autopsy studies later showed evidence of systemic organ involvement the name was changed to NSF.[3]

Gadolinum-based contrast agents (GBCAs) are intravenous drugs used in diagnostic MRI procedures to enhance the image quality. In 2006 a temporal relationship between the use of GBCAs and the onset of symptoms of NSF was identified.[4,5] Subsequently, gadolinium (Gd) deposits were identified in affected skin,[6,7] and a significant association between GBCA exposure and NSF (odds ratio 26.7, 95% confidence interval 3.7–69.4) was confirmed.[8] Previous gadolinium exposure is documented in 89% of biopsy-proven published cases.[9] Its precise role and mode of action in triggering fibrosis in NSF is still the subject of investigation.

Epidemiology

In December 2011, there were 580 unconfounded cases of NSF in which a single type of GBCA was implicated cited on the European Medicines Agency (EMA) website,[10] 613 on the United States Food and Drug Administration (FDA) Medwatch website,[11] and over 360 cases being followed at the Yale international NSF disease registry.[12] NSF affects males and females equally and has been found in all ethnic groups. The mean age of onset is 52 years, with an age range of 8–87 years. The documented prevalence of NSF, based on clinical examination and skin biopsy, is 0.77% and 0.64% in cohorts of haemodialysis patients from Scotland and the United States respectively.[13,14] The prevalence of NSF in renal failure patients exposed to GBCA varies from 0–18%.[9] This variability reflects the type of GBCA used, the dose, the time interval in between doses, and the severity of underlying renal insufficiency. In commercially available contrast agents, Gd is bound to a ligand or chelate, to render it less toxic. Ionic and non-ionic, linear and cyclical preparations are available (Table 123.1). The stability of the Gd–chelate

complex is dependent on its configuration and charge. In vitro, linear chelates are the least stable, and ionic macrocyclic chelates the most stable (by a factor of 10^5).[15] The greatest number of NSF cases are documented following exposure to the linear forms gadodiamide, gadoversetamide, and gadopentate dimeglumine,[10] which are more likely to release Gd into the tissues. Until 2008 these three products accounted for a majority of GBCA use worldwide. There are very few unconfounded cases reported after the use of macrocyclic GBCAs. Three cases have been attributed to gadobutrol, one of whom had had gadodiamide 7 years previously,[16,17] one case following multiple doses of gadoteridol,[18] and one after gadoterate, although this patient received another unknown GBCA 9 years earlier.[19] High cumulative GBCA exposure and administration of higher dosages (0.3 vs 0.1 mmol/kg) at shorter intervals have also been implicated.[20,21] High-dose GBCA was given in 87.5% of cases.[9,22] In one study, prevalence after exposure to two gadodiamide injections was 36% in patients with chronic kidney disease (CKD) stage 5.[23]

The incidence of new cases has reduced dramatically since 2007–2008 when screening of renal function was introduced and high-risk linear GBCAs became contraindicated in patients with glomerular filtration rate (GFR) less than 30 mL/min/1.73 m^2. The EMA now also recommends the avoidance of repeated GBCA exposures during the same imaging session and within 1 week of exposure, the avoidance of use in patients over 65 years and under 4 weeks of age, and in the peritransplant period for patients receiving liver transplants. A blood screen for renal function is recommended for all patients and mandatory for those given high-risk products. Additional recommendations include limiting the GBCA dose to 0.1 mmol/kg per scan, dialysing dialysis patients promptly after GBCA exposure, and delaying GBCA administration in patients with acute renal failure until renal function has recovered or dialysis has been initiated.[10,24]

Aetiopathogenesis

Risk factors for developing NSF have been identified. Renal impairment is present in 100% of cases and the highest risk is seen in patients with CKD 4 and 5 (GFR <30 mL/min).[19,21–23] In 79–85% of published cases, patients were on dialysis.[9,22] More rarely, NSF

Table 123.1 Types of gadolinium contrast agent and numbers of associated cases of nephrogenic systemic fibrosis

Gadolinium			NSF cases reported Unconfounded	Confounded
Linear	Non-ionic	Gadodiamide, Omniscan*	438	90
		Gadoversetamide, OptiMARK *	7	11
	Ionic	Gadopentetate dimeglumine, Magnevist *	135	276

has been described in patients with CKD 3 (GFR 30–60 mL/min). In some of these cases, the eGFR may have been overestimated because of acutely deteriorating renal function. A recent meta-analysis suggests that patients with liver disease in the peritransplant period are at increased risk as a result of their susceptibility to acute renal impairment, rather than as a result of their liver disease per se.[25]

Several different lines of investigation support Gd as the main trigger for NSF. NSF usually develops 2–10 weeks (median 5 weeks) after Gd exposure.[22] Some cases have presented over a year later, and the role of Gd in these cases is controversial. One possible explanation for a delayed presentation may be that Gd, deposited in bone in individuals with normal renal function,[26] is later released from bone if renal function deteriorates. In patients with renal failure, the elimination half-life of GBCA is increased substantially from 1.3 to 120 hours, dramatically increasing the exposure time of tissues to Gd.[15,26]

Since not all renal failure patients exposed to GBCA develop NSF, other cofactors are likely.[20,21] Proinflammatory events such as recent vascular surgery, recent renal transplant failure, hypercoagulability, and thrombotic events often precede the onset of NSF.[20] Many such events may be associated with acute kidney injury (AKI) and/or be investigated using MR angiography or venography requiring high-dose Gd. In one study, concurrent infection resulted in a 25-fold increased risk of developing NSF.[27] The use of high-dose erythropoietin, universal in patients with endstage renal failure, may also contribute, since combinations of iron and erythropoietin enhance the cutaneous changes triggered by Omniscan in rats.[28]

Gd release from its chelate is influenced by the presence of ligands with high affinity for Gd, such as phosphate and carbonate, and/or the presence of metals that have high affinity for the Gd-binding ligand, such as Zn^{2+}, Cu^{2+}, or Fe^{3+}.[15] These metals compete with Gd and displace it from its ligand by a process known as transmetallation. Gd is then 'free' to be deposited in the tissues as insoluble Gd phosphate. Scanning electron microscopy together with energy-dispersive spectroscopy has confirmed the presence of such deposits in NSF lesional skin.[6,7] Frenzel et al. showed that the dissociation of Omniscan occurs from day 1 in human serum and the release of free Gd^{3+} increases to over 20% over a 2 week period.[28] At low pH and in the presence of hyperphosphataemia, both often present in patients developing NSF,[21] the rate of Gd release is increased.[28] The Klotho protein signalling pathway and fibroblast growth factor-23 (FGF-23) may provide a link between renal impairment, hyperphosphataemia, and NSF.[17] FGF-23 is a phosphate-lowering factor. Klotho protein is responsible for converting FGF I (IIIc) receptor to a specific receptor for FGF-23. In renal failure, circulating FGF-23 levels increase, but the ability of the kidney to produce Klotho protein falls. As a result, phosphate levels may go unchecked, and excess FGF-23, unable to act on its own receptor, might cause fibrocyte activation via non-specific stimulation of other FGF receptors.

Further supportive evidence of a role for Gd comes from animal models.[26,28] In rats Gd has been identified in organs including skin, liver, and femur after injection of linear but not macrocyclic GBCAs. Repeated intravenous administration of linear, but not macrocyclic, GBCA can induce erythematous, ulcerated, crusted skin lesions with cellular infiltration and thickened collagen consistent with human NSF lesions. Upregulated production of proinflammatory and profibrotic cytokines including TIMP-1, tumour necrosis factor alpha (TNFα, and osteopotin have been observed in serum in this model.[29,30] Osteopontin regulates macrophage activity in response to calcification and cell–matrix interaction, and is a chemoattractant for dendritic cells and T lymphocytes, whereads TIMP-1-inhibits extracellular matrix (ECM) degradation. In humans, Gd compounds can upregulate expression of profibrotic cytokines and growth factors from peripheral blood mononuclear cells, and stimulate normal human fibroblasts in culture to proliferate and secrete increased amounts of ECM, hyaluronic acid, and collagen.[31] This effect can also be produced with the more stable macrocyclic GBCAs, but requires 10^5-fold higher doses.[32] These studies suggest that multiple repeat injections of low-stability GBCAs, even in the absence of renal impairment, could lead to gradual accumulation of Gd^{3+} in tissues until it reaches a level that triggers the fibrotic process.

Definitions and diagnostic criteria

The diagnosis of NSF is based on the presence of characteristic clinical features in the setting of CKD, and substantiated by skin histology on a deep biopsy extending at least into subcutaneous fat. Visualization and quantitation of Gd cannot be performed in most laboratories and is not essential to the diagnosis. A recent clinico-pathological scoring system to aid in diagnosis has been published by Cowper's group.[33]

Clinical features

In the early stages, erythema and oedema may predominate, often associated with burning pain or itch. Thickened erythematous to brawny plaques, papules, and nodules develop, producing a peau d'orange, cobblestone, or woody indurated appearance (Figure 123.1).

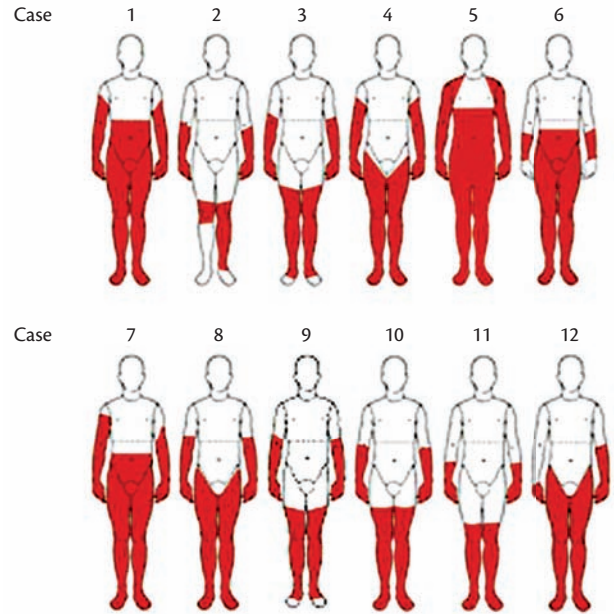
The pattern of cutaneous involvement is generally symmetrical, most commonly involving the extremities, especially the lower limbs (Figure 123.2).[34] In some series it was worse over fistula sites.[34] The trunk may be involved, but in contrast to scleroderma and scleromyxoedema, the face is spared. Rarely, diffuse involvement of the limbs, more closely resembling scleroderma, is seen. The cutaneous changes generally evolve over weeks, but in 5% a fulminant course is described.[12] Around 60% of patients develop joint contractures and reduced mobility. Other changes include yellow scleral plaques resembling pingueculae present in 20/408 published cases.[9] Autopsy studies have confirmed that NSF is associated with


Fig. 123.2 Pattern of cutaneous involvement in 12 patients with nephrogenic systemic fibrosis.

fibrotic damage to internal viscera including the heart, lungs, liver, oesophagus, skeletal muscle, dura, kidneys, and rete testes.[3,34] Calcification may also be present. Internal organ involvement was documented in 16/408 biopsy-confirmed published cases of NSF.[9]

Increased dermal cellularity with spindle and/or epithelioid cells is a key histopathological feature.[33] There is typically a massive infiltration of the dermis with CD34+ spindle-shaped and dendritic fibrocytes (Figure 123.3).[2,33,34]. These cells are thought to derive from the circulation and resemble cells which normally infiltrate injured tissue and are involved in wound healing. They exhibit dual staining with procollagen I. CD34+ cells may be less numerous during the later stages of the disease.[2,33] Elastic fibres are generally preserved and tram-tracking of CD34+ cell processes around a central elastic fibre is another key feature.[33] Small spicules of bone developing around elastic fibres are an uncommon but specific feature.[33] Mono- and multinucleate cells, dual staining for CD68 and factor XIIIa, may be present.[34] There are increased numbers of haphazardly arranged thick and thin collagen bundles throughout the dermis, surrounded by clefts. The process involves the entire dermis and extends deep, causing a widening of the septae of the subcutaneous fat, and sometimes extending into muscle. A variable increase in dermal mucin is seen.

Scleromyxoedema, scleredema, scleroderma, and eosinophilic fasciitis are the most important differential diagnoses (Table 123.2). Lipodermatosclerosis, porphyria cutanea tarda (sclerodermoid variant), and in the acute stages calciphylaxis, cellulitis, and panniculitis, should also be considered.

The prognosis is difficult to predict. A recent review by Zou identified 55/248 published cases in whom the disease improved, 63/248 in whom it remained stable, 25/248 in whom it progressed. 71 patients died. Although only 3 deaths were directly attributed to NSF, it may have contributed to death through reduced mobility, thrombotic complications, and malnutrition in others.[9]

Fig. 123.1 Well-defined erythematous to brawny indurated plaques on the leg in a 34 year old woman with nephrogenic systemic fibrosis.
Fig. 123.3 Histopathological features in nephrogenic systemic fibrosis: (A) Low-power view, H&E stain ×40 mag, showing a markedly increased cellularity in the expanded dermis. Spindle and dendritic cells stain positively with CD34 (×40 mag). CD68+ epithelioid and dendritic cells are identified (×200 mag). Alcian blue stain reveals an excess of interstitial mucin (×100 mag). Elastic Van Giesen stain confirms preservation of the elastic network (×100 mag). (B) High-power view, H&E stain (×100 mag), showing increased numbers of spindle-shaped cells extending deep into the subcutis, in between the fat lobules. (C) High-power view, H&E stain (×100 mag), showing increased numbers of haphazardly arranged thick and thin collagen bundles separated by mucin-filled clefts (as seen on alcian blue stain).

Management

Improvement in renal function and renal transplantation have been associated with improvement or resolution of disease in some patients; up to 40% of cases in some reports.[9] Pain control and physical therapies to maintain mobility are essential. Most treatments are reported in anecdotal cases and small case series.[35] High-dose corticosteroids, thalidomide, methotrexate, pentoxifylline, cyclophosphamide, plasmapheresis, and intravenous immunoglobulins have all been tried but with generally disappointing results. More promising responses have been documented following prolonged extracorporeal photopheresis, ultraviolet UVA1 phototherapy, intravenous sodium thiosulphate, rapamycin, and more recently imatinib. Imatinib is an inhibitor of Abelson kinase (c-Abl) and platelet-derived growth factor (PDGF). c-Abl kinase is a target of transforming growth factor beta 1 (TGF-β1) signalling. This cytokine stimulates fibrocytes and its expression is upregulated in the tissues of patients with NSF.[30] Several reports have suggested that imatinib is effective in preventing and reversing fibrosis in some patients with NSF.[36]

Prevention is key. Current recommendations are that GBCA should be avoided, unless essential, and particularly in acute renal failure until after renal function returns or dialysis is initiated. Dosage should be maintained at 0.1 mmol/kg or below, and repeated exposures avoided, particularly within a week of each other. Cyclic ionic compounds should be used as first line in all patients with eGFR less than 30 mL/min, especially when there are associated proinflammatory conditions. All patients should have blood taken to screen for renal dysfunction.[10] Patients already on haemodialysis should be dialysed within 24 hours of receiving gadolinium. This approach seems to be effective. Perez Rodriguez showed a dramatic effect of risk factor screening on the incidence of NSF, reducing it from 36.5 cases/100 000 Gd-enhanced MRI in 2003–2006, to 4 cases/100 000 in 2007–2008.[37]

Conclusion

NSF is a systemic fibrosing condition which occurs in patients with renal impairment following the use of GBCA. The type (linear non-ionic), dose (>0.3 mmol/kg) and overall amount of Gd exposure, and degree of renal impairment (CKD5>CKD3) are important risk factors. Other cofactors include the presence of a metabolic acidosis and hyperphosphataemia which both increase the likelihood of Gd dissociation from its chelate and deposition in the tissues.

Table 123.2 Differential diagnosis of nephrogenic systemic fibrosis: comparative features of related skin diseases

	Nephrogenic systemic fibrosis	Eosinophilic fascitis	Scleromyxedema	Scleredema	Scleroderma
Collagen	Increased thick and thin collagen collagen, haphazard orientation	Thickened increased collagen	Thickened increased collagen, clefting	Swollen collagen bundles look fenestrated	Enlarged eosinophilic collagen bundles orientated parallel to skin surface Loss of adnexal structures
CD34+ fibrocytes	yes	No	Yes	No	No
Mucin (mainly hyaluronic acid)	+++++	No	++++	++	+
Depth of skin involvement	Into panniculus, (thickened septae)	Fat and deep fascia	To mid reticular dermis	Into subcutis (fat replaced by collagen)	Into subcutis fascia and muscle
Inflammation	No/less obvious	Yes, ± eosinophils	Perivascular upper dermis	No	Perivascular prominent
Typical site	Extremities, trunk	Extremities	Face hands forearms	Back, sides, neck, face. May involve tongue	Generalized
ANA	No	ANA± eosinophilia	± ANA	No	ANA++ ENA++
Other associations	Renal failure, gadolinium exposure	Polyclonal hypergammaglobulinaemia, morphoea, immune cytopenias, haematological malignancy	Paraprotein IgGλ	Diabetes, infection (especially streptococcal), paraprotein IgGκ, IgA, myeloma	

ANA, anti-nuclear antibodies; ENA.

Patients develop thickening of the skin on the limbs and trunk, often complicated by joint contractures and sometimes by fibrosis of internal organs. The disease improves in 22%, stabilizes in 25%, and progresses in the remainder. In 5% it has a fulminant course. Diagnosis is based on the typical clinical history and findings and a deep skin biopsy. Treatment is largely unsatisfactory and prevention by reducing exposure of patients to GBCA is essential.

Myositis

This page intentionally left blank

CHAPTER 124

Polymyositis and dermatomyositis

Hector Chinoy and Robert G. Cooper

Introduction

The idiopathic inflammatory myopathies (IIM) are rare and heterogenous autoimmune diseases characterized by inflammation of skeletal muscle and other organ systems. The aetiopathology of IIM remains unknown, but genetic and environmental factors probably interact to produce disease.[1] Morbidity outcomes relate to skeletal muscle damage and to well-known complications such as cancer-associated myositis and interstitial lung disease (ILD). Adult-onset IIM can be broadly classified into polymyositis (PM), dermatomyositis (DM), and inclusion body myositis (IBM).

Epidemiology

Annual incidence rates for IIM vary from 2.18 to 8.7×10^{-6}.[2] Increased incidence rates have been observed over time and with age. The female to male incidence rate ratio in PM/DM varies between 1.5 and 2.4,[3] although in IBM prevalence rates are higher in men compared to women.[4] A higher incidence of PM/DM has been observed in black compared to white patients. The peak incidence of PM in adults is 40–60 years. The incidence of DM has two peaks, at 5–15 years and 45–65 years.[2]

Clinical and diagnostic criteria

Bohan and Peter introduced diagnostic criteria for myositis which remain the preferred criteria in clinical studies and trials worldwide (Table 124.1).[5,6] Further revised classification criteria have been proposed to take modern day diagnostics into account.[7] A further classification scheme has been developed following observations that specific HLA genotypes are associated with antibodies, which in turn predict clinical phenoypes.[8]

DM may be further subdivided. **DM *sine* dermatitis** describes patients where the rash is transient, subtle or absent, and/or where the histology pattern is in keeping with DM.[9] **Amyopathic DM** describes a subset whereby the rash is present in the absence of muscle weakness[10]; these patients may still be at risk of lung disease or malignancy. Patients without weakness, but who have slight creatine kinase (CK) elevation or disease activity on MRI/muscle biopsy, are described as having **hypomyopathic DM**.

There is a group of patients who have IBM clinically, but who do not meet the stringent histological requirements of the Griggs criteria.[11] In order to accommodate such patients, modified diagnostic criteria have been proposed by the MRC Centre for Neuromuscular Diseases (Table 124.2).[12]

Table 124.1 Bohan and Peter diagnostic criteria for polymyositis/dermatomyositis

Item	Description		
1	Symmetrical weakness of limb-girdle muscles and anterior neck flexors		
2	Muscle biopsy evidence typical of myositis		
3	Elevation of serum skeletal muscle enzymes, particularly CK		
4	Typical EMG features of myositis		
5	Typical DM rash, including heliotrope and Gottron's papules		
For the diagnosis of PM:		For the diagnosis of DM:	
Definite	All of items 1–4	Definite	Item 5 plus 3 of items 1–4
Probable	3 of items 1–4	Probable	Item 5 plus 2 of items 1–4
Possible	2 of items 1–4	Possible	Item 5 plus 1 of items 1–4

CK, creatine kinase; DM, dermatomyositis; EMG, electromyography; PM, polymyositis.
Exclusion criteria include congenital muscular dystrophies, central or peripheral neurological disease, infectious myositis, metabolic/endocrine myopathies, and myasthenia gravis.
Adapted from Bohan and Peter.[5,6]

Table 124.2 Proposed modified diagnostic criteria for inclusion body myositis

Pathologically defined IBM	
Conforming to the Griggs criteria[11]—invasion of non-necrotic fibres by mononuclear cells, and rimmed vacuoles, and either intracellular amyloid deposits or 15–18 nm filaments	
Clinically defined IBM	
Clinical features	Duration weakness >12 months
	Age >35 years
	Weakness of finger flexion > shoulder abduction AND of knee extension > hip flexion
Pathological features	Invasion of non-necrotic fibres by mononuclear cells or rimmed vacuoles or increased MHC-I, but no intracellular amyloid deposits or 15–18 nm filaments
Possible IBM	
Clinical criteria	Duration weakness>12 months
	Age >35 years
	Weakness of finger flexion > shoulder abduction OR of knee extension > hip flexion
Pathological criteria	Invasion of non-necrotic fibres by mononuclear cells or rimmed vacuoles or increased MHC-I, but no intracellular amyloid deposits or 15–18 nm filaments

From Hilton-Jones et al.[12]

Environmental risk factors

Infectious agents

Acute myopathies can ensue due to infection, with or without evidence of active muscle infection. Presentations include pyomyositis, rhabdomyolysis, or the self-limiting benign acute myositis.[13,14] Infectious agents such as cocksackie, cytomegalovirus, and toxoplasma and have been implicated in IIM, but studies have been largely unsuccessful in identifying evidence for specific infectious agents.[15,16]

Non-infectious agents

A number of drugs, foods, dietary supplements, and vaccinations have also been anecdotally associated with the onset of myositis (Table 121.3).

Genetic risk factors

Because of the scarcity of affected sibling pairs and twins, early evidence to suggest a genetic basis for IIM came from anecdotal familial aggregation and candidate gene studies.[17] Candidate gene studies provide the best evidence for a genetic basis in IIM. The strongest associations arise from the MHC region, as seen in other autoimmune diseases. Alleles forming part of the white European MHC common ancestral haplotype (*HLA-A1-B8-Cw7-DRB1*0301-DQA1*0501-C4A*Q0*) occur in strong linkage disequilibrium within white populations in northern and western Europe, and are associated with a large number of immunopathological diseases.[18] Thus, *HLA-DRB1*0301* and *HLA-DQA1*0501* are confirmed risk factors for white IIM.[17] The risk conferred by the common ancestral haplotype is further increased in patients who possess antisynthetase or anti-PM-Scl antibodies.[19]

A recent genome-wide association study in DM has suggested that many of the 'panautoimmunity' genes found in other autoimmune diseases are also important in DM susceptibility.[20]

Pathogenesis

Pathophysiology

As part of the adaptive immune response, both humoral and cell-mediated mechanisms are important in the pathogenesis of IIM. Evidence for a **humoral response** is as follows: (1) about 80% of patients with PM/DM possess autoantibodies; (2) B cells and plasma cell infiltrates are present in muscle tissue; (3) immunoglobulin transcripts are well represented in muscle tissue. The two differing patterns of distribution, location, and type of lymphocyte subsets in muscle biopsy tissue described below are suggestive of two differing **cell-mediated immune** pathways, which may overlap.[21]

Innate immune mechanisms require the presence of ancillary molecules, e.g. cytokines, chemokines, and their receptors. Proinflammatory cytokines such as interleukin (IL)-1α, IL-1β, tumour necrosis factor alpha (TNFα), type I interferons (INF-α and -β), and high-mobility group box 1 (HMGB1) are evident in PM/DM muscle tissue. IL-1α and HMGB1 may be present in muscle fibres in the absence of inflammatory infiltrates, suggesting a role in persisting weakness. A type I interferon gene signature is observed in muscle tissue and peripheral blood in PM/DM.[21] MHC class I expression in muscle fibres may link immune and non-immune mechanisms such as the endoplasmic reticulum stress response.

Muscle biopsy findings

Findings on muscle biopsy tissue may help to differentiate PM, DM, and IBM from each other. A pictorial representation of the muscle fibre is provided to aid interpretation (Figure 124.1).

DM

Early microvascular injury of muscle capillaries occurs through activation of the complement pathway and C5b-9 membranolytic attack complex deposition. Subsequent lysis of endothelial cells leads to necrosis of capillaries and perivascular inflammation. Ensuing focal capillary depletion, reduced capillary density, and

muscle ischaemia on the periphery of the muscle fasciculus leads to perifascicular atrophy. T/B lymphocytes, macrophages, and plasma cells are the main inflammatory cells found, where B cells and CD4+ T helper (Th) cells predominate in a perimysial and perivascular distribution. MHC class I expression is limited to damaged fibres in the perifascicular region (Figure 124.2).[22]

Table 124.3 Non-infectious environmental agents linked with myositis

Agent	Exposure
Drugs, foods, and dietary supplements	D-Penicillamine
	Lipid-lowering drugs
	Fibrates
	HMG-CoA reductase inhibitors
	Leuprolide acetate
	Hydroxyurea
	Adulterated rapeseed oil (toxic oil syndrome)
	L-Tryptophan (eosinophilia myalgia syndrome)
	Ciguatera toxin
Biological agents Vaccines	DTP, MMR, BCG, influenza, hepatitis A/B
Cytokines	INF-α
	IL-2
Hormones	Growth hormone
Occupational exposures	Silica, cyanoacrylate glue
Other exposures	UV light, chimerism, graft vs host disease

Adapted from Reed andYtterberg.[16]

PM

In PM and IBM, inflammatory infiltrates are endomysial, immunopathology is of an antigen-driven CD8+ T-cell cytotoxicity, and macrophages are involved in phagocytosis of necrotic cells. Inflammatory cell infiltrates surround and partially invade non-necrotic muscle fibres which demonstrate strong expression of MHC class I antigen. MHC class I is upregulated on virtually all muscle fibres, regardless of the presence of inflammation,[23] but this not specific to IIM (Figure 124.2).[24]

IBM

As well as the changes described above, amyloid deposition, vacuolation, and inclusion bodies, if present, will help discriminate PM from IBM. B lymphocytes tend to be almost absent from the endomysium.[22] Rimmed vacuoles are round or polygonal small basophilic granules within vacuolar walls. The name IBM derives from clusters of cytoplasmic inclusions containing phosphorylated tau protein. Abnormal deposits accumulate in muscle fibres, including tiny amyloid deposits which immunoreact to Congo Red and other similar proteins.[25] Other characteristic findings in IBM include hypertrophic fibres, fibre-type grouping, ragged red fibres, fatty replacement, and loss of cyclooxygenase staining (Figure 124.2).

Necrotizing myopathy

Muscle biopsy findings from anti-signal recognition particle (SRP) positive cases demonstrate degenerating (necrosis) and regenerating fibres often invaded by macrophage-like cells, and C5b9 in capillaries of endomysial regions. MHC class I upregulation or mononuclear inflammatory cells are not evident.[26] In statin-induced myopathy, muscle biopsy findings again show myonecrosis, macrophagic infiltration and a paucity of B/T cell infiltrates.[27]

In paraneoplastic myopathy, perimysial staining for alkaline phosphatase, a paucity of inflammation, and a more widespread pattern of necrotic C5b-9 positive muscle fibres compared to SRP-positive myopathy, are observed.[28]

Clinical features

Muscle weakness

In IIM, the pattern of weakness is usually proximal, bilateral, and symmetrical over a period of weeks or months. Myalgia is present in only 25% of cases, typically early on in the disease course. Patients may report difficulty with tasks using the proximal musculature. Upper limb symptoms include difficulty combing hair or reaching up for objects above head height. Lower limb weakness is suggested by difficulty rising to a standing position from sitting and difficulty climbing steps or pavement curbs. Weakness in the abdominal musculature may cause difficulty sitting up from a supine position, and neck weakness may lead to problems keeping the head held upright. The facial musculature is generally spared.[29]

Rash

DM is defined according to classification criteria by the presence of characteristic rashes (Figure 124.3).

Skin vasculitis is an especially recognized feature of juvenile DM (JDM), although rarely may also be found in adult disease. Findings in the nail bed include abnormal tortuous nailfold capillaries, seen as nailfold telangiectasia or on capillaroscopy, cuticular overgrowth, and periungal erythema. Skin lesions are typically photosensitive.

Other systems

Gastrointestinal involvement

Pharyngeal weakness may lead to dysphonia and/or dysphagia, due to weakness of the tongue and/or pharynx, or disordered upper oesophageal motility.[29] A loss of swallow can lead to aspiration of food/fluids and aspiration pneumonia.

Cardiac involvement

Clinical cardiac manifestations in IIM are uncommonly reported, but may manifest as subclinical ECG abnormalities.[30] A number of other cardiac abnormalities have been described, including conduction defects, congestive cardiac failure, pericarditis, and valvular heart disease. Right-sided heart failure secondary to ILD is a common cause of death in IIM.[31]

Joint involvement

Articular manifestations may occur early in IIM disease, in a mild, rheumatoid-like distribution, and usually respond to treatment of

Fig. 124.3 Skin manifestations in idiopathic inflammatory myopathy: (A) Heliotrope rash, a violaceous discolouration affecting the upper eyelids often associated with periorbital oedema. (B) Gottron's papules, symmetrical, palpable erythematous rashes most commonly present on the extensor surface of the metacarpophalangeal or interphalangeal joints. (C) Mechanics' hands, hyperkeratosis, scaling and often painful fissuring of the skin in the tips and sides of the fingers, often mistaken for contact dermatitis, usually seen in the context of the anti-synthetase syndrome. (D) V sign, discrete and confluent macular erythema over the lower anterior neck and upper anterior chest. (E) Shawl sign, discrete and confluent macular erythema in a shawl distribution.

Image C courtesy of Dr Herman Mann.

the underlying disease.[32] Arthralgia or arthritis is more common in connective tissue disease (CTD)/overlap patients or those possessing anti-synthetase antibodies, and may lead to an initial misdiagnosis of inflammatory arthritis.

Respiratory involvement

ILD in the context of IIM (IIM-ILD) may be present in up to 65% of cases at diagnosis.[33] The severity of ILD presentation may vary, with some presenting subclinically, with abnormal chest radiographs or pulmonary function tests (PFTs) in the absence of cough or dyspnoea. Respiratory symptoms in IIM may be attributable to either intrinsic or extrinsic (e.g. aspiration pneumonia, respiratory muscle weakness, pulmonary arterial hypertension) lung disease.[34]

Clinical signs due to ILD involvement may range from asymptomatic to acute respiratory distress syndrome. The main forms of IIM-ILD are non-specific interstitial pneumonia (NSIP) and usual interstitial pneumonia (UIP). NSIP is distinguished by the presence of an inflammatory component, which is considered amenable to immunosuppression, and thus associated with a more favourable prognosis.[34]

Anti-Jo-1 (anti-histidyl-tRNA synthetase) is found in about 20% of PM/DM patients,[19] and up to 70% of anti-Jo-1 patients have associated ILD, as part of the anti-synthetase syndrome (Table 124.4). Patients possessing anti-synthetases, especially other than anti-Jo-1, may never develop features of myositis, or may only do so on subsequent follow-up.

Malignancy

A well-described association exists between malignancy and IIM, mainly based on population-based cohort studies, where the reported frequency of cancer in IIM ranges from 7% to 30%, and the risk is increased compared to population-matched control groups.[35] These studies clearly suggest that malignancy risk is greater in DM than PM. A decreasing trend for increased malignancy risk is observed over time post-IIM diagnosis, although risk may still be increased 5 years after the myositis diagnosis.[36]

Risk factors for malignancy include male gender, older age at disease onset, more severe skin or muscle disease, elevated erythrocyte sedimentation rate(ESR)/C-reactive protein (CRP), low serum albumin, negative result for routinely tested myositis antibodies, and a positive 155/140 antibody (TIF-1γ, see Table 124.4 and section 'Cancer screening'). The risk of malignancy is reduced but not negated in patients with other defined CTDs and the anti-synthetase syndrome. Further discussion about screening and investigation of cancer-associated myositis is found in the section on cancer screening.

Overlap disease

Myositis may also be found in association with other CTDs, such as systemic sclerosis, systemic lupus erythematosus, Sjögren's disease, rheumatoid arthritis, and as part of mixed CTD. In CTD/overlap disease, muscle involvement is usually less severe, and higher doses of steroids may not be required.

Inclusion body myositis

Sporadic IBM typically presents in patients over the age of 50 and unlike PM/DM, has a male predominance.[37] It is a slowly progressive disease that can affect both distal and proximal musculature, often asymmetrically. The mean time to diagnosis is from 1–9 years.[38] Selective quadriceps involvement can cause walking problems, legs giving way, and falls. Finger flexor weakness (flexor digitorum profundus) can lead to problems with grip. Quadriceps and forearm wasting are therefore common presenting features. A DM rash and other CTD features are uncommon, and serum CK is usually no more than five times the upper limit of normal.

Laboratory investigations

Muscle enzymes

Elevated muscle enzymes reflect the presence of injured or necrotic muscle fibres. Serum enzymes used include CK, lactate dehydrogenase, aldolase, aspartate aminotransferase (AST), and alanine aminotransferase (ALT).[39] Improvement in muscle strength usually lags behind normalization of enzymes, and an enzymatic rise may predict an impending disease flare.[40] However, patients

Table 124.4 Autoantibodies associated with myositis

Autoantibodies		Target autoantigen and function	Clinical phenotype	Frequency in adult IIM (%)
Myositis-specific antibodies				
Anti-aminoacyl-tRNA synthetases—associated with anti-synthetase syndrome				
	Anti-Jo-1	Histidyl	Myositis, mechanics' hands, Gottron's papules, arthritis, Raynaud's phenomenon, interstitial lung disease	11–20
	Anti-PL-7	Threonyl		2
	Anti-PL-12	Alanyl		1
	Anti-EJ	Glycyl		1–3
	Anti-OJ	Isoleucyl		1
	Anti-KS	Asparaginyl		<1
	Anti-Ha	Tyrosyl		<1
	Anti-Zo	Phenylalanyl		<1

Table 124.4 (*Continued*)

Autoantibodies		Target autoantigen and function	Clinical phenotype	Frequency in adult IIM (%)
Antibodies associated with acute necrotizing myopathy				
	Anti-SRP	Ribonucleoprotein complex comprising 6 polypeptides and 7SL RNA (intracytoplasmic protein translocation)	Acute necrotizing myopathy, high CK (up to 25 000), severe weakness, may be refractory to treatment. Usually respond well to steroids, but may flare on tapering thus requiring long-term immunosuppression	5
	Anti-200/100	HMG CoA reductase	Acute necrotizing myopathy, associated with statin use. Proximal weakness despite statin cessation. CK 2–35 000	unknown
Antibodies associated with adult dermatomyositis				
	Anti-Mi-2	Nucleosome remodelling histone deacetylase complex (nuclear transcription)	Cutaneous disease, milder muscle disease, acute onset, good response to treatment, lower mortality rates	5–10 (10–20% adult DM)
	Anti-155/140	TIF1-γ (nuclear transcription and cellular differentiation)	Severe cutaneous disease, cancer-associated myositis	5–10 (13–21% adult DM)
	Anti-NXP-2	Nuclear matrix protein 2 (p140) (nuclear transcription and RNA metabolism)	Cutaneous disease, systemic features, ILD (calcinosis more common in juveniles)	3
Antibodies associated with amyopathic dermatomyositis				
	Anti-SAE	Small ubiquitin-like modifier activating enzyme (post-translational modification)	Cutaneous disease precedes muscle disease	5
	Anti-MDA5	Melanoma-differentiation associated gene 5 (innate immune responses against viral infections)	Amyopathic dermatomyositis, rapidly progressive interstitial lung disease	Unknown
Myositis-associated antibodies				
	Anti-PM-Scl	Nucleolar protein complex (human exosome)	SSc overlap, Raynaud's phenomenon, interstitial lung disease	8–10 (50% myositis-scleroderma overlap syndrome)
	Anti-U1 RNP	U1 small nuclear RNP	Mixed CTD	10
	Anti-Ku	DNA-PK regulatory subunit	SSc overlap, interstitial lung disease	20–30
	Anti-Ro	Y1-Y5 RNP	Sjögren's overlap, frequently associated with Jo-1	10–20
	Anti-La	RNA polymerase III termination factor	Sjögren's overlap	5

Adapted from Hengstman et al.[44] and Hirakata.[45] Additional data from Casciola-Rosen et al.[46] and Gunawardena et al.[47]

may present with new active myositis or flare with normal muscle enzymes.[41] Other causes of raised muscle enzymes may be present (Box 124.1).

Muscle enzymes should thus not be used in isolation to monitor disease activity. In active disease, a CK increase can typically be tenfold. Increases above about 6000 may be seen but should prompt a search for other causes. A higher upper limit of normal may be seen in Afro-Caribbean patients. Cardiac troponin T may be raised in inflammatory myositis, in the absence of cardiac disease; cardiac troponin I does not correlate with skeletal muscle injury and is thus more accurate in assessing cardiac injury. Transaminases (ALT, AST) can be raised in IIM, which may lead to misdiagnosis of liver dysfunction during drug monitoring.

Other laboratory markers

The presence of urinary myoglobin may lead to the false-positive detection of blood on urinalysis testing—an absence of red blood cells is found on urine microscopy. ESR may be slightly raised and

Box 124.1 Causes of elevated creatine kinase other than inflammatory myositis

Muscle trauma
- Direct muscle injury
- Needle stick
- EMG
- Surgery
- Convulsions, delirium tremens

Diseases affecting muscle
- Myocardial infarction
- Rhabdomyolysis
- Metabolic or mitochondrial myopathies
- Muscular dystrophies
- Infectious myositis
- Amyotrophic lateral sclerosis (motor neuron disease)

Drug/toxin-induced myopathy
- Lipid-lowering agents, especially HMG CoA reductase inhibitors
- Alcoholic myopathy
- Drugs of abuse, e.g. cocaine, amphetamines, phencyclidine
- Malignant hyperthermia, neuroleptic malignant syndrome
- Other medications, e.g. zidovudine, colchicine, chloroquine, ipecac

Drug-induced myositis
- D-Penicillamine
- Interferon
- HMG-CoA-reductase inhibitors

Drug-induced CK elevation
- Inhibition of excretion, e.g. barbiturates, morphine, diazepam

Endocrine and metabolic abnormalities
- Hypothyroidism
- Hypokalaemia
- Hyperosmolar state or ketoacidosis
- Diabetic nephrotic syndrome with oedema
- Renal failure

Elevation of brain-type creatine kinase
- Central nervous system disease
- Tumours (e.g. gastrointestinal, bronchial)

Elevation without disease
- Strenuous, prolonged, and/or unaccustomed exercise
- Ethnic group (black > white)
- Increased muscle mass

Adapted from Targoff.[39]

CRP is not typically raised in acute inflammatory myositis; raised levels of inflammatory markers may suggest concurrent infection. Low serum creatinine may correlate with a general loss of muscle mass and atrophy.

Biomarkers including mucin-like glycoprotein KL-6, serum B-cell activating factor, and serum ferritin, have been described in IIM-ILD. The level of serum ferritin is higher in IIM-ILD, and may exceed 8000 ng/mL.[42]

Myositis-specific and associated autoantibodies

Great advances have been made over the last few years in our understanding of the relevance of myositis-specific and associated autoantibodies (MSA/MAA), in particular that an individual patient's antibody is predictable for their disease phenotype. Autoantibodies against nuclear or cytoplasmic antigens can be detected in 80–90% of IIM cases.[43] MSA are specific for inflammatory myositis, while MAA may also be detected in other rheumatic disorders without signs of inflammatory muscle disease; thus they are not specific to myositis (Table 124.4).

Clinical assessment

It is important to clinically differentiate disease activity from disease-induced tissue damage, to avoid immunosuppressing a patient with muscle weakness and no active inflammation, while treating disease activity in others, e.g. a patient who has ongoing inflammatory disease, but without CK elevation. The International Myositis Assessment and Clinical Studies (IMACS) Group have agreed core-set measures to assess myositis disease activity, including assessment of: (1) physician/patient global activity assessment by visual analogue scale; (2) muscle strength by manual muscle testing; (3) physical function; (4) muscle enzymes; (5) extraskeletal muscle disease.[41]

Muscle strength can be evaluated through isokinetic or isometric testing. Manual muscle testing (MMT) is widely used in clinical practice and a 0–10 point scale is used widely by the international myositis community (https://dir-apps.niehs.nih.gov/imacs/).[48] An abbreviated group of 8 proximal, distal, and axial muscles performs similarly to examination of 24 muscle groups.

Physical impairment may affect the function of patients, and can be measured with the Stanford Health Assessment Questionnaire (HAQ) which has been used as a measure of improvement in adult IIM trials.[41]

Muscle tissue is the primary organ affected in myositis, but other organs may also be involved.[49] The measures developed to assess disease activity include the Myositis Intention to Treat Index (MITAX) and the Myositis Activity Assessment by Visual Analogue Scales (MYOACT).[50] The Myositis Damage Index (MDI) assesses extent and severity of damage.[51]

Investigations

Muscle biopsy

Muscle biopsies can positively identify non-inflammatory myopathies, and differentiate between IIM subtypes. Open biopsy provides a large sample, thus reducing sampling error,[52] but is inconvenient, costly, and results in larger scars. The percutaneous conchotome method[53] is less invasive, and allows for repeat biopsies when monitoring disease activity or treatment response. Needle-based biopsy

techniques, although yielding small samples, can produce adequate samples for diagnostics.

Vastus lateralis is usually selected for biopsy in IIM, although electromyography (EMG) (contralateral side to avoid contamination) and MRI can guide the choice of muscle group. Where extensive fatty replacement is present, the deltoid may provide better yield. Despite being more distal, tibialis anterior may also show characteristic changes and is technically an easier muscle to sample.

Neurophysiology

Neurophysiology provides an extension of the clinical examination in IIM and is important for the exclusion of non-inflammatory myopathies and neurogenic disorders. Classical (EMG) findings in IIM consist of: (1) early recruitment of low amplitude, short duration and polyphasic motor unit action potentials; (2) spontaneous fibrillations, positive sharp waves, and increased insertional activity; and (3) high-frequency complex repetitive discharges, which all correlate inversely with muscle strength in IIM patients. These changes are not specific for IIM and may also be seen in dystrophies and metabolic myopathy.[54] EMG has approximately 90% sensitivity for picking up inflammatory myopathy but this partly depends on the skill of the neurophysiologist.

Muscle imaging

MRI is a very sensitive non-invasive technique for localizing muscle oedema in inflammatory myositis. MRI allows sequential examination of large volumes of muscle and identification of focal myositis, and can also be used to target areas for muscle biopsy. However, mitochondrial/metabolic myopathies, dystrophies, or even motor neuron disease, may also manifest secondary inflammatory changes on MRI, thus the technique lacks specificity for IIM.

Muscle oedema is demonstrated as a multifocal or diffuse pattern of high signal intensity on T2-weighted sequences. Clearer images can be obtained with fat-suppressed (short tau inversion recovery, STIR) sequences (Figure 124.4).[55] Muscle atrophy is found on T1-weighted images as increased signal intensity, which correlates with disease-related damage.

Other investigations

If dysphagia is present, patients should be appropriately investigated with speech and language therapy assessment, barium swallow, and/or videofluoroscopy as appropriate.

Diagnosis of interstitial lung disease

PFTs may help detect subclinical ILD, and are useful for monitoring progression of disease or therapeutic response. ILD is suggested by a normal/raised FEV_1/FVC ratio, FVC or total lung capacity less than 80% predicted, and/or a decrease in diffusing capacity for carbon monoxide (DL_{CO}). Patients with respiratory muscle weakness may also present with a restrictive pattern and decreased DL_{CO}. A decreased DL_{CO} may also be seen in pulmonary hypertension. A number of biomarkers may be useful in the assessment of IIM-ILD (see Other laboratory markers).

Chest radiographs are also useful for screening and detection of ILD complications, e.g. pneumothoraces. High-resolution CT (HRCT) is sensitive and can also distinguish between fibrotic disease and active inflammation.[56] Irregular linear opacities with areas of consolidation and ground-glass attenuation suggest active inflammation. Honeycombing is suggestive of endstage lung disease with established fibrosis. Bronchoscopy and bronchoalveolar lavage may be useful to exclude opportunistic infections. The use of surgical biopsy in IIM-ILD is not routine in CTD-ILD patients unless diagnostic uncertainty remains.

Cancer screening

In addition to careful history-taking and examination, laboratory evaluation should include the following: full blood count, ESR, routine biochemistry, tumour markers, chest radiography, urinary cytology, and chest/abdomen/pelvis CT scans. Mammography and gynaecological examination is justified in female patients, as is testicular examination in males. Faecal occult blood testing and gastroscopy/colonoscopy should be carried out in all patients over 50 years of age. These investigations are of special importance in DM, and should be repeated yearly for at least 3 years following IIM
Fig. 124.4 MR changes in idiopathic inflammatory myopathy: (A) T1 and (B) axial STIR thigh sequence of a 34 year old patient with anti-SRP-positive dermatomyositis, CK>3000, proximal weakness. Muscle oedema (in white) is predominantly affecting the hamstrings.

diagnosis. The use of FDG-PET scanning appears to be comparable to conventional screening methods for detecting occult malignancy in the setting of myositis.[57]

A subtype of paraneoplastic necrotizing myopathy has been described in association with a wide spectrum of different solid tumour types. CK levels can vary from 8 to 100 times the normal range.[28]

Anti-TIF1-γ (p155/140) antibodies are found in about one-fifth of patients with adult and juvenile DM (Table 124.4). In adults, this antibody is 78% sensitive and 89% specific for the detection of cancer-associated myositis,[58,59] and generally not found in association with other MSA. Anti-TIF1-γ (p155/140) detection should prompt intensive cancer screening in DM patients for 3–5 years after myositis onset.

Differential diagnosis in myositis

There are many differential diagnoses when encountering an adult patient with muscle weakness where accurate clinical assessment is vital. For example, dystrophies tend to present at an earlier age, are slowly progressive, and do not respond to immunosuppression. Muscle weakness in myasthenia gravis or Eaton–Lambert syndrome may affect extraocular or bulbar musculature, and worsens with repetitive or prolonged use. Prominent muscle wasting, fasciculations, and brisk reflexes should alert to possible motor neuron disease which can also present with a raised CK. These conditions should be differentiated from IIM on EMG testing. Raised inflammatory markers and proximal stiffness may point towards polymyalgia rheumatica.

Mitochondrial disease, metabolic myopathies, and dystrophies may also mimic the presentation of IIM; a comprehensive discussion of these non-inflammatory myopathies is provided in Chapter 126.

Management and treatment of myositis

Initial treatment of choice in inflammatory myositis is with corticosteroids. The typical initial dose is 0.75–1 mg/kg (e.g. 60–80 mg prednisolone) per day for 3–4 weeks, and after normalization of CK and clinical parameters, dose reduction by 20–25% every 3–4 weeks until the lowest dose to control the disease is reached.[40] Treatment with intravenous methylprednisolone 1 g daily for 3 days may be necessary in aggressive disease.

Other treatments may be initiated for further control of disease and as steroid-sparing agents, e.g. methotrexate, azathioprine, ciclosporin, tacrolimus, cyclophosphamide, and mycophenolate mofetil (various trials reviewed by Oddis[40]). Intravenous immunoglobulin use has also been studied; a study in refractory DM showed improvement of muscle strength after 3 months.[60]

Plasma exchange has shown limited results in the treatment of myositis.[61] Anti-TNFα therapy is not recommended in IIM, where only variable improvements have been noted in serum muscle enzyme levels and muscle strength. The largest randomized placebo-controlled trial in IIM to date investigated rituximab with crossover at 8 weeks.[62] No significant difference in improvement was noted between the two arms at 12 months, but 83% of patients achieved the definition of improvements and a significant glucocorticoid-sparing effect was noted.

Exercise and rehabilitation programmes are safe and of benefit in stable treated myositis patients, improving function, aerobic fitness, and muscle strength. Creatine supplementation in addition to a home exercise programme is of benefit in clinically stable but weak PM/DM.[63] The issues of muscle weakness, loss of joint motion, and fatigue in myositis should be addressed in physiotherapy-led programmes.

Inclusion body myositis

IBM unfortunately does not respond to currently available pharmacological treatment. Due to inflammatory infiltrates observed in muscle biopsy tissue, steroids have been used to suppress inflammation, which may reduce the serum CK, but with no discernible improvement in muscle strength or attenuation of disease progression. Trials of a number of therapies, including intravenous immunoglobulin, anti-T-lymphocyte globulin, alemtuzumab, etanercept, IFNβ1-a, have all yielded mixed results, therefore none can currently be recommended for treatment.[38]

Lack of response

Patients may not respond to conventional treatment for a number of reasons[64]:

◆ Inadequate dose and/or length of treatment with glucocorticoids.

◆ Steroid-induced myopathy, manifesting usually as a deterioration of muscle strength without elevated CK levels after initial improvement.

◆ In patients with muscle atrophy, evidenced by MRI or muscle biopsy, immunosuppressive treatment will not be of help.

◆ Improvements in serum CK are not always associated with concurrent improvements in muscle strength, where there is often a delay.

◆ The presence of occult malignancy should always be considered, and comprehensive screening is recommended. Cancer-associated myositis should improve with treatment of the underlying neoplasia, but will depend on the type, stage, and grade of the tumour.

◆ Repeat biopsy should be considered in cases of disease-resistant IIM, in case of undiagnosed underlying IBM or non-inflammatory myopathy, especially if the initial biopsy findings were not specific for PM/DM.

CHAPTER 125

Paediatric polymyositis and dermatomyositis

Clarissa Pilkington and Liza McCann

Introduction

Juvenile dermatomyositis (JDM) is the commonest idiopathic inflammatory myopathy (IIM) in childhood with juvenile polymyositis (JPM) being extremely rare. Skeletal muscle inflammation leads to progressive weakness, which can be confused with tiredness in young children and needs to be distinguished from infectious myositis or neuromuscular disorders such as muscular dystrophy. JDM affects the skin with a typical rash, as well many other organs. JPM does not affect the skin and has little published literature. This chapter will focus predominantly on JDM.

Epidemiology

JDM has an annual incidence of 2–3 per million children per year. A UK British Paediatric Surveillance Unit survey (1992–3) found an incidence of 1.9 (sex ratio 5:1 girls to boys).[1] This was felt to be unusually low and under-representative of the true incidence. In 2000, the Juvenile Dermatomyositis National (UK and Ireland) Cohort and Biomarker Study and Repository for Idiopathic Inflammatory Myopathies was established. In the first 10 years of this study, 275 IIM patients were recruited from a UK-wide network using standardized data collection forms,[2] with 182 girls and 76 boys, giving a sex ratio of 2.39:1. This is closer to the ratio from the National Institute of Arthritis and Musculoskeletal and Skin Disease (NIAMS) registry in the United States, which collected 395 cases with a sex ratio of 2.3:1.[3] In the UK cohort, ethnic differences mainly reflected ethnicity of the United Kingdom population; 80% were white European. This was also true of the NIAMS registry, with 79% classed as white non-Hispanic or Hispanic. In the UK cohort, median age of onset was 6.3 years, but 37% of patients presented under the age of 4. The incidence of JPM is unknown, but the UK cohort included 7 cases of JPM (4 definite, 3 probable) out of a total of 275 IIM cases. Seasonal variations in the incidence of IIM have been suggested, with clustering of cases in one study of 55% with onset between February and April.[4] The UK 1992–3 survey saw variable clusters between years, with the largest between April and May 1992. It is thought that environmental triggers including viruses, photosensitivity, and noxious substances may interact in genetically predisposed individuals (see below), but no one viral trigger has been identified.

Diagnostic criteria for juvenile dermatomyositis

The most widely accepted diagnostic criteria are those suggested by Bohan and Peter in 1975 (Table 125.1).[5] JDM/JPM are usually defined with onset before the age of 16 (Europe) or 18 (America). Definite dermatomyositis requires a characteristic rash (heliotrope rash over eyelids with periorbital oedema, Gottron's papules) plus three of the four muscle features documented in Table 125.1. Definite polymyositis requires all four muscle criteria (excluding rash). Polymyositis is more common in adults than in children, and has different muscle biopsy features (inflammatory infiltrates often widespread, particularly CD8+ T cells). These diagnostic criteria were based on clinical observations and have not been tested for sensitivity or specificity against all appropriate disease confounders. Other diagnostic criteria have been proposed as more advanced investigative techniques (MRI, autoantibodies) have become available, but they suffer from the same drawbacks.

Recent international collaboration led to an American College of Rheumatology/European League Against Rheumatism (ACR/EULAR) funded classification criteria study for adult and paediatric IIM. The International Myositis Classification Criteria Project (IMCCP) working group included rheumatologists, neurologists, and dermatologists (adult and paediatric). Expertise was pooled to devise a questionnaire capturing major symptoms, physical findings, investigational results, and treatment responses for patients with inflammatory myopathies and confounding diseases. Data were collected on 262 DM, 240 PM, 200 JDM, 172 inclusion body myositis (IBM), and 601 comparator cases. These data will allow more robust classification criteria to be devised, enhance understanding of differential diagnoses, and enable clinical trials to recruit suitable patients.

Aetiopathogenesis

The aetiopathogenesis of JDM is poorly understood, but is likely to include a combination of environmental triggers in genetically susceptible individuals, causing immune dysregulation resulting in tissue inflammation. There is speculation as to the primary target of the inflammatory response; whether it is endothelium or muscle cells. Evidence supports both hypotheses. Autoimmune diseases

Table 125.1 Bohan and Peter diagnostic criteria[5]

	Feature	Details
1	Symmetrical weakness	Usually progressive, of the limb-girdle muscles.
2	Muscle biopsy evidence of myositis	Necrosis of type I and type II muscle fibres. Phagocytosis. Degeneration and regeneration of myofibres with variation in myofibre size with perifascicular atrophy. Endomysial, perimysial, perivascular or interstitial mononuclear inflammatory cells
3	Elevation of serum levels of muscle-associated enzymes	CK, LDH, aldolase,[a] transaminases (ALT/SGPT and AST/SGOT)
4	Electromyographic (EMG) triad of myopathy	Short, small, low-amplitude polyphasic motor unit potentials, fibrillation potentials, even at rest, bizarre high-frequency repetitive discharges
Definite JDM/JPM = presence of 3 out of 4 features (plus rash for JDM)		
Probable JDM/JPM = presence of 2 out of 4 features (plus rash for JDM)		
Possible JDM/JPM depends on the presence of one feature (plus rash for JDM)		

CK, creatine kinase; JDM, juvenile dermatomyositis; JPM, juvenile polymyositis; LDH, lactate dehydrogenase.
[a]Not routinely available in UK.

often run in families, suggesting a complex polygenic influence; variations at many genetic loci contributing to an autoimmune phenotype. Genetic studies require large case numbers to have sufficient power to reveal genetic effects. This is particularly difficult for rare diseases such as JDM. Recent collaboration has led to an international genetics consortium in myositis (MYOGEN) collecting a large number of DNA samples from adult and paediatric cases. Results are likely to confirm the importance of the human leucocyte region (HLA), but may lead to the discovery of previously unknown risk and protective alleles. Previous studies demonstrated alleles found in greater numbers in cases than controls (i.e. alleles conferring risk), as well those found in fewer cases than controls (protective alleles), some of which may be involved in regulation of autoreactive T cells. In white Europeans, known loci conferring risk are *HLAB*08*, *DRB1*0301*, *DQA1*0501*, whereas protective alleles are *DQA1*0201*, *DQA1*0101*, and *DQA*0102*.[6] Other loci involving proinflammatory cytokines are known to be risk factors for JDM (such as TNFα variant TNF308A, IL-1α, and IL-1β) and some are associated with more severe disease (calcinosis, ulceration). In the future, these may help clinicians tailor patient treatments according to genetic risk.

Autoantibodies in IIM can be divided into two categories. Myositis-specific antibodies (MSA) are more specific to myositis patients. Myositis-associated antibodies (MAA) are seen with different myositis subtypes and overlap syndromes (such as anti-PM-Scl in scleroderma overlap) and are also found in other autoimmune conditions. Although traditionally thought to occur more frequently in DM than JDM, recent studies have shown approximately 70% of JDM patients have detectable MSA or MAA.[7] Novel MSAs have been identified including anti-TIF1-gamma (anti-p155/140) and anti-NXP2 (anti-p140). In JDM, anti-TIF1-gamma (found in 23–29% of cases) was associated with worse skin disease and lipodystrophy, whereas in adult patients it was associated with malignancy. Anti-NXP2in JDM cases was associated with increased risk of calcinosis.[8] In a study of 114 JDM patients, many cases were ANA positive with no identifiable MSA or MAA, suggesting that JDM patients may have autoantibodies not yet identified that differ from those found in adult DM, or may confer different risks than in DM.[7]

The perivascular infiltrates characteristic of JDM are made up of T cells, B cells, and macrophages. Activation of plasmacytoid dendritic cells (antigen-presenting cells that initiate immunity through the activation of naive T cells) may play a role in pathogenesis. Mature plasmacytoid dendritic cells are found in inflammatory lesions from JDM muscle biopsies, compared to scattered immature plasmacytoid dendritic cells seen in normal muscle tissue. These may induce T-cell-mediated responses leading to muscle damage, though it is not known what initiates initial maturation and collection of the cells.[9] Increased plasmacytoid dendritic cells have also been found in skin from JDM cases. An increase in mast cell numbers (compared to normal controls) was found in skin, both in areas affected by rash, and in unaffected areas, though not in muscle. This suggestion that a different mechanism may be present in skin inflammation is paralleled by clinical observation that skin and muscle inflammation do not mirror each other.

Cytokines are likely to play an important role in pathogenesis, particularly type 1 interferon, which is produced by activated plasmacytoid dendritic cells, and upregulates MHC class I proteins on muscle cells. Upregulation of MHC class I can be seen in muscle biopsies from JDM patients, even when there are few other changes, but this is not specific to JDM and can be seen in Duchenne's muscular dystrophy.

Microchimerism describes the presence of maternally derived cells (acquired in utero during fetal stages or neonatally around time of birth) in children and adults. These cells, found in the blood and inflammatory infiltrates of JDM patients more frequently than their healthy siblings or healthy controls, may cause a graft-vs-host response leading to the autoimmune process.

Clinical features: disease onset

Presenting symptoms of JDM can be variable (Table 125.2).[10–14] Skeletal proximal muscle weakness may be mild and manifest as fatigue and difficulty doing tasks. Many children adapt, so symptoms may not become apparent to parents for some time. Myalgia is often a predominant feature. Weakness is progressive and can become profound, starting with difficulty climbing stairs, combing hair, or lifting objects above the head (proximal weakness) and

Table 125.2 Features present (percentages) at presentation of juvenile dermatomyositis

Feature	Percentage with feature present at presentation of juvenile dermatomyositis				
	UK cohort (n = 151) 2006[10]	Toronto cohort (n = 105) 2002[11]	USA cohort (n = 79) 1998[12]	Danish cohort (n = 57) 2010[13]	European/Latin American cohort (n = 490) 2011[14]
Proximal muscle weakness	82	95	100	93	84.9
Gottron's (JDM rash)	88[a]	91	100	74	72.9
Arthritis	36	6	35	26	35.7

[c]Grouped as fever or any other systemic symptom in UK cohort (including fatigue, alopecia, weight loss, headache, irritability, chest pain, abdominal pain, diarrhoea, melaena, haematuria).

progressing to an inability to roll over in bed. The truncal muscles most commonly affected are the neck flexors and abdominals. Children will be unable to lift their head off the pillow, but will use compensatory manoeuvres. Symmetrical proximal muscle weakness is typical, but as weakness progresses, distal muscles can become involved, resulting in poor grip strength. If palatal muscles are affected, there can be swallowing difficulties and change in voice (sometimes misdiagnosed as bulbar palsy). The commonest manifestation of swallowing difficulty is coughing during eating or drinking, which may not be noticed by parents until asked repeatedly. A recent study demonstrated high incidence of self-reported dysphagia in 18 adult patients with IIM and found symptoms follow a characteristic pattern.[15] In JDM, silent aspiration has been recognized in asymptomatic children, with swallow dysfunction or aspiration not restricted to those who were severely weak.[16]

Gowers' sign is an excellent screening test for pelvic girdle or lower extremity muscle weakness. Patients are asked to rise from lying supine or sitting on the floor. With muscle weakness, a typical pattern emerges (Gowers' positive):

◆ The child rolls prone, extending arms and legs far apart (reduces forces required for knee extension).

◆ With most weight on extended arms, they push the body backwards (shifts weight of trunk over extended legs). Early changes of muscle weakness include exaggerated torso flexion, wide base, and equinus posturing.

◆ To extend the hip, the child places hands onto their knees and 'walks' arms up the thighs until upright. Note: this is only seen when muscle weakness becomes more pronounced (children with mild disease are able to bend at the hips once knees extended).

The salient feature of Gowers' sign is turning prone to rise from a supine position. This is a normal developmental phase in toddlers, but is rarely seen in healthy children over the age of 3 years. Healthy toddlers or obese children may use a hand to push off the thigh or the floor, giving a false-positive Gowers'. It is therefore important to repeat the test if positive and may be helpful to ask children

to get up from a kneeling position with arms folded across their chest. Although first described in Duchenne muscular dystrophy, Gowers' sign will be positive in many other conditions, including other types of muscular dystrophy, inflammatory myopathies, proximal pseudomyopathic disorders, spinal muscular atrophy, sarcoglycanopathy, and discitis. Children with juvenile idiopathic arthritis can have a positive Gowers' sign, particularly when they have active arthritis of the hips.[17]

Parents may not notice a rash (Figure 125.1), as it can be transient and precede the muscle weakness. The facial heliotrope rash over eyelids can be mistaken for sunburn, even when associated with periorbital oedema. Gottron's papules (erythematous plaques) can be mistaken for psoriasis, especially when affecting skin overlying the distal/proximal interphalangeal joints as well as the better known metacarpophalangeal joints. The rash can affect other areas of the body such as the back (shawl sign) and trunk. Generalized erythema or livedo-type rash can be seen. Skin ulceration can occur in severe cases over the flexor surfaces, trunk, or medial canthus of the upper eyelid (usually heals leaving a scar similar to a chickenpox lesion). Nail beds are often erythematous and swollen, with abnormal capillary dilatation. This is more easily seen magnified by KY jelly and an auroscope/ophthalmoscope, or with a capillaroscope.

Polyarticular arthritis occurs in one-third of patients, and can cause the myositis to be overlooked. Systemic features such as tiredness, weight loss, fevers, and irritability are common. Headaches, diarrhoea, alopecia, and mouth ulcers are less common. Lipoatrophy, although infrequent, can be associated with insulin resistance, and is often difficult to reverse. Interstitial lung disease and gut vasculitis (which can lead to perforation) are uncommon, but are associated with severe disease that can be fatal.

Calcinosis can be present at onset, or can develop later if disease is not controlled. Calcium can be deposited as nodules, usually in the subcutaneous layers or in the fascia around muscles. It can form sheets or liquefy to form pools of 'milk of calcium', which may be extensive enough to cause compartment syndrome. Calcium nodules can extrude from the skin and can cause tendons to shorten, especially the Achilles tendon.

Diagnosis

In typical cases, diagnosis of JDM is made clinically by the presence of classical rash and symmetrical proximal muscle weakness, supported by investigative results. However, no one investigation—muscle enzymes, MRI, electromyography (EMG), or muscle biopsy—is abnormal in all cases of JDM and therefore a high index of suspicion is required. The gold standard is still a tissue biopsy, but muscle inflammation in JDM affects muscle groups in a patchy manner, as well as being patchy within individual muscles. A biopsy can therefore look normal due to 'sampling' error or may look normal histologically, even when newer immunohistochemical stains (such as for MHC class I) pick up abnormalities. In atypical cases, it is crucial to undertake a biopsy to exclude muscular dystrophies and mitochondrial cytopathies.

In the absence of rash, diagnosis may be challenging and other causes of weakness including neuromuscular aetiologies need to be considered. It may be helpful to evaluate:

◆ onset of weakness: neonatal (hereditary causes)/infancy/childhood

◆ pattern of weakness: asymmetrical/symmetrical; proximal/distal/bulbar/cranial muscle (ptosis, facial weakness, dysphagia or dysarthria)

◆ time course: acute/subacute/chronic; episodic/persistent; progressive/non-progressive

◆ muscle features: pain/cramps/wasting

◆ presence of fatigue and its relationship to exercise

◆ associated features: sensory changes, abnormal reflexes; systemic/organ involvement; myotonia/hypertrophy, fever

◆ history of exposure to drugs or toxins

◆ family history: genetic causes/autoimmune disease.

The presence of myotonia (delayed relaxation of skeletal muscle following voluntary contraction; improves with repeated exercise), paramyotonia (gets worse with repeated exercise), or muscle hypertrophy may suggest neuromuscular causes. When primary pathology is in the nerve (cell body, axon or myelin), weakness is often more distal and associated with sensory loss. Disorders of the neuromuscular junction tend to cause patchy or diffuse weakness. Cranial weaknesses occur early. In contrast, muscle pathology tends to result in symmetrical, proximal, persistent weakness with less wasting, no sensory changes and normal reflexes (decreased only in areas of prominent weakness).[18]

Differential causes of systemic myopathy should be excluded before diagnosing inflammatory myopathy (Table 125.3).[19] Infections may be the cause of an acute myopathy or may trigger onset of JDM/JPM in susceptible individuals.[19] Fatigue, rather than weakness, is characteristic of endocrine myopathy. Constant weakness can be seen in myopathy due to systemic disease, whereas metabolic myopathy is classically associated with exercise-induced myalgia, exercise intolerance, and muscle cramps. Fatigue is a non-specific complaint but abnormal fatigability after exercise can be due to metabolic or mitochondrial myopathy or disorders of the neuromuscular junction.[19] Myalgia may be seen in infectious, inflammatory, drug-induced, or endocrine myopathy, but tends to be persistent in inflammatory muscle disorders and episodic in metabolic disease. Muscle cramps are usually benign but can be seen

in dehydration, hyponatraemia, and myxoedema. Muscle hypertrophy can be seen in hypothyroid myopathy, amyloidosis, sarcoidosis, neoplastic, or inflammatory processes.[20] Organ involvement should be considered (cardiac disease in particular is an important cause of mortality). The presence of optic atrophy or pigmented retinopathy suggests non-systemic causes. In adults, DM is associated with malignancy in approximately 24% of cases; this is thought to be due to an immune reaction to the tumour that cross-reacts with antigens in skin and muscle, leading to DM.[21] Although malignancy is reported in childhood myositis, it is so infrequent that routine assessment for occult malignancy is not warranted.

Inflammatory myopathy may be associated with other autoimmune diseases in 3–10% of cases.[22] The most common JDM overlap is with scleroderma, but any autoimmune disease may be seen including arthritis, lupus, or Sjögren's. A small minority of children have RNP+ve mixed connective tissue disease.[23] Vasculitis in the context of JDM should also be considered.

Muscle strength should be assessed at diagnosis and serially during follow-up. This can be achieved using the Childhood Myositis Assessment Scale (CMAS), a 14-item observational, performance-based instrument developed to evaluate muscle strength, physical function, and endurance in children with IIM. It addresses activities important in clinical assessment, such as timed neck flexion duration, ability to go from standing to seated position, and ability to perform sit-ups. The CMAS exhibits good reliability, construct validity, and responsiveness. A full description is provided on the ACR website (www.rheumatology.org). There is an important discrepancy between the CMAS scoring sheet found here and the original published by Lovell et al.,[24] due to typographical errors in the original article regarding scoring of certain variables (acknowledged by the authors, who agree the descriptions on the ACR website are correct). Normal scores for head lift manoeuvre and sit-ups are age and sex dependent and should be interpreted with caution, particularly in children less than 4 years of age.[25] Despite limitations, the CMAS is a valuable tool when used within its primary purpose to objectively and quantitatively compare a given patient's current performance with past performances. Although initially designed for research, it has been widely adopted as a reliable clinical tool for muscle strength assessment in units around the United Kingdom.[23]

Traditionally, muscle strength has been tested by five-point manual muscle testing (MMT), including the Medical Research Council Scale. However, recently, an expanded 0–10-point MMT scale has been used in therapeutic trials, postulated to be more sensitive in delineating weakness. The Kendal MMT-8 (Table 125.4) is now recommended, along with CMAS, as an outcome measure in JDM trials and is also a useful tool in clinical practice. The inclusion of a uniform set of muscle groups (including proximal, distal, and axial muscles with more emphasis on proximal and lower extremity muscle groups) with standardized scoring, should provide clinicians and researchers with more reliable MMT data in patients with juvenile PM/DM.[26]

Investigations should be carried out to exclude systemic causes of myopathy, confirm diagnosis of inflammatory myopathy (JDM/JPM), and determine extent of organ involvement. In light of this, blood tests should include inflammatory markers (erythrocyte sedimentation rate, C-reactive protein), renal function, liver function, muscle enzymes (creatine kinase, lactate dehydrogenase, aspartate aminotransferase, alanine aminotransferase, aldolase),

Table 125.3 Differential diagnosis of systemic myopathies[19]

Subgroup	Causes	Characteristics
Infectious	Viral: influenza, coxsackie B, HIV. Less common: adenovirus, parainfluenza	Acute weakness associated with prominent myalgia and painful muscle cramps affecting distal and proximal muscles. HIV myopathy is indistinguishable from idiopathic polymyositis clinically and histiologically
	Bacterial: *Staphylococcus aureus*, yersinia, streptococcus, anaerobic bacteria (e.g. clostridia). Less common: *Borrelia burgdorferi*, *Legionella pneumophila*	Suppurative myositis/pyomyositis. Rare in the West, but is seen in occasionally in AIDS patients
	Parasitic: protozoa, cestodes, nematodes	Focal or diffuse inflammatory myopathy ± neuropathy. May be associated with fever, myalgia, periorbital/facial oedema, or encephalopathy depending on cause
	Fungal: sporotripchosis, histomplasmosis, mucormycosis, cryptococcus, candidiasis	Uncommon but can be seen in immune-compromised patients. Can involve a single muscle group or may be diffuse. Mucormycosis can spread to the orbit causing ophthalmoplegia, proptosis or eyelid oedema
Endocrine	Hypothyroidism (proximal muscle weakness seen in one-third of patients)	Muscle complaints (pain, cramps, stiffness) frequent with proximal muscle weakness in one-third. Serum CK often elevated up to 10 times normal. Reflexes slow relaxing
	Hyperthyroidism	Often asymptomatic despite muscle weakness and atrophy on examination. Occasional bulbar muscle involvement with dysphagia, dysphonia, aspiration. Serum CK normal
	Hypoparathyroidism	Neuromuscular symptoms usually related to localized or generalized tetany, and if sustained, may cause elevation in CK
	Hyperparathyroidism	Proximal muscle weakness, muscle wasting, brisk reflexes. CK usually normal or slightly elevated
	Cushing's	Glucocorticoid excess (endogenous/exogenous) causes proximal weakness associated with cushingoid appearance. Muscle wasting may be striking
	Adrenal insufficiency (e.g. Conn's)	Muscle fatigue. Weakness typically mild. Serum CK may be elevated
	Agromegaly	Mild proximal muscle weakness without muscle atrophy
Metabolic myopathy associated with other systemic diseases	Vitamin D deficiency	Proximal muscle weakness and ataxic neuropathy. Pain due to osteomalacia. Progressive external ophthalmoplegia
	Hypokalaemia	Proximal or generalized weakness. Painless
	Hyperkalaemia	Weakness of cardiac and skeletal muscle likely secondary to effect on nerves
	Hypernatraemia	Proximal muscle weakness (rare). CK elevated
	Hypercalcaemia	Weakness with hyperreflexia
	Hypocalcaemia	Tetany more than weakness
	Hypophosphataemia	Acute severe areflexic weakness with rhabdomyolysis
	Chronic renal failure	Proximal limb weakness and bone pain. Painful myopathy may occur
	Hypomagnesaemia	Tetany with weakness
	Organ failure (cardiac, respiratory, hepatic failure)	Severe muscle wasting and complaints of weakness and fatigue
Drug- or toxin-induced myopathies	Glucocorticoid related	Proximal weakness and cushingoid features. CK usually normal
	Lipid lowering agents	Myalgia, malaise and muscle tenderness. Pain may be related to exercise. Proximal muscle weakness may be seen. CK elevated
	Alcohol and illicit drugs	Acute muscle weakness or painful chronic myopathy
	Other drugs, e.g. D-penicillamine, procainamide, L-tryptophan, amiodarone, chloroquine	Largely proximal muscle weakness, often painless
Paraneoplastic myopathy	Associated with numerous malignancies; most commonly ovary, lung, or gastrointestinal tract in Western nations (more common in adults but has been reported in children)	Myalgia and rapid progression of weakness involving proximal and distal muscles, pharyngeal and respiratory muscles. Tendency for more severe skin disease, less extramuscular or overlap features. CK normal or slightly elevated. MSA and MAA usually negative. Amyopathic DM also linked to malignancy
Critical illness myopathy	Thick filament myopathy, Acute necrotizing myopathy, cachetic myopathy	Major criteria include critical illness, difficulty with ventilator weaning and possible limb weakness. Myalgia less common. CK usually elevated

Table 125.4 Kendal MMT-8[26]

Muscle group (test right side only)	Starting position	Details
Neck flexion	Lying on back (completely flat bed)	Lift neck to 40° and place resistance on forehead
Shoulder abduction	From sitting	Shoulder abducted to 90°, arm straight at elbow, resistance placed at elbow
Elbow flexion	From sitting	Elbow flexed at 45°, supported with one hand, resistance at wrist
Wrist extension	Sitting	Forearm supported, hand pronated and wrist extended 60°, resistance on back of hand
Hip extension	Lying prone	Knee flexed to 90°, lift leg up, resistance on back of leg near knee
Hip abduction	Lying on side	Top leg slightly extended backwards, pelvis slightly rolled forward, abduct top leg, support pelvis. Resistance below knee, above ankle
Knee extension	Sitting over edge of bed	Knee extended but not locked, resistance placed above ankle. Modified if hamstrings tight (lean back onto elbows)
Ankle dorsiflexion	Lying on back	Dorsiflex the foot, resistance on top of foot
Score	**(maximum score = 80)**	
0	No movement	
1	Moves through partial range of movement in horizontal plane	
2	Moves through complete range of movement in horizontal plane	
3	Moves to completion of range of movement against resistance or moves to completion of range and holds against pressure or moves through partial range of movement in an anti-gravity position	
4	Gradual release from test position in an anti-gravity position	
5	Holds against test position (no added pressure)	
6	Holds test position against slight pressure	
7	Holds test position under slight to moderate pressure	
8	Holds test position under moderate pressure	
9	Holds test position under moderate to strong pressure	
10	Holds test position against strong pressure	

autoantibodies, thyroid function (plus other endocrine tests if relevant), virology/infection screen, bone profile (including parathyroid hormone and vitamin D). Other tests should be considered to look for other autoimmune disorders such as coeliac disease. Toxicology screen should be considered. Urine for albumin:creatinine ratio and microscopy should be taken, particularly if lupus overlap is suspected.

More than 20% of patients have normal creatine kinase (CK) at presentation,[10,13] and muscle enzymes may be normal despite ongoing active disease or disease flare. Likewise, inflammatory markers may be normal. Serum CK may help differentiate IIM from other causes of myopathy; if extremely high, Duchenne muscular dystrophy, muscle damage (rhabdomyolysis, trauma, injection), hypothyroidism, or immune polymyopathies should be considered. IIM tends to be associated with a moderately raised CK. This is also true of endocrine myopathy (hypothyroid, hypoparathyroid), asymptomatic dystrophy, metabolic or hereditary causes, exercise or trauma induced myopathy, drug toxicity, idiopathic hyperCKaemia, and certain races/genders (typically African American men).[18]

Antibody tests should be taken, including ANA and anti-ENA. Other antibody tests should be considered if overlap features are present and may include rheumatoid factor (RF), anti-dsDNA,

anti-C1q antibody, and anti-thyroid antibodies. Tests for MSA and MAA (see above) are reliable, but currently not routinely available.

Traditional diagnostic criteria of JDM/JPM include EMG. This remains important if neuropathy is suspected, but an international survey of 118 clinicians from 92 centres (32 countries) caring for children with JDM found routine use of EMG was as low as 56%.[27] In contrast, MRI is increasingly used to help diagnose JDM/JPM and appears to be a valid indicator of disease activity. T2 weighted STIR images (fat suppressed) detect muscle inflammation and oedema in the subcutaneous tissue, myofascia, and skin. T1-weighted images may detect muscle atrophy and fatty infiltration. An MRI scoring system has been developed that objectively defines acute inflammatory change in JDM into four muscle groups and surrounding soft tissues.[28] Retrospective analysis of MRI scans by two paediatric radiologists showed fair to moderate agreement for all muscle groups and good intra-observer agreement between two readings. Further studies are needed. An evaluation of MRI in 45 children (36 with sufficient clinical data to assess duration of symptoms at time of MRI) with biopsy-proven JDM showed MRI appearance of muscle or fascia at diagnosis could not be used to predict clinical outcome, but abnormal increased signal intensity in subcutaneous fat had a high specificity (91%) for predicting ultimate progression

to chronic or chronic ulcerative disease, independent of duration of symptoms at presentation.[29] Young children need sedation or general anaesthetic for MRI imaging. Musculoskeletal ultrasound may provide a safe, inexpensive, non-invasive means of supporting the clinical diagnosis of JDM and monitoring disease progression, without sedation. Ultrasound findings appear to correlate well with other markers of disease activity.[27]

Analysis of muscle biopsy tissue will often lead to confirmation of the diagnosis of JDM/JPM (Table 125.2). In order to determine the severity of JDM, an internationally agreed scoring system for muscle biopsies has been developed by consensus.[30] Muscle biopsies are scored using four domains: (1) inflammatory, (2) vascular/endothelial changes, (3) muscle fibre abnormalities (including staining for MHC class I overexpression), and (4) connective tissue changes. Prospective testing of this tool is underway. Greater understanding of muscle biopsy changes, including early abnormalities detected by advancing techniques, may allow prediction of disease course and prognosis.

The presence or extent of calcinosis should be determined by radiography (Figure 125.2) if clinically indicated. Investigations should also look for organ involvement including interstitial lung disease (chest radiograph, lung function tests, HRCT chest), cardiac involvement (ECG, echocardiogram), or abdominal pathology (ultrasound). A speech and language assessment may be needed with videofluoroscopy if there is dysphagia, dysphonia, or symptoms of aspiration. Nailfold capillaroscopy is helpful for distinguishing JDM from muscular dystrophies or other myopathies. It is a valuable marker of muscle and skin activity in JDM and has been found to be associated with other clinical measures of disease activity when analysed in 92 patients.[31] Within this cohort, 28 children had nailfold capillaroscopy at diagnosis; nailfold capillary density was reduced at onset but improved as the disease improved.

Disease course

Severity of disease can be difficult to judge at onset. Milder disease is usually monocyclic; a single episode, often recovering within a few years. Polycyclic disease course occurs with remissions and relapses, with the most severe disease being classed as 'chronic persistent': the disease may persist with no remission, for 15 years or more. Prior to the steroid era, one-third of JDM cases recovered, one-third were left with sequelae that caused severe disability, and one-third died.[32] Since the introduction of immunosuppressant medication, mortality has reduced significantly. In the first 10 years of the United Kingdom JDM Cohort and Registry Study, 285 patients were recruited (175 within 12 months of diagnosis), of which 3 died, giving an approximate mortality of 1%. This study has not recruited all British cases of JDM, and will not capture patients with severe disease who die prior to, or around time of diagnosis. In an international (European and South American) long-term follow-up study of 490 patients, mortality was 3.1%.[33] A prolonged course was predictive of poorer outcome, with persistently active disease at mean follow-up of 7.7 years in 40–60% of patients. In JDM, disease activity in the muscles often differs from that in the skin. Patients with prolonged disease course often have persistent skin activity even when myositis has come under control. One of the most difficult aspects of JDM to control once it has occurred is calcinosis. It is thought that increasing calcinosis is due to active disease and it can regress on treatment (unlike adult disease), but no one medication has been successful in halting progression of calcinosis. Cardiovascular mortality is significant in adult IIM. Subclinical cardiovascular changes are suggested in JDM and a recent study in a small number of adult patients with a history of definite or probable JDM (n = 8) found increased atherosclerotic burden compared to healthy controls.[34] Further studies are needed to assess long-term cardiovascular risk.

Disease activity and damage assessment tools

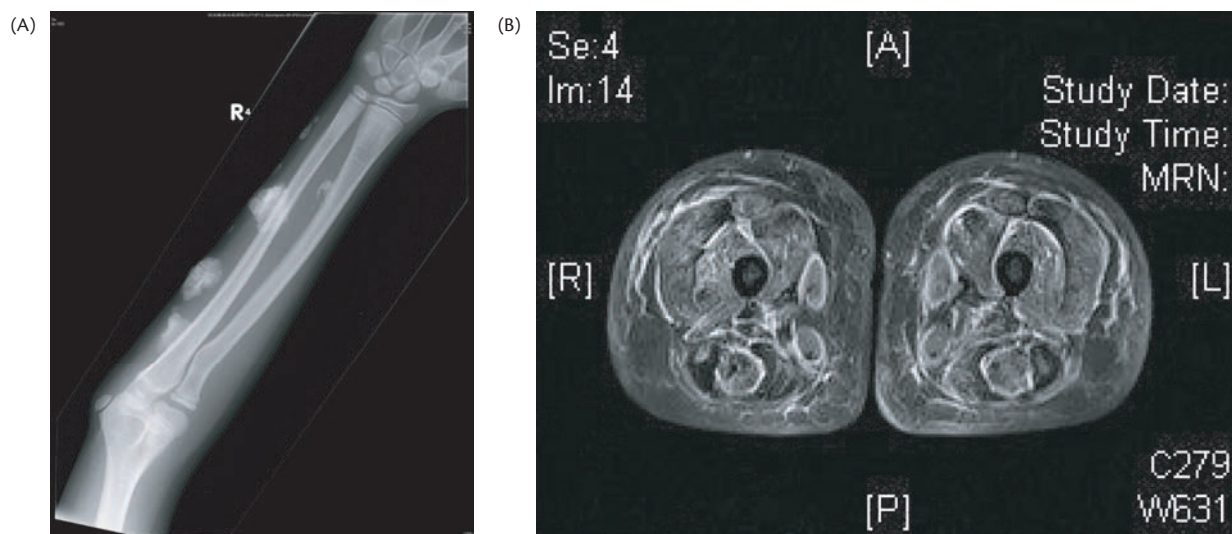
Disease severity at onset, as well as disease course, needs to guide aggressiveness of medical treatment. The multisystem aspect of disease makes assessments complex. Disease activity needs to be separated from disease damage. This can be difficult in paediatric


Fig. 125.2 Radiological signs of juvenile dermatomyositis: (A) radiograph of calcinosis; (B) MRI scan of thigh (axial STIR sequences) showing increased signal intensity (brightness) consistent with severe inflammation (myositis). Changes seen include soft tissue oedema, perifascicular oedema, and muscle oedema.

cases, where the power to repair is different from adults; during childhood, eroded bones can remodel, and calcinosis can regress and disappear. In order to study patients, disease activity assessment tools have been developed. The Disease Activity Score (DAS) rates muscle and skin disease.[35] A more comprehensive disease activity tool (MDAA) has been developed and standardized by an international group for use in adult and paediatric trials, but needs time and standardized training to be reliable. Two core set measures for clinical studies and criteria for response to treatment have been proposed for use in clinical trials. A separate disease damage tool (the Myositis Damage Index) has also been developed.[36]

Management

There are few published randomized controlled trials (RCTs) for myositis; most of the evidence base comes from case series and expert consensus. The first-line treatment for patients with JDM is corticosteroids. Evidence for use of steroids comes from the mortality rate of the presteroid era (one-third of patients),[32] compared to 10% in the early poststeroid era.[37] Route of administration has little evidence base, and varies depending on local healthcare systems and historical practice, but oral steroids are often started at 2 mg/kg, and maybe divided into two to four doses a day. The intravenous (IV) route may bypass absorption problems secondary to gut inflammation,[38] giving faster symptom control but with little effect on long-term outcome. In the United Kingdom, many centres start with IV followed by oral steroids.[23]

Drug treatment: disease-modifying drugs

Many centres use methotrexate (MTX) as the disease-modifying anti-rheumatic drug (DMARD) of choice, irrespective of disease severity. Over 90% of patients in the UK cohort study were given steroids and MTX.[23] There is evidence that early introduction of these drugs reduces incidence of calcinosis.[39] Previously, ciclosporin was used, based on a case series of 14 patients,[40] but it has been less frequently used since 2000,[14] when MTX became more widely utilized.[41] A randomized study to compare steroids (monotherapy) as first-line therapy vs steroids and MTX vs steroids and ciclosporin has been undertaken by PRINTO (the Paediatric Rheumatology International Trial Organization). Preliminary results show better response with MTX or ciclosporin compared to steroid alone. More side effects were seen with ciclosporin than MTX, supporting the usual UK practice of prednisolone and MTX as first-line treatment.

Intravenous immunoglobulin (IVIG) is widely used. An RCT in adult DM demonstrated effectiveness in 15 patients resistant to treatment.[42] In a Children's Arthritis and Rheumatology Research Alliance (CARRA) survey, physicians used IVIG for severe or refractory disease, and for significant skin disease.[43] In the United Kingdom, the Department of Health National Demand Programme for IVIG has approved IVIG for long-term use in JDM when alternative therapies have been used where appropriate (www.ivig.nhs.uk/clinicianinfo.html).

Other DMARDs used include azathioprine (often in combination with MTX), hydroxychloroquine, and mycophenolate mofetil (MMF). A retrospective case series of 12 patients showed improvement in myositis and skin rash with MMF including regression of calcinosis in one case.[44] Another retrospective case series showed improvement in muscle strength and skin rash at 6 months in 50 patients, with a further improvement in skin rash by 1 year.[45] Severe disease (such as skin ulceration, interstitial lung disease, and gastrointestinal perforation) is treated with IV cyclophosphamide; demonstrated to improve outcome in a retrospective case series of 12 patients with severe disease refractory to a combination of DMARDS.[46] Due to the side-effect profile of IV cyclophosphamide, it is reserved for patients with severe disease.

Anti-TNF (tumour necrosis factor) monoclonal antibodies have been used to treat IIM. An adult RCT of 16 patients refractory to treatment demonstrated improvement in muscle strength at 6 months in 9 of 11 patients on etanercept.[47] A retrospective case series of five JDM patients on infliximab showed improvements in all five,[48] and an updated case series from the UK cohort with 30 patients showed improvement in muscle strength, skin rash, and calcinosis.[49] The first international RCT in adult and juvenile DM has taken place using the anti-CD20 monoclonal antibody rituximab. Previous case series showed promising results in refractory patients. Although the trial failed to meet primary and secondary endpoints, the overall response rate, steroid-sparing effect, and retreatment response in a refractory group of patients suggest rituximab does have an effect.[50]

Anecdotal reports of treatments that have helped to treat calcinosis include diltiazem, infliximab, and bisphosphonates. Diclofenac is a useful non-steroidal anti-inflammatory drug (NSAID) to help inflammation around calcinotic deposits, and flucloxacillin can help secondary infection that may prolong or worsen calcinosis. In JDM, increasing calcinosis should be treated with more intense DMARD use, as widespread calcinosis causes severe morbidity and disability.

As JDM is rare, it will be difficult and expensive to undertake international RCTs. Many in the paediatric rheumatology community have advocated a system of using treatment plans to enrol all children with JDM. This system would parallel the system for childhood malignancies (which have allowed protocols to be evaluated and refined, leading to improved survival). To this end, CARRA have undertaken a survey of treatment practices in JDM,[43] followed by consensus conference to produce three consensus treatment plans for moderate severe cases of JDM.[51] Physicians can choose the treatment plan most akin to their practice and most suitable for their patient. Patient data are collected, and using statistics (taking into account intention to treat differences), plans can be compared and evaluated. The three consensus treatment plans are summarized in Table 125.5.

Non-drug treatment

The role of allied health professionals in the treatment of JDM is crucial: physiotherapists, clinical nurse specialists, occupational therapists, and psychologists provide important therapeutic input. It is important to prevent contractures as these can cause severe disability even when muscle strength has returned. Historically, active physiotherapy in the early stages of disease was discouraged, due to concerns that it would worsen inflammation and cause calcinosis. There is little evidence to support this; in a small study of JDM patients and normal controls, no increase was seen in muscle enzymes or MRI signal after undertaking a short exercise programme.[52] Patients with JDM have been shown to have impaired maximal aerobic exercise capacity when using a treadmill.[53] They can be helped to improve muscle strength and regain stamina through a targeted exercise programme.

Table 125.5 CARRA consensus treatment plans for moderately severe juvenile dermatomyositis[51]

Consensus treatment plan A	Consensus treatment plan B	Consensus treatment plan C
IV methylprednisolone 30 mg/kg/day (max 1g) × 3; may continue 1×/week (optional). Followed by: **Oral prednisone** 2 mg/kg/day (max 60 mg) once daily for 4 weeks, then decrease by 20% (as dictated by the treating physician)	**IV methylprednisolone** 30 mg/kg/day (max 1 g) × 3; may continue 1×/week (optional). Followed by: **Oral prednisone** 2 mg/kg/day (max 60 mg) once daily for 4 weeks, then decrease by 20% (as dictated by the treating physician)	**Oral prednisone** 2 mg/kg/day (max 60 mg) divided into twice daily doses for 4 weeks, then consolidate to once daily (as dictated by the treating physician)
Methotrexate (SC unless only oral possible); either 15 mg/m² or 1 mg/kg (maximum 40 mg) once weekly	**Methotrexate** (SC unless only oral possible), either 15 mg/m² or 1 mg/kg (maximum 40 mg) once weekly **IVIG** 2g/kg (max 70g), fortnightly for 3 doses, then monthly **Optional IV methylprednisolone** × 1 with each IVIG	**Methotrexate** (SC unless only oral possible). Lesser of 15 mg/m² or 1 mg/kg (maximum 40 mg) once weekly

A recent study of sleep and fatigue in patients with childhood rheumatic diseases, including 33 patients with JDM, found sleep was disturbed in approximately one-half of the patients, correlated with increased pain and decreased quality of life.[54] Children may need to return to school on a part-time basis initially, building up to full-time as they regain stamina. Liaison with schools is often beneficial. For families, coping with JDM and its impact on daily lives can be very difficult and support from experienced nurses, play specialists, and psychologists can be invaluable.

Case histories

Case history 1

6 year old girl: 2-year history of knee pain. Weakness implied by history of not being able to pull herself out of a swimming pool (twin sister had no difficulty). Frequent abdominal pain and poor growth compared to twin. Serum CK raised (2018 iu/litre), inflammatory markers (ESR, CRP) normal, ANA positive (>1:160), anti-ENA negative. O/E: Skin changes over MCP and PIPs suggestive of old Gottron's patches. Nailfold capillary changes seen using KY jelly and ophthalmoscope. Mild synovitis of wrists, decreased end range movement. Neck flexors and abdominal muscles weak, but normal muscle strength in limbs. MRI scan of thighs normal but muscle biopsy demonstrated changes consistent with JDM. Treatment started (steroid and methotrexate) with good response.

Learning points: Diagnosis of JDM was delayed in this child for the following reasons:

1. JDM considered unlikely because of normal inflammatory markers.
2. Skin features not recognized as old Gottron's.
3. Muscle weakness was subtle and required careful examination of neck flexor and abdominal muscles.
4. Muscle biopsy was needed to confirm diagnosis (MRI normal). MRI more likely to show abnormalities in acute phase (more oedema and inflammation).

Case history 2

12 year old boy: presented with rash, aching feet, shortness of breath, difficulty swallowing and nasal regurgitation. O/E: Rash typical of JDM (heliotrope changes, malar erythema with nasolabial involvement, Gottron's patches, nailfold capillary changes). CK and LDH elevated (2021 iu/litre and 1178 iu/litre respectively). ANA positive (1:160). EMG showed myopathic potential. MRI (T2 weighted) showed inflammatory changes consistent with JDM. Treated with intravenous methylprednisolone, followed by weaning course of oral steroid; good response. Two years later, complained of muscle weakness and tenderness. O/E: Active nailfold capillaries and Gottron's patches, weakness (CMAS score 15/53), mild restriction of elbows, knees, wrists and hips. Serum CK and LDH normal (61 iu/litre and 500iu/litre respectively). Treated with steroid (IV methylprednisolone followed by oral prednisolone) and methotrexate. Weakness improved, but skin remained active. Developed skin ulceration (armpits and elbow). Cyclophosphamide added with good effect.

Learning points:

1. Muscle enzymes may be normal in disease flares or later in disease.
2. Disease should be treated early and aggressively to obtain remission. Steroid monotherapy was inadequate and DMARD should have been added at presentation.
3. Stepwise approach needed; increase in immune-suppressive therapy if inadequate response. Cyclophosphamide indicated for severe ulcerative skin disease or major organ involvement.

Case history 3

4 year old boy: 2–3 months of tiredness, leg pain, not wanting to walk far; asking to go in buggy. Following holiday in Florida, developed sore throat, maculo-papular rash, particularly over axilla, violaceous skin rash over periorbital area, puffy eyes, erythema of nail beds and fingers. Two weeks later, developed generalized swelling of limbs and abdomen. Became extremely tired

with loss of appetite and activity. O/E: Lethargic, unwell with generalized oedema, violaceous macular rash over periorbital area, face, chin, neck, nail beds, knees and elbows. Macular-papular rash over both axillae, mild oral ulceration and gum swelling. Hepatomegaly (2–3cm), proximal muscle power of 3/10, distal power of 5/10, nasal speech. Muscle enzymes raised: CK 6926 iu/litre (5–120), LDH 3062 iu/litre (470–900). MRI showed significant increase in T2 signal bilaterally in the quadriceps and the thigh abductors consistent with myositis. Management: Treated with IV methyl prednisolone (high-dose, then maintenance) and subcutaneous methotrexate but developed skin ulceration in axillae: IV cyclophosphamide added for 6 doses. Muscle enzymes started to fall after the first week, but unable to tolerate oral steroids (abdominal pain and distension) for 3 months, requiring IV steroids (maintenance) daily via Hickman line. Remained on steroids for 18 months; stopped all treatment after 3.5 years. Muscle enzymes normalized by 4 months, but mild residual muscle weakness remained at 12 months. Currently well with no sequelae 4 years after stopping treatment.

Learning points:

1. In young children, parents may think their child is being lazy rather than weak.

2. Muscle enzymes recover faster than muscle strength.

Case history 4

4 year old Afro-Caribbean girl: presented to neurologist with difficulty climbing stairs, frequent falls, fatigue and joint pain. O/E: Facial rash around eyes and on neck. CK elevated (5000 iu/litre). Muscle biopsy consistent with JDM. Treated with oral prednisolone. Azathioprine added eight months later for recurrence of symptoms. Failed to improve – treated with IV steroids and ciclosporin. Eight months later she was osteoporotic and developed calcinosis in her right cheek. Transferred to rheumatology. O/E: Active capillary loop dilatations of nail beds, calcinosis in her left cheek, muscle strength of 3 to 7/10, patchy myositis on MRI thigh. CK normal, insignificantly raised LDH of 925 iu/litre (470–900). Treated with subcutaneous methotrexate, but soon flared and developed calcinosis on anterior chest wall. Infliximab added; calcinosis slowly regressed, with none in the chest 3 years later. Calcinosis of the cheek successfully removed by plastic surgeons.

Learning points:

1. Use DMARD early to control disease and prevent calcinosis. Add additional DMARD if calcinosis occurs (prolonged use often required for regression of calcinosis).

2. Surgical removal of calcinosis only if absolutely necessary; ensure disease controlled before surgery to prevent recurrence or discharging fistulae.

Non-inflammatory myopathies

Mark Roberts

Introduction

Non-inflammatory myopathies (NIM) are a diverse group of genetic disorders characterized by neuromuscular weakness, fatigue, muscle wasting, and pain due to inherited defects in proteins critical in the structural integrity and function of muscle fibre or in enzymes involved in energy production in this most metabolic tissue. The shared clinical and laboratory features (including elevated muscle enzyme levels, myopathic change on electromyography, and even inflammatory changes on muscle biopsy) of myositis and NIM frequently cause diagnostic confusion. Failure to distinguish these disorders will result in unnecessary immunosuppression, lack of screening for cardiorespiratory and other associations of NIM, and a missed opportunity for genetic counselling and potential future treatments. A strong index of suspicion is required in all patients presenting with neuromuscular syndromes if a long diagnostic odyssey is to be avoided. A clinically focused multidisciplinary approach, with a working knowledge of subtypes of NIM (as summarized in Box 126.1) is outlined in this chapter.

Clinical assessment: history

Weakness

Neuromuscular disorders commonly present with weakness, and focused enquiry into this symptom often accelerates a diagnosis of NIM. An accurate history documents the onset, nature and pattern, and progression of weakness, and is crucial in differentiating subtypes of NIM.

Reduced fetal movements and difficulties at delivery may suggest a congenital myopathy, metabolic, or myotonic disorder. Initially normal and then delayed motor milestones may suggest a muscular dystrophy such as Duchenne muscular dystrophy (DMD). It is common for weakness to be falsely attributed by doctor and patient alike to laziness, growing pains, or asthma in childhood, or to normal ageing or painful conditions in later life. A directive questioning style is required with questions such as 'when did you first use a stick?' Inquiries into sporting abilities, occupational history, and military service will often also help time the onset of symptoms, as will consultations with both patients and their relatives.

The nature and pattern of weakness is again often suggested by the history. Proximal weakness is seen in most NIM, and in the upper limbs causes practical difficulties reaching up to a shelf or combing

hair. Weakness in the legs presents with difficulty in rising from a low chair, climbing stairs, and stepping up on to a train or bus. Many patients with NIM either never run, or do so in an idiosyncratic fashion. Patients with distal weakness, for example in myotonic dystrophy (DM1), develop altered walking patterns (including high-stepping gaits) to prevent tripping, or may have problems turning a key or opening a jar. An inability to whistle, or to smile in family photographs, often indicates weakness of facial muscles (fascioscapular humeral muscular dystrophy (FSHD), or DM1). Speech and swallowing problems, and unexplained recurrent pneumonia may suggest weakness of bulbar musculature (DM1, and other

dystrophies). Weakness of the cervical muscles will often lead to a complaint of the head falling forward ('head ptosis'), and is common in NIM including DMD and DM1. Shortness of breath on exertion, swimming in a front crawl, and lying flat all indicate involvement of respiratory musculature and are common in NIM.

The majority of NIM slowly progress as charted by a decline in motor function such as first use of a walking aid, furniture walking, and wheelchair use. Wheelchair dependence should always prompt consideration of NIM in patients with apparent steroid-resistant myositis and when correction of metabolic deficiencies such as hypocalcaemia, hypothyroidism, and vitamin D deficiency fails to improve clinical status.

Pain

Myalgia—muscle pain—is a common and relatively non-specific feature in both acquired (myositis) and genetic NIM, especially muscular dystrophies including FSHD and Becker muscular dystrophy (BMD), as well as less defined conditions such as fibromyalgia. Temperature-dependant exacerbation of myalgia may well indicate myotonia—delayed muscle relaxation. Specific enquiry into exercise-induced pain is useful in helping to identify metabolic myopathies, with glycogenolytic and fatty acid oxidation disorders associating with early and delayed pain respectively. A question such as 'Have you ever had Coca-Cola-coloured urine?' is useful in patients with muscle pain; it suggests myoglobinuria, and again suggests a metabolic disorder, particularly if a recurrent feature. Many NIM patients suffer with hip knee and lumbar spinal pain, whose presentation may predate the neuromuscular diagnosis.

Systemic enquiry

In patients with known NIM enquiry about cardiorespiratory symptoms is mandatory given common associations such as cardiomyopathy, cardiac arrhythmia, and respiratory failure. Equally, uncovering unexpected symptoms in patients suspected to have myositis such as palpitations (arrhythmias), blurring of vision (cataracts), deafness, and diabetes may suggest a multisystem disorder such as DM1 or a mitochondrial cytopathy.

Family history

Probing into a family history of neuromuscular disease/symptoms, facets of multisystem diseases, together with a gentle enquiry into cosanguinity together with causes of (including premature) death will often indicate the nature and pattern of inheritance of NIM. Examination of affected relatives, where permitted and practical, may also yield valuable insights into both diagnosis and prognosis, and is particularly useful when novel mutations in candidate genes of uncertain pathogenic significance are detected.

Clinical assessment: examination

Examination of the neuromuscular system seeks to confirm the distribution of muscular involvement suggested by the history, and to assess its severity using the MRC scale or (timed) functional tests e.g. the Gower s' manoeuvre. Weakness and wasting of proximal limb muscles are common to many muscle disorders, and only detailed examination will reveal physical signs suggestive of NIM:

Gait

Inspection of gait may reveal expected features such as a 'waddling' pattern, and additional signs such as an excessive lumbar lordosis (a very common sign in NIM patients), foot drop (indicating distal weakness) and genu recurvatum in patients with severe quadriceps involvement.

Craniobulbar muscles

Cranial nerve signs are common in NIM. Weakness of facial muscles with reduced eye or lip closure is found in several NIM such as FSHD (Figure 126.1). Ptosis is a prominent feature in several muscular dystrophies, e.g. DM1 and oculopharngeal muscular dystrophy, and mitochondrial disease, and may be associated with compensatory overactivity in frontalis muscles. Involvement of extraocular muscles with strabismus and diplopia is found in several NIM, including mitochondrial disease and congenital myopathies. Bulbar palsies with a nasal dysarthria and a risk of aspiration are common in NIM, especially DM1. Neck extension weakness results in head drop and is common in DM1, and seen later in the clinical course of FSHD and acid maltase deficiency (Pompe's disease).

Limb muscles

Although most myopathies tend to cause symmetric proximal weakness, examination of the patient undressed can be justified as unanticipated muscular involvement may prove crucial in making a NIM diagnosis. A number of clinical algorithms are available to narrow the diagnosis.[2] Though not exhaustive, the following examples illustrate the utility of this approach:

◆ A generalized global reduction in muscle bulk is likely to indicate a congenital myopathy.

◆ Generalized muscle hypertrophy is seen in some congenital myotonic syndromes, producing the so-called Herculean appearance. Pseudohypertrophy, with fatty infiltration of weak muscles best seen in the calves, is seen in a number of dystrophies including

Fig. 126.1 Fascioscapular humeral muscular dystrophy weakness of facial muscles with reduced smile, and widening of palpebral fissures.

BMD (Figure 126.2) and several LGMDs. Amyloid and glycogen deposition, e.g. Pompe's disease, may also lead to muscular hypertrophy including the tongue.

- Predominant proximal weakness of the lower limbs with an elevated creatine kinase (CK), in the absence of extraocular and facial weakness, and having considered DMD/BMD, may suggest a limb girdle muscular dystrophy (LGMD).

- Scapular winging is rare in myositis and is seen in a number of muscular dystrophies (including FSHD where it often asymmetric (Figure 126.3), and a number of LGMDs), metabolic syndromes such as Pompe's disease, and hereditary inclusion body myopathy with Paget's disease and dementia.

- Distal upper and lower limb involvement occurs in DM1, and a number of rare conditions including young-onset (e.g. Nonaka and Myioshi myopathies) and older-onset disorders (e.g. Welander's, tibial myopathy of Udd).[3]

- Myotonia, delayed relaxation of skeletal muscle following voluntary contraction, is seen prominently in myotonic dystrophies such as DM1 and ion-channel disorders such as myotonia congenital (but can occur in a subclinical form detectable on electromyography (EMG) in DM2 and Pompe's disease)

- Contractures are rare in acquired myopathic syndromes such as myositis but common in long-standing NIM with Achilles tendon shortening often resulting in toe walking in childhood with DMD and frequently requiring surgery or splinting. Finger and elbow contractures are uncommon even in NIM and are likely to indicate a disorder of collagen expression such as Bethlem myopathy, Emery–Dreifuss muscular dystrophy, and are also seen in some forms of LGMD.

- In DM1 deep tendon reflexes are reduced or absent; in other NIM reflexes are normal, except in disorders with associated neuropathy.

Spine

Involvement of paraspinal muscles is common in NIM including congenital myopathies, DMD, LGMD and metabolic myopathies such as Pompe's disease. Muscular weakness resulting in various combinations of undue prominence of the spinous processes, scoliosis, kyphosis, lordosis, or with contractures a rigid spine with limited forward flexion. Secondary disorders such as accelerated lumbar spondylosis, and hip dysfunction are common with an antalgic component to gait.

General examination

Cardiac and respiratory examination is prudent as these systems are often affected in NIM. Screening for cataracts and deafness is recommended if a multisystem disorder is suspected.

Neuromuscular investigations

Muscle enzymes

CK is expressed in a variety of tissues including heart, skeletal muscle, and liver. CK is elevated modestly in neurogenic disorders, and can be normal or significantly elevated in patients with both myositis and NIM. CK values greater than five times normal always indicate muscle disease. Persistently high CK levels (>10 times normal) are often found in patients with muscular dystrophies, including DMD and LGMD, and during episodes of rhabdomyolysis in

Fig. 126.2 Becker muscular dystrophy pseudohypertrophy of calves.

Fig. 126.3 Fascioscapular humeral muscular dystrophy striking asymmetric scapular winging, and excessive lumbar lordosis (same patient as shown in Figure 126.1).

patients with metabolic myopathies such as McArdle's disease. High variable CK levels may indicate myositis but also occur in NIM such as metabolic and myotonic myopathies.

Neurophysiology

Concentric needle electromyography (EMG) has a high sensitivity in distinguishing neurogenic and myopathic disorders. Muscle is normally electrically silent at rest. In neurogenic disorders positive sharp wave and fibrillation potentials are seen at rest in EMG studies, and on activation a reduced interference pattern is seen, reflecting the loss of motor neuron units. In chronic myopathy patients EMG reveals small-amplitude, short-duration motor unit potentials on activation and cannot reliably distinguish individual myopathic disorders, though spiky, unstable, and myotonic changes favour myositis and NIM respectively.

Muscle imaging

Ultrasound and CT can be useful in guiding muscle biopsies increasing their diagnostic yield. MRI scans of muscle can resolve selective muscle involvement more precisely, indicate pathological change (oedema and fatty change), and have been used for many years in the work-up of patients with suspected myositis. More recently MRI scans have been used in NIM, including congenital myopathies where the imaging phenotypes are providing diagnostic 'signatures' which may focus genetic tests and so reduce the diagnostic odyssey. MRI phenotypes are also being defined for some forms of LGMD (Figure 126.4) and Pompe's disease, speeding diagnosis, and with volumetric techniques may provide adjuncts to clinical measures in drug and other trials.

Muscle biopsy

Currently surgical open or percutaneous needle/conchotome muscle biopsies remain an essential diagnostic tool. Common features of myopathies include variation in muscle fibre size and increased internal nuclei.

Split and regenerating fibres with increased endomysial connective tissue are the hallmarks of musucular dystrophy. Immunological stains to define specific scarolemmal protein depletion in frozen sections and western blotting techniques help to distinguish subtypes of LGMD (Figures 126.5 and 126.6), confirmed by subsequent DNA analysis. Considerable care is required to not overinterpret inflammatory changes in dystrophic biopsies as these are relatively common, particularly in early stages of these diseases.

In metabolic myopathies accumulation of substrates such as glycogen and lipids may be apparent, though often such stains are normal and formal quantitation of enzyme in muscle, cultured skin fibroblast, or lymphocytes is often required in suspected cases.

Changes in oxidative enzymes such as cytochrome oxidase may suggest a mitochondrial disorder, with muscle providing a useful source of mitochondrial DNA for further analysis (Figure 126.7).

Inclusion bodies and other degenerative features may suggest a dystrophy or a still rarer myofibrillary diosorder

Descriptions of the pathologies seen in the more common NIM are now given in their order of frequency.

Myotonic disorders

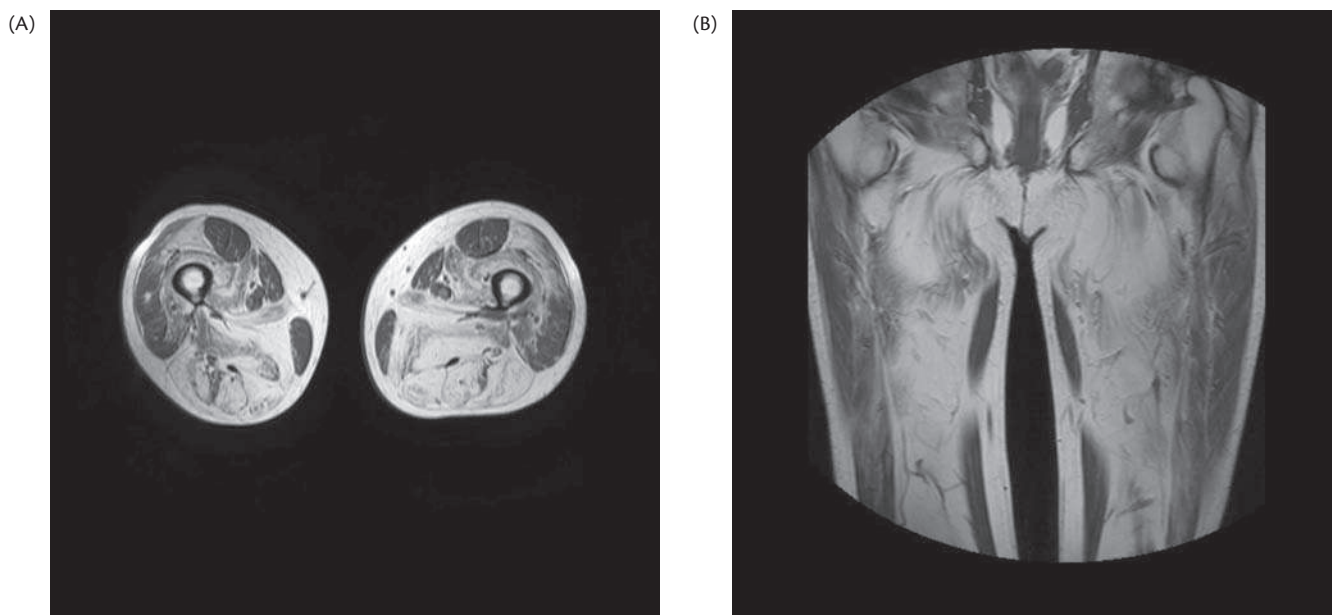
DM1 or Stienhert's disease is the most common adult-onset inherited neuromuscular disorder with progressive wasting of the face, masticatory, neck, and distal limb muscles. The myotonia can be troublesome, and lessens as wasting advances. Associations of this multisystem condition are well known and include cardiac arrhythmias, cardiomyopathy, respiratory failure, cognitive dysfunction, somnolence, cataracts diabetes, hyopgonadism, and gastrointestinal dysfunction. DM1 is an autosomal dominant disorder with variable penetrance due to a trinucleotide (CTG) expansion in the untranslated *DMPK* gene on chromosome 19. This expansion is unstable, get larger in successive generations, and correlates with earlier, including congenital onset and worsening clinical phenotype—anticipation.[4] Abnormalities in RNA production or function other proteins coded for by neighbouring genes account for the diverse


Fig. 126.4 Limb girdle muscular dystrophy 2I (common *FKRP* mutation). MRI scan: striking atrophy of hamstring muscles on axial (A) and sagittal (B) images.
Fig. 126.5 Becker muscular dystrophy: (A) haematoxylin and eosin slide showing marked variation in muscle fibre size; (B) upregulation of dystrophin related protein/utrophin (brown sarcolemmal staining); (C) reduced staining with anti-dystrophin antibodies (DYS1).

features of the condition. DNA-based diagnosis is straightforward, can promote genetic counselling, and, with the availability of pre-implantation genetic diagnosis now possible, potentially reduce the impact and frequency of this life-shortening condition.[5]

DM2 or proximal myotonic myopathy is a less common, and generally milder, multisystem disorder due to a tetranucleotide (CCTG) expansion in the *ZNF9* gene on chromosome 3. Weakness is proximal and only in late stages distal. Muscle pain is a prominent feature, myotonia may only be detectable on EMG and rheumatologists may well be referred such patients. Paroxysmal atrial fibrillation is a common feature and a clue to the diagnosis, which is sometimes unmasked by the development of hypothyroidism.[6]

Myotonia congenita is a non-dystrophic condition with troublesome and occasionally painful myotonia, due to mutations in sarcolemmal chloride ion channels which can be inherited in a dominant (Thomsen) or recessive (Becker) fashion. The condition may mimic fibromyalgia but, of note, myotonia is aggravated by cold temperature, and improves with exercise. Muscle hypertrophy is common. Mexilitene may help myotonia and is currently undergoing clinical trials.

Dystrophinopathies, Duchenne and Becker muscular dystrophy

DMD and BMD are X-linked dominant allelic disorders due to mutations in the dystrophin gene, the largest gene in the body.

DMD is a severe disorder occurring in around 1/3000 live male births and associated with mutations (around one-third of which are spontaneous) which disrupt the open reading frame, resulting in stop codons, and little or no dystrophin production in muscle biopsies confirmed with western blotting. CK is often very high and may be detected in newborn screening programmes. Initial development is often normal, but by 2–3 years of age delayed motor milestones are apparent, and historically by 11 most boys are in a wheelchair, and die of cardiorespiratory failure in their late teens or early 20s. Patients have typical proximal neuromuscular phenotype with additional scoliosis (calf) pseudohypertophy and joint contractures. Mental retardation is frequent; skin ulceration and gastrointestinal problems including volvulus are less common. Early use of steroids defers both loss of ambulation and respiratory failure. Non-invasive ventilation and cardiac support (ACE inhibitors and atypical beta-blockers) prolong life by 10 years or more.[7]

Gene therapy shows promise and may alter the natural history with patients having a clinical course akin to BMD.[8]

BMD is less severe and is associated with in-frame mutations in the dytrophin gene with some protein product. BMD may present in mid childhood and even adulthood, and is likely to be referred to rheumatologists, particularly as myalgia (especially calf pain) is a common feature. CK is often elevated to 5000 iu/mL or more. Calf pseudohypertrophy, ECG changes with tall right precordial R waves, and family history enquiry distinguish BMD from myositis. Dilated cardiomyopathy can be a prominent feature of BMD and can be disproportionately severe when compared to skeletal muscle weakness. Particular care is needed in considering BMD/DMD manifesting carrier status in females where again it might mimic myositis.

Fascioscapular humeral muscular dystrophy

FSHD, or Landouzy–Dejerine syndrome, is a progressive autosomal dominant disorder with descending weakness and atrophy of facial, shoulder, and humeral muscles. Scapular winging is typically asymmetric and worse on the side of handedness. Pelvic and distal leg weakness also develops in most patients, lumbar lordosis is common, and around 20% require a wheelchair. Pain and fatigue are common features which might cause confusion with myositis, or fibromyalgia. A strong clinical suspicion is required in making the diagnosis as one-third of patients are a de-novo mutation, and laboratory investigations are either non-specific (EMG chronic myopathic, CK is either normal or modestly elevated) or confusing (muscle biopsy may show dystrophic, neurogenic, or inflammatory features). Fortunately genetic testing is readily available, and around 95% of FSHD patients have a DNA rearrangement with shortening of chromosome 4q3. Recent work has shown this chromosomal shortening is due to deletion of D4Z4 repeats which allow derepression of the *DUX4* gene which in turn affects the function of nearby genes.[9] A European database has been proposed to facilitate clinical trials.[10]

Limb girdle muscular dystrophies

The term LGMD refers to significant numbers of both male and female patients with a high CK and predominately proximal lower limb weakness in the absence of phenotype suggestive of DMD/BMD or FSHD. This concept, first suggested by the Rare Muscles Diseases group in Newcastle, was initially controversial but with increasing linkage and DNA-based studies is now widely accepted. An alphabetical classification delineates rare
Fig. 126.6 Limb girdle muscular dystrophy 2B (complex heterozygote dysferlin mutation): western blot of leg muscle showing reduction in dysferlin band in patient (PT) compared to control (C).
Fig. 126.7 Mitochondrial disorder (patient with POLG1 mutation) showing (A) muscle fibres deficient in cytochrome oxidase staining blue on COX/SDH preparation and (B) subsarcolemmal aggregates of mitochondria staining red ('ragged red') on Gomori trichome preparation.

autosomal dominant (LGMD1A–E) and more common recessive (LGMD2A–N) variants.

The frequent absence of a family history may readily cause diagnostic confusion with myositis, particularly as muscle biopsies in some forms of LGMD can show inflammatory features (e.g. LGMD2B),[11] as discussed in detail on www.jain-foundation.org.

Additional clinical features such as age of onset, pseudohypertophy (1C, 2D, 2E, 2I), scapular winging (2A,2I, 2N), selective quadriceps involvement without iliopsoas weakness (1B, 2B), rippling muscles (muscle movements with electrical silence on EMG, 1A) may suggest a particular variant though typically diagnosis depends on immunohistochemical and western blot analysis followed by a candidate gene approach.[12] Knowledge of the most prevalent LGMD in the local neuromuscular patient population, e.g. LGMD2I in the north-east of England, may facilitate DNA-based diagnosis and avoid muscle biopsy.[13]

Metabolic myopathies

Muscle pain, cramps, and fluctuating weakness are frequently seen in the rheumatology clinic. Occasionally these symptoms reflect metabolic myopathies—rare autosomal recessive conditions of muscle energy metabolism.[14] Metabolic disorders typically present with exercise-induced myalgia and rhabdomyolysis, or progressive myopathy.

McArdle's disease (glycogen storage disorder type V) is the most common glycogenolytic disorder and due to a deficiency of myophosphorylase; it is associated with muscle fatigue and pain within minutes of initiating activity, second wind phenomenon, painful contracture often lasting for days, rhabdomyolysis which can be complicated by renal failure, and in a minority with muscle weakness. Ischaemic lactate test and absent phoshorylase staining in muscle biopsies (Figure 126.8) support the diagnosis, with confirmatory DNA analysis now available. However, in a recent study of 59 patients non-exercise related chronic pain/fatigue was found in 42%,[15] and this and technical issues in muscle biopsy interpretation may delay diagnosis, prevent advice on diet such as sucrose and exercise,[16] and potentially contribute to a greater risk of renal failure.

Disorders of fatty acid oxidation are a group of inherited metabolic disorders of mitochondrial energy production. Most will present to paediatricians at an early age with multisystem problems such as hepatic failure.[17] Some milder phenotypes such as carnitine plamitoyl transferase 2 (CPTII) deficiency can remain asymptomatic until adulthood. Sporting stoics may have disregarded exercise-induced myalgia and present with postexercise rhabdomyolysis and uraemia. There is limited evidence that bezafibrate may help this disorder.[18]

Pompe's disease (glycogen storage disorder type II, acid maltase deficiency) is a rare, progressive, autosomal recessive disorder caused by deficiency of the lysosomal enzyme acid α-glucosidase (GAA) with glycogen accumulation in many tissues, especially muscle. There is a wide spectrum of disease. In infants with less than 1% of enzyme levels the condition is rapidly fatal with cardiorespiratory failure. In adult-onset cases, with higher enzyme levels, there is a wide range of phenotypes including fatigue, myalgia, limb girdle weakness, diaphragm involvement, and scoliosis, which could readily be confused with other NIM and myositis.[19,20] Standard laboratory investigations can be suggestive (myotonic discharges on paraspinal EMG, glycogen accumulation, and vacuoles on muscle biopsy) but crucially can be normal, particularly in milder late-onset cases. A high index of suspicion is required, as enzyme replacement therapy is now available which prolongs life in infants and stabilizes adult patients.[18,21,22] Fortunately dried blood spot analysis is now readily available and is a simple and reliable screen for Pompe's disease.

Mitochondrial diseases

Mutations in mitochondrial or nuclear DNA-encoded subunits of the mitochondrial respiratory chain cause fundamental defects in energy production within all cells. The energy requirements of muscle, with a high number of mitochondria per cell, ensure that myopathy is a common feature in mitochondrial disorders (MtD), which could result in confusion with both myositis and other NIM.

The clinical features of these MtD are typically diverse, variable, and multisystem, and a high index of suspicion is required in patients
Fig. 126.8 McArdle's disease (glycogen storage disease type V) muscle biopsy showing absent phosphorylase staining (A) compared to control (B).

with myopathy who have additional features on clinical assessment such as exercise intolerance, deafness, diabetes, short stature, cognitive problems, epilepsy, peripheral neuropathy, cardiac arrhythmia, ptosis, and ophthamoplegia.[23] Regular cardiorespiratory and endocrine assessments are recommended in these patients.

Recognition of MtD syndromes, such as mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS), may prompt DNA-based diagnosis. Often other investigations such as a muscle biopsy are required to confirm the diagnosis, revealing defects such as cytochrome oxidase negativity, with disrupted mitochondrial structure and ragged red fibres.

Conclusion

Recognition of NIM in patients presenting with myopathy depends on an integrated clinical and laboratory assessment with a high index of suspicion if misdiagnosis of myositis is to be avoided. Novel markers of disease and in particular MRI scanning of muscles, together with other biomarkers, as well traditional techniques such as CK, EMG, and muscle biopsy will enable accurate diagnosis of NIM in most patients.

Sjögren's syndrome—clinical features

Simon Bowman, John Hamburger, Elizabeth Price, and Saaeha Rauz

Introduction

Sjögren's syndrome (SS) is named after Henrik Sjögren, a Swedish ophthalmologist, who published a doctoral thesis describing the condition in 1933.[1] He used the term 'keratoconjunctivitis sicca' to specifically distinguish the ocular surface features from those seen in vitamin-A deficiency (xerophthalmia) although the latter term is often used incorrectly to describe ocular dryness in SS ('xerostomia' is, however, legitimately used to describe oral dryness). Henri Gougerot, a French dermatologist had previously described three patients with sicca syndrome and salivary gland atrophy in 1925.[2] Jan Mikulicz-Radecki, an Austro-Polish surgeon, described the histological features in 1892 in a patient with parotid gland swelling.[3] As well as dryness of eyes and mouth, dryness of the trachea, skin, nose, vagina, and bowel are also common.

The distinction between primary SS (pSS) and secondary SS was set out in the 1960s.[4] The link with mucosa-associated lymphoid tissue (MALT) B-cell lymphoma was also reported,[5] and Chisholm and Mason described their scoring system for the histological features of salivary gland biopsies in pSS.[6] The anti-Ro (SS-A) and anti-La (SS-B) antibodies were first identified[7] in 1969 and subsequently shown to be associated with pSS, HLA DR3 and other human lymphocyte antigen (HLA) haplotypes[8] and the neonatal lupus syndrome.[9]

The glandular features and management of pSS and secondary SS are generally regarded as being similar although fibrosis, for example, is a more typical feature in scleroderma-related secondary SS. Unless otherwise stated, this chapter focuses on pSS.

Epidemiology

SS is a worldwide disease with a strong female bias—traditionally reported as 9:1 but possibly as high as13:1.[10] Typically pSS presents in the fifth or sixth decade but can present at any age including, rarely, in childhood.

Classification criteria

In clinical practice it is up to the clinician to use their judgement in making a diagnosis of pSS. In research it is essential to have agreed classification criteria so that there is confidence that participants in a study have the specified condition. During the 1980s a number of classification criteria were proposed, with a major debate as to the advantages and disadvantages of each of these criteria.[11]

In 1988 a working group of 29 experts from 12 European countries initiated a study to develop consensus criteria and published their initial findings in 1993. The preliminary European criteria[12] included six components: symptoms of oral dryness identified through the presence of at least one out of three specified dry mouth questions and similarly for dry eyes, objective eye dryness, objective oral dryness, a positive labial salivary gland biopsy (>1 focus score/4 mm^2) and positive anti-Ro/La antibodies. Four out of the six components were required to make a diagnosis of pSS. Exclusion criteria were also proposed (head and neck radiotherapy, hepatitis C infection, AIDS, pre-existing lymphoma, sarcoidosis, graft-vs-host disease, use of anti-cholinergic drugs). These criteria were subsequently modified to require the presence of either positive anti-Ro/La antibodies or positive labial salivary gland biopsy to form the American–European Consensus Group (AECG) criteria,[13] thus requiring evidence of an immunological basis for the dryness. The diagnosis of pSS is also fulfilled if three out of the four objective criteria are present. The criteria also propose that secondary SS is present if at least one oral or ocular symptom is present and two objective criteria (other than anti-Ro/La antibodies, as these are not associated with secondary SS in rheumatoid arthritis (RA) or scleroderma).

The AECG criteria are the most widely used 'gold standard' criteria for the classification of pSS in research studies. Criteria are never fixed in perpetuity, however, and as new technology such as ultrasound becomes more widely used or new data becomes available[14] further revision is likely. For example, one of the differences between the various criteria is whether to score a focus score of ≥1or >1 as positive, and recent data suggests that the former is more closely linked with the clinical phenotype of pSS.[15]

Differential diagnosis of salivary gland enlargement and the IgG4 syndrome

Systemic diseases such as sarcoidosis can cause salivary gland enlargement. Metabolic or nutritional disorders such as diabetes,

bulimia, and chronic alcohol excess can also cause generalized swelling of the glands (sialosis). HIV infection can cause the diffuse infiltrative lymphocytosis syndrome (DILS) (see below) and this together with other conditions will be discussed further in the section 'Oral features of Sjögren's syndrome' below. IgG4-related disease has recently been described.[16] Characteristic features include raised serum IgG4, IgG4-positive plasma cells infiltrating tissues, particularly the pancreas, causing autoimmune pancreatitis, and the salivary glands, resulting in swelling and/or dryness. There is no female bias, no association with anti-Ro/La antibodies, and generally a good response to corticosteroid therapy.

Prevalence

Initial research into the prevalence of pSS came up with estimates of up to 3% of the adult female population,[17] much higher than in subsequent reports. One explanation for this was the use of different, more permissive, classification criteria in the earlier studies.

More recent studies using the AECG criteria have estimated the prevalence in women in the United Kingdom at 0.1–0.4%.[18] Other studies using the AECG criteria have estimated the prevalence at around 0.2%[19] in the community and 0.05% in the hospital setting.[20]

Diagnostic autoantibodies

The best-described autoantibodies in pSS are the anti-Ro and anti-La antibodies, which are routinely identified as part of the ENA (extractable nuclear antigen) laboratory screen. The Ro autoantigen was originally identified as a 60 kDa ribonucleoprotein. A structurally distinct 52 kDa protein called Ro52 also colocalizes with Ro60 to surface membrane blebs on cells undergoing apoptosis where they may become targets of an autoimmune response. The 47 kDa La antigen is thought to be a transcription termination factor for RNA polymerase.

Approximately two-thirds of patients with pSS have anti-Ro antibodies and one-third have anti-La antibodies.[21] These figures, however, depend on the classification criteria used, referral bias, and access to labial salivary gland biopsy. Few patients have anti-La antibodies in the absence of anti-Ro antibodies and one suggestion is that the initial autoantibody response is directed against the Ro antigen and then 'spreads' to involve the La antigen as a secondary process.[22] Anti-Ro/La antibodies are also classically seen in patients with systemic lupus erythematosus (SLE), albeit at a lower frequency than in pSS. ANA and rheumatoid factor positivity are very commonly seen in pSS but are not sensitive or specific for the condition and hence are not included in the AECG classification criteria.

Other autoantibodies potentially related to pathogenesis

Other autoantibodies that have generated significant interest at times include anti-fodrin antibodies,[23] anti-muscarinic M3 receptor antibodies,[24] and anti-carbonic anhydrase antibodies,[25] as well as anti-ICA69 antibodies[26] and anti-aquaporin antibodies,[27] although this is not an exhaustive list.

Anti-muscarinic M3 receptor antibodies are of particular interest because the M3 receptor is found in exocrine cells and interference by anti-M3R autoantibodies with signalling through these receptors could explain reduced secretory function in pSS. Again, the

initial studies were promising, but more recent reports show conflicting results.[28]

Genetics, genomics, and proteomics

There have been no large-scale twin studies in pSS. Based on case reports and small studies, the estimated concordance rate for SS is low and the sibling prevalence likewise, suggesting that the heritability of SS is low and environmental factors play a greater role.[29]

pSS has been closely linked to the presence of particular genes of the human major histocompatibility complex (MHC) that encodes HLA proteins.[21,22] These links are principally between the HLA types and the anti-Ro/La autoantibodies rather than with the disease per se. Patients with high levels of both anti-Ro and anti-La antibodies have a very high (~90%) likelihood of being HLA DR3 DQ2 positive (typically associated with the *DRB1*03-DQB1*02-DQA1*0501* extended haplotype), whereas pSS patients who have high levels of anti-Ro antibody only and are negative for anti-La antibodies have an increased frequency of DR2(15) and DQ6 (typically associated with the *DRB1*1501-DQA1*0102-DQB1*0602* extended haplotype). Conversely, secondary SS in patients with RA is associated with HLA DR4,[30] emphasizing that the clinical and histopathological similarities between pSS and secondary SS do not extend into identical genetic backgrounds.

Other potential genetic markers include cytokine genes—e.g. for interleukins IL-10, IL-1 family, IL-6, and tumour necrosis factor (TNF)—MHC-related genes such as *TAP* and *TNF*, and the Ro/La autoantigens themselves.[31]

Gene expression profiling using microarray technology can be used to identify genes that are over- or underexpressed in particular circumstances, which may be relevant to disease pathogenesis. In pSS (and SLE and some other autoimmune disorders), one current theme, across a range of studies, is of overexpression of interferon (IFN)-inducible genes including Toll-like receptors, *STAT4*, *IRF5*, *BAFF*, and *MECP2*.[32] IFN is typically upregulated by viruses and this may provide a link between the 'disease trigger' in these disorders and subsequent pathogenic processes.

Microarray technology can also be extended to genotype large numbers of single nucleotide polymorphisms whose frequency can be compared in thousands of cases and controls to identify novel associations between genes and disease for further study. Such studies are now under way in pSS.

Another area of genetics that is currently of interest is that of epigenetics, i.e. the effects of processes such as DNA methylation or histone acetylation on gene expression, and some data is emerging in pSS in this field.[33]

Proteomics—the study of disease-associated variation in protein and peptide levels in biological samples—is another promising area of interest in pSS.[34]

Potential triggers

A number of viruses have been associated with a SS-like disease. Perhaps the best characterized is the hepatitis C virus (HCV).[35] HIV has been linked with a phenotype of swollen salivary and other glands infiltrated with CD8 cells (DILS).[36] Other potential viral associations that have been suggested include human herpesvirus 6, human T-lymphotropic virus type 1, cytomegalovirus, and Epstein–Barr virus. At present, however, there is no clear evidence to suggest that an infectious agent triggers pSS.

Mouse models

There are a number of mouse models for SS.[37] The best-known is the non-obese diabetic (NOD) mouse which develops diabetes mellitus at 2–3 months of age and an SS-like syndrome of salivary gland lymphocytic infiltration, anti-Ro/La and anti-muscarinic M3R antibodies and sicca features at 4 months. Another interesting model, particularly to explore the potential role of apoptosis and lymphoproliferation, is the MRL/lpr mouse. This has a genetic mutation of the lymphoproliferation (*lpr*) gene on chromosome 19, which encodes the structural gene for the Fas antigen involved in apoptosis and is typically a model for SLE. The mice also develop some features of RA and some SS-like features. There are a number of cytokine-transgenic mice including those for IL-6, IL-10, IL-12, IL-14, and BAFF, which develop some SS-like features. Antigen immunization graftvs host, gene knockout, and virus infection models also exist. Each of these models can be used to identify or investigate specific environmental or genetic components of the condition that might be difficult to isolate among the heterogeneity of human disease.

Immunopathology

The concept of 'autoimmune epitheliitis'[38] starts with the idea that individuals with a particular genetic background (e.g. HLA DR3 DQ2) and/or a permissive IFN gene profile (see above) (and predominantly women) are more likely to react to a triggering factor or factors (e.g. a virus?) with some form of initial tissue damage. This initial tissue insult could cause, for example, epithelial cell death (apoptosis) and hence the exposure of Ro and La in apoptotic blebs to the immune system and the generation of the anti-Ro/La autoantibodies.[39] It could explain the upregulation of 'non-specific' (innate) immunity e.g. of Toll-like receptors, interferons, and molecules involved in tissue breakdown such as metalloproteinases, the expression of HLA class II molecules on epithelial and endothelial cells primed to present antigens, and the upregulation of adhesion molecules on blood vessel walls that allows immune cells to enter the tissue and of a range of cytokines such as IL-6, IL-10, TNFα, IL-17, IL-23, and BAFF to mention but some.[40] BAFF/BlyS (B-cell activating factor/B-lymphocyte stimulator) has been of particular interest given the evidence for B-cell activation in pSS.[41,42] The assumption is that, once triggered, the process develops a momentum of its own with the tissue expressing homing molecules such as chemokines and their receptors drawing immune cells into the glands and stimulating their formation into organized self-perpetuating lymphoid structures that contribute to gland dysfunction, autoantibody formation, and lymphomatous transformation.[43–45]

Another aspect of the pathogenesis of pSS is the detailed mechanisms underpinning reduced glandular function. One component of this may be reduced hypothalamic–pituitary axis function and reduced sex-steroid levels having a direct downregulatory effect on glandular secretory function.[46] As described above, anti-muscarinic receptor antibody formation could interfere with normal acetylcholine signalling through the M3 receptors on the gland cells. Glandular cytokines themselves may increase cholinesterase activity, thus inhibiting normal stimulation of secretory mechanisms.[47] Abnormalities of water-specific membrane-channel proteins such as the aquaporins and other glandular proteins such as mucin proteins may also be contributory to this process.[48]

Oral features of Sjögren's syndrome

Symptoms

The major oral symptom of SS is that of dryness of the mouth (xerostomia). In younger individuals in particular, e.g. below 40 years of age, swelling of the parotid and/or submandibular salivary glands, often painless, is commonly the presenting feature.

Xerostomia is a common oral symptom[49] and most individuals with a complaint of oral dryness do not have a diagnosis of SS. The differential diagnosis of dry mouth can be classified according to whether there is salivary gland disease per se, resulting in glandular hypofunction, or whether the xerostomia is occasioned by other aetiological factors.

Other symptoms of oral dryness include reduced taste perception, difficulty in swallowing and speech, poor denture retention, bad breath, increased rate of dental decay, and possibly more marked periodontal disease (although this is a matter of debate), generalized oral discomfort with oral mucosal surfaces sticking together and to the teeth, and salivary gland swelling.

Xerostomia and its associated symptomatology have a significant impact on the quality of life, in terms of specific aspects of oral function as well as socially.[50,51]

Differential diagnosis of xerostomia

Xerostomia can result from the ingestion of various drugs, particularly but not exclusively those with anticholinergic activity (e.g. psychotropics including anti-depressants, anxiolytics and anti-psychotics), muscarinic antagonists (e.g. tamsolusin hydrochloride, ipratropium hydrochloride), anti-histamines, opiates, anti-hypertensives (e.g. beta-blockers; ACE inhibitors), proton pump inhibitors (e.g. omeprazole), head and neck radiotherapy, dehydration (e.g. poorly controlled diabetes), renal failure, acute anxiety, mouth breathing and rarely central lesions. Xerostomia can be a feature of oral dysasthaesias with no objective reduction in salivary flow rate. Such patients may complain of a constellation of oral symptoms, including burning sensations and unusual taste as well as oral dryness and their symptomatology is not uncommonly associated with anxiety states and occasionally, clinical depression. There may also be a history of low back pain, fibromyalgia, and irritable bowel syndrome.[52]

Primary salivary gland pathology, other than SS, that can cause salivary gland hypofunction includes sarcoidosis, HIV-associated salivary gland disease, graft-vs-host disease which produces an analogous condition to SS,[53] hepatitis C, sicca syndrome (dryness where there is no known obvious case for the salivary gland hypofunction) and very rarely salivary gland aplasia and ductal atresia which may be related to FGF10 missense mutations.[54]

A syndrome comprising histological evidence of sialadenitis, nodular osteoarthritis, and xerostomia ('SNOX') has also been described,[55] but in view of the frequency of the individual clinical features, clustering could also be expected to occur on a simple statistical basis.

Ageing per se is not a cause of xerostomia. Although there is a broadly linear reduction in the amount of functional acinar tissue within the salivary glands over time, this does not lead to clinically significant salivary gland hypofunction.[56] Xerostomia in the ageing population is more a function of intercurrent disease and medication rather than that of loss of acinar apparatus.[57]

(A)

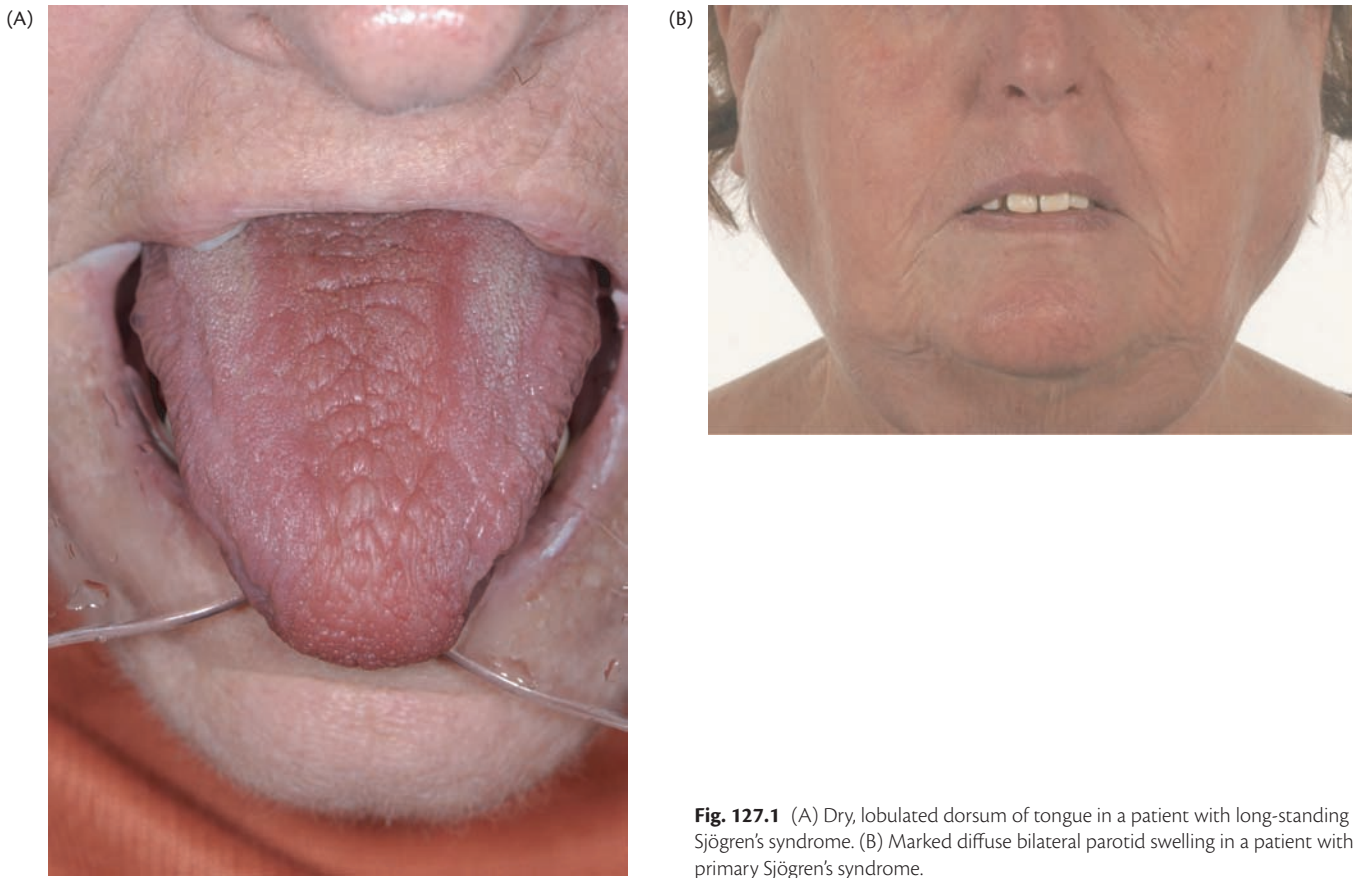
(B)


Fig. 127.1 (A) Dry, lobulated dorsum of tongue in a patient with long-standing Sjögren's syndrome. (B) Marked diffuse bilateral parotid swelling in a patient with primary Sjögren's syndrome.

Clinical signs of xerostomia

External signs of xerostomia may include angular cheilitis, dry flaky lips, and salivary gland swelling, involving any or all of the major salivary glands. However, these signs are not specific for dry mouth, and they may be indicative of a variety of other conditions (Figure 127.1).

Salivary gland swelling merits careful examination. Assessment should be made as to whether the swelling is diffuse or nodular, its texture, particularly if indurated, the presence of inflammation of the overlying skin, and associated VII nerve motor weakness or palsy in the case of parotid swellings, which frequently involve the lower pole of these glands.

Intraorally, milking the salivary glands may reveal thick mucoid saliva, sometimes containing blood or pus, which is suggestive of ascending infection, particularly when the swelling is painful. A history of pain associated with meal times suggests an obstructive aetiology of the swelling, which may be due to intraglandular ductal stenosis in SS, but other obstructive aetiologies including tumours must be excluded. Although bilateral salivary gland swelling due to tumours is uncommon it does occur and therefore bilateral salivary gland swelling should not necessarily be regarded as a reassuring sign (e.g. Warthin's tumour which may occur bilaterally at a frequency of 5–10%[58]).

Intraoral signs of xerostomia include those of a dry, sticky mucosa, with the gloved fingers sticking to the poorly lubricated mucosa; there is absence of a pool of saliva in the floor of the mouth and there may be difficulty in expressing saliva from the major duct openings. Oral clearance times are prolonged, leading to persistence of food debris around the mouth.[59] As a longer-term consequence of xerostomia, smooth-surface dental caries develops, particularly around the cervical margins of the dentition. Mucosal atrophy with fissuring especially of the dorsum of the tongue may present, sometimes with oral mucosal ulceration and superinfection with candida species.

Clinical assessment of the oral component of Sjögren's syndrome

Salivary gland involvement can be assessed objectively by measuring salivary flow rates, salivary gland biopsy, usually of the minor glands within the lower lip, and various imaging techniques. These modalities are described in detail in Chapter 128.

Ocular features of Sjögren's syndrome

The tear film and its dysfunction in pSS, including meibomian gland dysfunction

Dry eye is a critical component of pSS. Dry eye is defined as a multifactorial disease of the tears and ocular surface that results in symptoms of discomfort, visual disturbance, and tear film instability with potential damage to the ocular surface.[60] It is accompanied by increased tear film osmolarity and ocular surface inflammation. Dry eye occurs principally as a result of abnormalities of the lacrimal functional unit, which represents an integrated system consisting of the lacrimal glands, the ocular surface (cornea, conjunctiva), eyelids and meibomian glands (MG) together with the sensorimotor nerves that connect them.[61] The

aetiopathogeneis of dry eye is broadly divided into aqueous deficient and evaporative forms, with the aqueous deficient component comprising of either SS dry eye (SSDE) or non-Sjögren's dry eye (NSDE).

Tear film pathology

The ocular surface is coated with a tear film, which is vital for lubrication, nutrition, and immunological defence of the eye. The tear film has a highly intricate structure, illustrated in Figure 127.2.[62] It consists of a negatively charged, hydrophilic mucinous glycocalyx synthesized by conjunctival goblet cells that limits adhesion of foreign debris or pathogens to the surface of the eye, and a more superficial aqueous phase secreted predominantly by the lacrimal gland that supports epithelial cell proliferation, maturation, and movement over the ocular surface.[63] The mucoaqueous gradient is critical for delivering essential nutrients and oxygen to the ocular surface and avascular cornea. The most superficial layer is a predominantly lipid layer secreted by the MG, which lie within the eyelids with their orifices behind the lash roots. Secreted lipids interact with aqueous proteins in a complex arrangement consisting of (1) proteins (lipocalin, lysozyme, surfactant proteins) intercalated with an outer non-polar lipid layer mediating tear film physical properties including surface tension and (2) long chain (*O*-acyl)-hydroxy fatty acids that form an intermediate surfactant polar lipid sublayer adjacent to the aqueous phase of the underlying mucoaqueous gradient. This lipoprotein construction not only confers tear film stability by minimizing evaporation and maintaining tear film integrity, it also forms an effective barrier protecting the eye from bacterial agents and organic matter.

SSDE is a principal cause of aqueous tear-deficient dry eye that results from lacrimal infiltration and/or destruction due to an immune-mediated process that releases inflammatory mediators into the tear film and ocular surface. The aqueous component evaporates at normal rates from a reduced pool of tears, resulting in both tear film and ocular surface epithelial cell hyperosmolarity.[64] This stimulates a cascade of signalling pathways involving MAP kinases and NFκB and the production of inflammatory cytokines perpetuating the autoimmune response.[65] An evaporative dry eye component secondary to loss of lipid layer due to MG obstruction, stagnation, dysfunction (MGD—Figure 127.3) and eventual destruction (with or without associated staphylococcal colonization and/or hypersensitivity) compounds ocular surface inflammation.

The basis for the dry eye symptoms is not fully understood, but activation of sensory nerves subserving nociception at the ocular surface is implicated.[66] This, together with a combination of tear film hyperosmolarity, rapid tear film break-up (TFBUT) in the interblink period, increased shear-stresses between the lids and globe due to reduced aqueous tear volume, reduced expression of mucins and lipids, the presence of inflammatory mediators, together with a hypersensitivity of the nociceptive sensory nerves, are likely candidates for neural activation and symptomatology.

Symptoms and signs

Patients typically complain of ocular discomfort described as dry, gritty, or burning of varying degrees of severity, ranging from mild and/or episodic discomfort frequently triggered by environmental stress, to severe, constant discomfort with visual disturbance, which in the severest cases may be constant and debilitating. The 'tear film dysfunction syndrome' describes a spectrum of conjunctival inflammation, staining of the ocular surface with vital dyes (fluorescein, lissamine green), reduced Schirmer's 1 test and TFBUT, increased debris and mucus clumping with or without filamentary keratitis, and MGD (Figure 127.3).[67] The symptoms and clinical features together formulate levels of dry eye disease severity, which provide a gauge for therapeutic strategies, although in some patients symptoms exceed clinical signs, presumably due to nociceptive sensory receptor hypersensitivity.[68] Photophobia is common and may be attributed to uveitis which is a rare complication of usually seropositive pSS, but should be recognized, as treatment with topical or systemic corticosteroid, or long-term maintenance with immunosuppression, may be required.
Fig. 127.2 Schematic representation of the tear film architecture (based on a novel model proposed by the International Meibomian Gland Dysfunction Workshop 2011). An outer lipoprotein layer confers architecture stability and reduces evaporation. The polar and non-polar lipids are secreted predominantly from the eyelid meibomian glands. The negatively charged glycocalyx, derived from the conjunctival goblet cells, reduces surface tension forces increasing the wettability of the ocular surface and forms a gradient with the largely lacrimal gland derived aqueous phase. The mucoaqueous component delivers essential nutrients (carbohydrates, proteins, enzymes, vitamins, hormones) to the ocular surface and the avascular structures of the external eye.

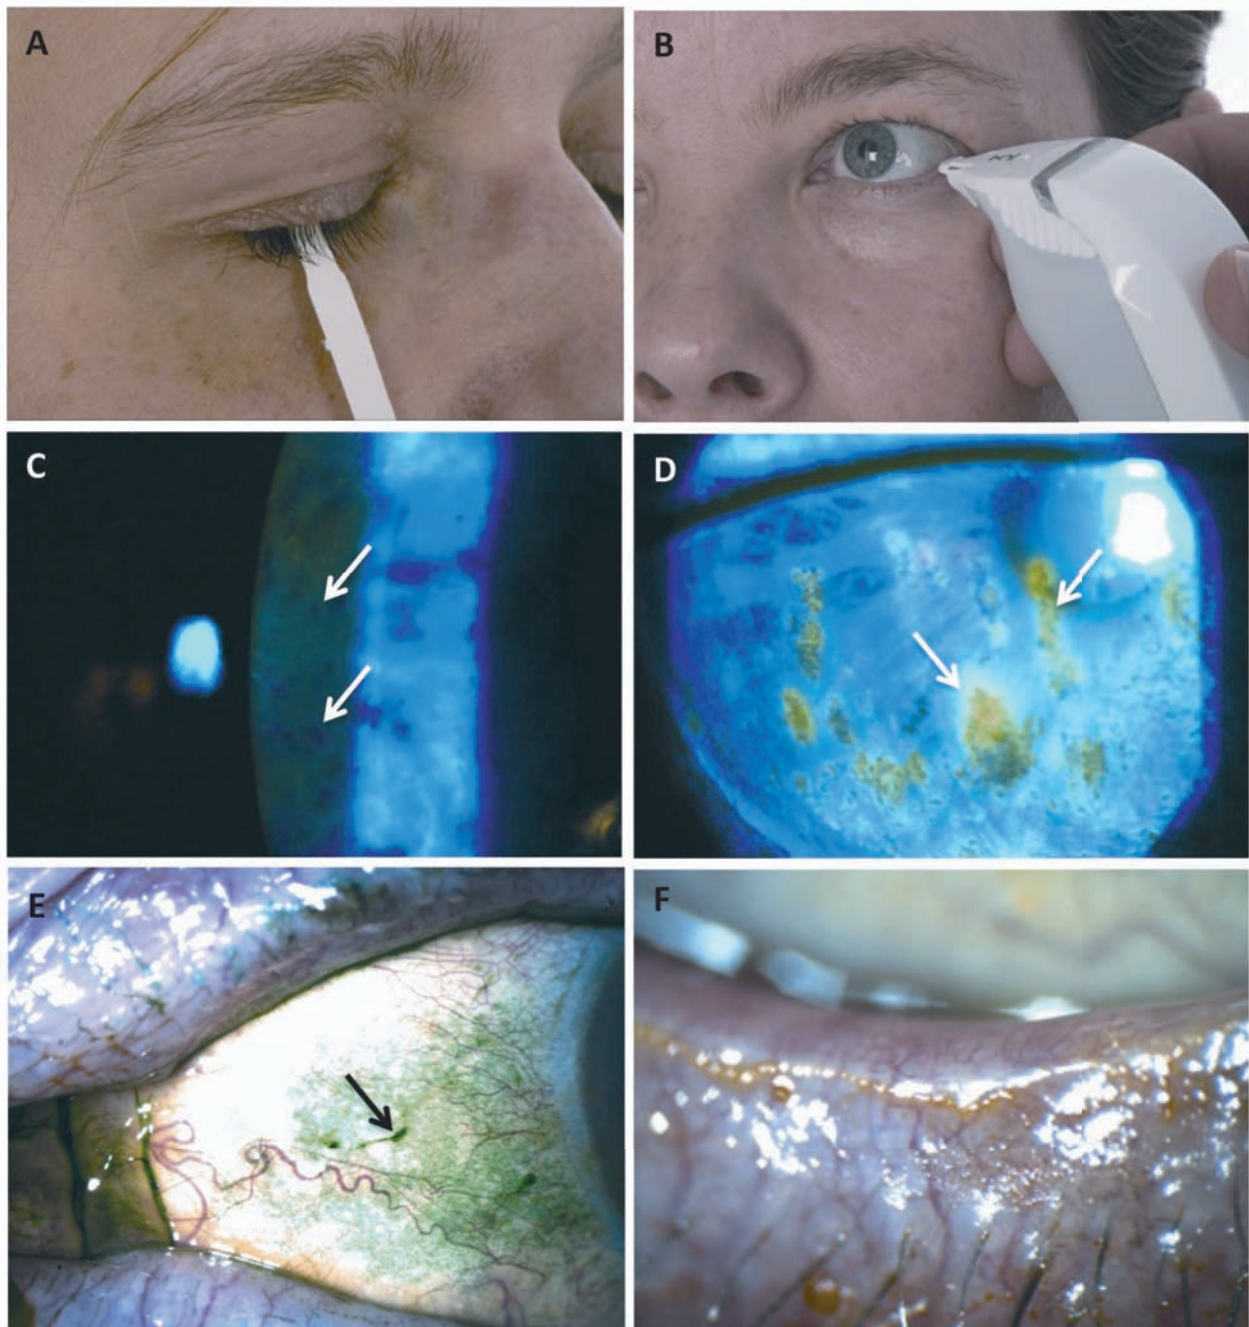

Fig. 127.3 Dry eye is traditionally diagnosed by (A) performing a Schirmer's I test, but measurement of tear film osmolarity using devices such as the TearLab Osmolarity System (B) has gained popularity as it provides an objective biomarker of dry eye severity. Tear film break-up time grades tear film stability (C)—note 'break-up' areas (arrows) in the fluorescein stained tear film—image taken 2 seconds after blink). Evaluating vital dye staining patterns with either (D) fluorescein showing punctate epithelial erosions on the corneal surface (arrows), or (E) lissamine green showing wedge-shaped staining of devitalized conjunctival epithelial cells and filaments (arrows) remain a key part of ocular examination. Meibomian gland dysfunction is more prevalent in pSS—(E) upper and lower lids, (F) lower lid. Note the telangiectasia at the eyelid margin (E, F)and inflammation at the mucocutaneous junction (F).

Objective assessment of dry eye

There is a wide range of clinical tests that may potentially be utilized in the assessment of SSDE.[69] These are frequently abridged to a practical sequence of taking a clinical history, grading the disease according to a symptom severity questionnaire, fluorescein TFBUT, ocular surface vital staining, and assessment of MGD.

Vital staining

Probably the most commonly adopted grading system in clinical practice is the Oxford Schema where vital dye staining is represented by punctate dots on a series of panels depicting the ocular surface (Figure 127.3).[70] Fluorescein dye (2 μL of 2% sterile solution) stains epithelial defects but has the disadvantage of a blurred

staining pattern if slit-lamp reading with excitation and barrier filters is delayed. By contrast, staining with lissamine green is dose dependent, but maps devitalized epithelial cells that are present on the intact ocular surface.

Tear film break-up time

The TFBUT is a measure of tear film stability defined as the interval between the last complete blink and the first appearance of a dry spot or disruption in the tear film. It is performed by instilling 5 μL of 2% sodium fluorescein onto the bulbar conjunctiva; the patient instructed to blink naturally several times to distribute the fluorescein. Within 10–30 seconds of the fluorescein instillation, the patient is asked to stare straight ahead without blinking, and using a standard slit-lamp magnification (×10) and constant-intensity background illumination, the duration of the tear film integrity over the cornea is observed. A TFBUT of 10 seconds or more is considered to be normal, and a time of 5 seconds or less is reduced.

Schirmer's test

The Schirmer's 1 test without anaesthetic is considered the gold standard screening tool for dry eye.[71] The Schirmer's test I estimates unstimulated tear flow by inserting filter paper strips into the conjunctival sac over the lower lid margin, midway between the middle and outer third, with the eye closed in an anaesthetized eye (Figure 127.3). The strips are read at 5 minutes with a cut-off of 5 mm or less defining the probability of misclassification of patients with dry eye as 15% and of controls as 17%. In contrast, Schirmer's I with anaesthetic delivers an estimate of basal secretion, and Schirmer's II involves induction of 'reflex' secretion by irritating the nasal mucosa.

Tear film osmolarity

Because of its simplicity, increasing availability and affordability, osmolarity readings are becoming integral to dry eye assessment in the clinical setting for both ophthalmologists and rheumatologists. Osmolarity has the advantage of functioning as a non-invasive, easily performed, objective, continuously variable, clinical biomarker for dry eye severity.[72] Tear analysis is determined by a direct nanolitre specimen collection tool utilizing lab-on-a-chip technology. The test card for devices such as the TearLab Osmolarity System (Figure 127.3) is a single-use, polycarbonate lab-on-a-chip containing a sigmoidal nanofluidic channel collecting 50 nL of tear fluid sample by passive capillary action onto gold electrodes embedded in the card. Osmolarity values greater than 308 mOsm/L are generally indicative of dry eye disease (mild ⬚ 308 mOsm/L; moderate ⬚ 320 mOsm/L; severe >355 mOsm/L).

Impression cytology

Emerging objective assessment tools for quantifying disease include tear film proteomic analyses, ocular surface in-vivo confocal microscopy, and impression cytology of the conjunctiva coupled with flow cytometry to phenotype ocular surface damage and markers. The technique of impression cytology of the conjunctival epithelium provides a non-invasive histological evaluation of conjunctival epithelial morphology by using nitrocellulose filters to sample superficial epithelial cells followed by conventional histological stains for squamous metaplasia, keratinization, and inflammatory cells in situ.[73] Combined with flow cytometry of recovered sampled cells from a hydrophilic polyethersulfone filter, it provides a highly sensitive and specific tool that uses monoclonal antibodies for analysing expression of almost any cell marker allowing identification of conjunctival epithelial cells, inflammatory, cells and goblet cells.[72] Importantly, HLA-DR, which is minimally expressed in the healthy eye, is strongly overexpressed in cases of ocular surface inflammation and its measurement provides a biomarker of inflammatory dry eye disease activity.

Systemic features of Sjögren's syndrome

Fatigue

Seventy-five per cent of patients with pSS report mental and physical fatigue with levels of fatigue higher than healthy controls and similar to those affecting patients with other rheumatic diseases.[75] Fatigue is often the most disabling symptom,[76] and may correlate with night-time musculoskeletal pain causing sleep disturbance and anxiety. High levels of psychological distress are found in pSS patients and certain personality features (negativity, preoccupation with detail, perfectionism, and anxiety) prevalent in pSS[77] may contribute to fatigue.

Lymphoma

The prevalence of lymphoma increases from 3.4% in the first 5 years to 9.8% at 15 years.[78] The majority of lymphomas are of the MALT B-cell type and the risk is increased in Ro/La-positive patients. Presentation is usually with a firm, palpable swelling within the parotid gland or occasionally elsewhere. Open biopsy is usually essential (although fine-needle aspiration cytology may be useful initially in some cases) and CT scanning is helpful for staging. Treatment is generally with chemotherapy regimes that include rituximab. Occasionally, surgical excision and/or radiotherapy may be indicated. The prognosis is good, with a complete response to initial treatment in more than 90% of cases and 5 year disease-free survival of more than 75%. The median age of onset is in the mid-50s and the diagnosis of Sjögren's generally predates the lymphoma by a mean of 7 years. Predictive factors for later development of lymphoma include neutropenia, lymphadenopathy, and low C4 levels.[79]

Musculoskeletal

Arthralgia or arthritis are a presenting feature in one-third of cases and occur during the course of the disease in over one-half of cases.[80] The arthritis is generally peripheral, symmetrical, polyarticular, and intermittent. It is usually non-deforming and non-erosive, affects the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints and wrists, and synovitis is generally mild.

Cutaneous

Dry skin affects at least 50% of cases and can cause pruritus. Treatment is with simple moisturizers and avoidance of perfumed products. Hypergammaglobulinaemic purpura affects about 9% of pSS patients[81] and causes a non-palpable purpura usually on the lower legs. It is associated with high immunoglobulin levels and histological examination demonstrates immune complex deposition. Subacute cutaneous lupus is a photosensitive, non-scarring rash, usually on the face, arms, and front of the chest. Treatment includes sun avoidance, the use of a high factor sunscreen, hydroxychloroquine, and occasionally additional immunosuppressive drugs.

Raynaud's phenomenon

Raynaud's phenomenon affects up to 80% of patients with pSS and may precede the sicca symptoms.[82] Precipitants such as smoking

and beta-blockers should be avoided. Treatments include the calcium antagonists and ACE inhibitors.

Pulmonary

A chronic cough related to drying of the mucous membranes is common. Significant lung disease is rare. One study found plain radiograph abnormalities in 14% (most commonly fine reticular changes affecting the lower lobes) and abnormalities on high-resolution CT scanning in 34% (most commonly parenchymal linear opacities and bronchiolar abnormalities) but only 26% had symptoms; the majority of these were mild with poor correlation between symptoms, clinical signs, and radiological findings.[83]

Occasionally patients present acutely with lymphocytic interstitial pneumonitis (LIP). Clinical manifestations include fever, cough, and dyspnoea, with bibasilar pulmonary infiltrates consisting of dense interstitial accumulations of lymphocytes and plasma cells. LIP usually responds well to treatment with corticosteroids and the main differential diagnosis is infection.[84]

Neurological complications

A diffuse sensorimotor neuropathy may affect up to 25% of patients with pSS.[85] It usually presents insidiously and is probably not improved by treatment with steroids or cyclophosphamide,[86] but progress may be slowed with hydroxychloroquine.

Trigeminal neuropathy/neuralgia has been described in up to 5% of patients with pSS. It does not usually respond to treatment with corticosteroids and should be treated as for idiopathic trigeminal neuralgia. Mononeuritis multiplex is seen in less than 3% of pSS patients over their lifetime. It commonly affects the lateral popliteal nerve and may result in foot drop. It is associated with vasculitis and may respond to treatment with corticosteroids and cyclophosphamide.[84]

Autonomic neuropathy can cause a multitude of symptoms including postural hypotension, nocturnal diarrhoea, urinary retention, sweating, and dizziness, and may be under-recognized in SS. There is conflicting data on prevalence—it was not seen at all in one study,[88] affected 3% in a neurological case series [89] and 70% in a series focusing on gastrointestinal and urological features.[90] It is usually mild and may not require any specific treatment.

SS myelopathy can mimic multiple sclerosis (MS) and, although rare, distinction from MS is important as it may respond to immunosuppression.[91] Patients may present with paraplegia, sensory changes, and bladder dysfunction. Diagnosis requires MRI scanning, which shows white matter lesions and lumbar puncture, which demonstrates mild elevation of cerebrospinal fluid (CSF) protein and matched oligoclonal bands in CSF and serum.

Renal involvement

Significant renal disease is rare. One study found mild proteinuria (1.5–0.42 g/24 h) in 44% and distal renal tubular acidosis (RTA) in 33%.[92] The RTA patients tended to have a longer disease duration and were more likely to have proteinuria, hypertension, and raised creatinine than those without. The RTA was generally mild and often required no treatment or simple measures such as bicarbonate to restore the urine pH.

Symptoms of urinary dysfunction are common and Haarala and colleagues [90] found mild urinary symptoms in 61% of patients with SS compared with 27% of women without. Severe symptoms were seen in 14% and 7% respectively. Overall 27% of SS patients report urinary frequency and 36% complain of suprapubic pain. The frequency of urinary tract infection (UTI) in patients with pSS is not known but the frequency of recurrent UTI is increased from 6% in those with RA to 30% in those with coexistent SS.[94]

Interstitial cystitis is often seen in association with connective tissue diseases; 90% of sufferers are female. There is no good data on the prevalence in SS although one study suggests that SS is present in 23% of all patients with interstitial cystitis.[95]

Haematological

A mild normochromic anaemia is seen in approximately 20% of patients, leucopenia in 15%, and thrombocytopenia in 11%. Autoimmune haemolytic anaemia (AIHA) and neutropenia are occasionally reported.[96]

Thyroid disease

Thyroid disease, most commonly hypothyroidism, accompanies SS in up to 20% of cases.[97] Another interesting observation is that 37% of patients with autoimmune thyroid disease have an objectively dry mouth and 23% have objectively dry eyes.[98]

Gastrointestinal and liver involvement

Antibodies to tissue transglutaminase (TTG) are found in up to 5% of cases and confirmed coeliac disease in 4.5%,[99] a prevalence of approximately 10 times greater than expected.

Mild abnormalities of liver enzymes are found in 7% of cases,[100] with primary biliary cirrhosis (PBC)-associated autoantibodies in 6% of patients with SS and confirmed PBC in the majority of these.

Studies have shown mild elevation of pancreatic enzymes in about 35% of patients with SS[101] but more serious problems occur in no more than 1% of patients.

Biological

Hypocomplementaemia is seen in a subgroup of patients and is associated with a higher frequency of vasculitis, lymphoma, leucopenia, and cryoglobulinaemia.[11] It is an independent risk factor for the development of lymphoma. Hypergammaglobulinaemia is found in the majority of the Ro/La-positive patient group and is strongly associated with the presence of extraglandular manifestations.[102] A low positive dsDNA antibody has been described in a small proportion (<5%) of the Ro/La-positive patients.

Obstetric and gynaecological features of Sjögren's syndrome

Fertility and pregnancy

Fertility is normal in patients with SS, with a possible increased risk of recurrent miscarriage in the Ro/La-positive patients.[103] Neonatal lupus rash occurs in about 5% of live births in Ro/La positive women usually appearing at 6 weeks of age and lasting about 17 weeks before fading and clearing completely, although a few children have persistent depigmentation or telangiectasia. Congenital heart block (CHB) occurs in less than 2% of pregnancies in women with anti-Ro or -La antibodies[104] and may be detected by ultrasound scanning from about 16 weeks' gestation. Following an affected pregnancy the risk goes up to 17%[105] for subsequent pregnancies.

Seventy per cent of affected children survive but nearly all require pacemakers in the first few months of life.[106] Up to one-half of mothers are asymptomatic at the time of the birth although many go on to develop autoimmune disease later.[107]

Vaginal dryness and dyspareunia

Vaginal dryness affects 76% of women with SS compared to 5% of those without[108] and dyspareunia is a problem in 40%. Treatment includes the use of lubricating gels to aid intercourse and longer-acting vaginal moisturizers to improve moisture levels.

Prognosis and outcome

In general pSS is not associated with increased mortality, with the exception of patients who develop lymphoma.[106,110] There are, however, very major effects on patients and their quality of life, which in turn has health economic consequences, and these aspects are addressed in detail in the Chapter 128.

CHAPTER 128

Sjögren's syndrome— management

Wan-Fai Ng, Arjan Vissink, Elke Theander, and Francisco Figueiredo

Introduction

To date, few therapeutic strategies for Sjögren's syndrome (SS) have been formally evaluated and treatment guidelines for SS have not been developed. The management approaches recommended are based on the collective experience of three large European tertiary referral centres for SS and relevant published data when available.

The most widely accepted classification criteria for SS are the American European Consensus Group (AECG) criteria. Diagnostic criteria are not available, but the AECG criteria may guide assessment of patients with suspected SS. In clinical practice, however, other investigations are usually necessary to exclude other conditions that mimic SS (Table 128.1) and to fully assess these patients (Table 128.2). The common diagnostic pitfalls in SS are listed in Box 128.1.

Disease assessment

Oral manifestations

Loss of salivary gland (SG) function is already prominent in the early stages of SS. The submandibular and sublingual glands, the most active glands at rest, are being affected first, whereas the parotid glands, which become active gland upon stimulation, appear to be affected last.[1] Thus, in early SS, xerostomia is often predominantly present at rest and at night. As the disease progresses and affects all SG, oral dryness is also present during the day with difficulties in chewing and swallowing food. Hyposalivation may also lead to difficulties in speaking, burning sensations in the mouth, a diminished ability to taste foods, and sensitivity to spicy or coarse foods.

Patients with advanced SG hypofunction have overt signs of mucosal dryness: cracked, peeling, and atrophic lips; pale and corrugated buccal mucosa; a smooth, reddened tongue with loss of the dorsal papillae or a fissured appearance. Dental erosion and caries are common and can be progressive despite vigilant oral hygiene. Greater accumulations of food debris at the smooth surfaces and cervical regions of the teeth also occur. SS patients are prone to oral infections, particularly candidiasis and fungal lesions of the mouth corners (angular cheilitis).

Chronic or episodic enlargement of the SG, especially the parotid and submandibular glands, is common. This is generally due to the underlying autoimmune inflammatory process. In the parotid glands this inflammatory process can occur unilaterally, but most often bilaterally. Glandular enlargement, especially the parotid glands, may also be due to lymphoma. Since the incidence of lymphomas is 15–20 times increased in SS patients, physicians should maintain a high index of suspicion on painless nodular glandular masses.[2]

Ocular manifestations

The grading scheme agreed at the 2007 International Dry Eye Workshop is the most widely used system for assessing the severity of dry eye.[3] It is based on the frequency and degree of severity of a combination of factors including discomfort, visual symptoms, conjunctival injection, conjunctival/corneal staining, corneal/tear signs (corneal filaments and tear debris), presence of meibomian gland diseases, tear break-up time, and Schirmer's score.[4]

Ocular symptoms questionnaires/patient-reported outcomes

Dry eye symptoms correlate poorly with objective assessments.[5] An accurate assessment of symptoms is essential, as often it is symptoms that dictate requests for treatment by patients. As a minimum, we recommend the use of the European League Against Rheumatism (EULAR) Sjögren's Syndrome Patient-Reported Index (ESSPRI).[6] In this instrument, ocular dryness, like oral dryness, is measured using a single Likert (0–10) scale. Additionally, a composite EULAR-sicca score defined as [(2 × oral dryness + ocular dryness)/3] can be calculated.

The Ocular Surface Disease Index is a reliable and validated 12-item instrument for measuring dry eye-related ocular surface disability.[7] It is frequently used in specialized dry eye clinics and clinical trials.

Systemic assessment

Although oral and ocular dryness are the cardinal features of SS, dryness also occurs at the skin and other mucosal surfaces such as the respiratory tract, vagina, and vulva, which can cause symptoms mimicking other conditions. Therefore, clinicians should consider

Table 128.1 Differential diagnosis of Sjögren's syndrome and non-Sjögren's syndrome causes of sicca syndrome and salivary gland enlargement

	Differential diagnosis of SS	Non-SS causes of sicca syndrome	Non-SS causes of salivary gland enlargement
Infections	Viral infections: HIV, EBV, Hep A, B, C, HTLV-1, mumps	Viral infections	Viral or bacterial infections, mumps, HIV, EBV, CMV
Inflammatory	Sarcoidosis, amyloidosis	Sarcoidosis	Sarcoidosis
Endocrine/ metabolic	Lipoproteinaemia (types II, IV, V), diabetes	Endocrine: diabetes	Endocrine: diabetes, acromegaly Metabolic: alcohol excess, cirrhosis, lipoproteinaemia, chronic pancreatitis, bulimia, anorexia nervosa, endurance athletes
Malignancy	Lymphoma		Malignancy, irradiation
Iatrogenic		Irradiation	
Others	Fibromyalgia, chronic fatigue syndrome	Medications, psychogenic, age-related lacrimal gland disease, ocular hypoesthesia	Sialolithiasis, sialoadenitis, medications (e.g. isoproterenol)

CMV, cytomegalovirus; EBV, Epstein–Barr virus; GVHD, graft vs host disease; Hep, hepatitis; HTLV, human T-lymphotropic virus.

Table 128.2 Useful investigations for the diagnosis and assessment of Sjögren's syndrome

Systemic	Oral	Ocular
Essential *Blood tests:* FBC, electrolytes, Ur, Cr, liver enzymes, CK, TSH, ESR, CRP, G, Ig & EPS, C3, C4, ANA, RF, SSA/SSB, dsDNA *Urine*: Dipstick analysis *Imaging*: Chest radiograph	UWS Salivary gland biopsy	Schirmer's I test Tear film break-up time Ocular surface staining (e.g. Lissamin green, fluorescein or Rose Bengal staining)
If indicative Serology for hepatitis A, B, C, EBV & HIV; sACE, ENA, ACPA, AMA, cryoglobulins, amylase, HbA1c, haemolytic screen	Sialography	
Optional		
	SWS Selective sialometry Sialochemistry Ultrasound salivary glands MRI salivary glands Scintigraphy	Tear function index Impression cytology of the conjunctiva Tear osmolality Ocular surface disease index

ACPA, anti-citrullinated peptide antibodies; AMA, anti-mitochondrial antibodies; ANA, anti-nuclear antibodies; CK, creatinine kinase; Cr, creatinine; CRP, C-reactive protein; dsDNA, anti-ds DNA antibodies; ENA, extractable nuclear antigen; ESR erythrocyte sedimentation rate; FBC, full blood count; G, glucose; Ig & EPS, immunoglobulins and electrophoresis; RF, rheumatoid factor; sACE serum angiotensin converting enzyme; SWS, stimulated whole sialometry; TSH, thyroid stimulating hormone; Ur, urea; UWS, unstimulated whole sialometry.

dryness of these organs being a contributing factor to their presenting symptoms.

Furthermore, all SS patients should be assessed for systemic manifestations. For patients with secondary SS, this should also include the assessment of the disease activity and damage of the associated autoimmune rheumatic disease. To facilitate standardized evaluation of SS disease activity, the EULAR SS study group has developed a scoring system, the EULAR Sjögren's Syndrome Disease Activity Index (ESSDAI).[8,9] The ESSDAI also provides a useful framework for structured assessment of SS patients in clinics (Table 128.3). The ESSDAI consists of 12 domains: constitutional, lymphadenopathy, glandular, articular, cutaneous, pulmonary, renal, muscular, peripheral nervous system, central nervous system, haematological, and biological. These domains were selected on the basis of clinical experience, literature review, and a panel of

SS experts. Each domain is given a score of 0 (no activity), 1 (low activity), 2 (moderate activity), or 3 (high activity) with the exception of the constitutional, glandular, and biological domains which are scored between 0 and 2, and the central nervous system domain which is scored 0, 2, or 3. Each domain score is weighted according to its relative contribution to the overall disease activity. The total score is the sum of the weighted domain scores.

Patient-reported outcomes, functional capacity, quality of life

Dryness, fatigue and bodily discomfort are the most prominent clinical features of primary SS (pSS). In order to measure the impact of pSS on subjective well-being in clinical trials and clinical practice, the EULAR SS study group has developed the ESSPRI which give a composite total score defined as the mean of the Likert scores

(0–10) of dryness, fatigue, and pain.[6] Both ESSDAI and ESSPRI are sensitive to change in response to therapeutic intervention.[10]

Fatigue is an important and distressing symptom of pSS[11] and is a key predictor of reduced social activities and work productivity.[12,13] The best approach to assess fatigue has not been defined. A visual analogue scale (VAS) is often used, but numerous more complex instruments have also been applied.[14–16] The Profile of Fatigue (ProF) was developed specifically for pSS.[17–19] ESSPRI contains two Likert scales (0–10) on fatigue (physical and mental) and may also be used.[6]

Patients with established pSS have significantly impaired health-related quality of life (HRQL).[12,20,21] pSS patients may also have reduced functional capacities due to their symptoms of fatigue, dryness, and pain. There is currently no disease-specific instrument for measuring HRQL or functional capacity in SS. Therefore, generic tools such as EQ-5D (www.euroqol.org),[22] Short form (SF) health survey (www.sf-36.org),[23] Health Assessment Questionnaire (HAQ),[24] or appropriate instruments from the Patient-Reported Outcome Measurement System (PROMIS) (http://aramis.stanford.edu/HAQ.html) may be used.

Management

Oral manifestations

Management strategies are summarized in Box 128.2.

Preventive measures

Regular dental visits (3–4 monthly) and working closely with dentist and dental hygienist to maintain optimal dental health is important. Meticulous oral hygiene is essential for reducing the risk of developing new and recurrent carious lesions. Proper oral hygiene includes tooth brushing, flossing, the use of interproximal plaque removing agents, and mouth rinses. Regular use of topical fluorides is critical to control dental caries. Cariogenic foods (especially fermentable carbohydrates) and beverages should be minimized if possible. Chronic use of alcohol and caffeine can worsen oral dryness. Non-fermentable dietary sweeteners are recommended.

Salivary gland stimulation

Dry mucosal surfaces, difficulty in wearing dentures, accumulation of dental plaque and debris on surfaces normally cleansed by the mechanical washing action of saliva, difficulty in speaking, tasting, and swallowing may all benefit from strategies that stimulate salivary secretions. These strategies, however, will only be effective if there are residual functional SG cells. In long-standing SS, the atrophic

---

Box 128.1 Common diagnostic pitfalls in Sjögren's syndrome

- Symptoms such as fatigue and dryness may not always be reported by patients unless specifically sought by clinicians
- Objective tests can be positive despite the lack of symptoms (Note: SS can be diagnosed with 3 of the 4 objective AECG criteria met)
- Patients with dry eyes may notice 'intolerance of smoky environment', 'eye strain', 'intolerant of contact lens' rather than 'dryness'
- Dry eyes in contact lens users not further investigated for other underlying causes
- Patients with dry mouth may not report difficulty in swallowing *dry* food unless specifically asked
- Biopsy not performed in patients with negative anti-SSA/SSB
- Full history of medication (prescribed and non-prescribed) use and its relationship to the onset of sicca symptoms not obtained
- Lack of appreciation that there is no 'gold standard' test to diagnose dry eyes

---

Table 128.3 Suggested structured assessment of systemic disease activity of pSS

Organ systems	Symptoms	Signs
Constitutional and lymphatic	Fatigue, fever, night sweat, weight loss (unintentional)	Fever, lymphadenopathy, splenomegaly
Glandular	Glandular pain and swelling	Glandular tenderness and/or enlargement
Articular	Arthralgia, early morning stiffness	Synovitis
Cutaneous	Rash, pain, itch, skin ulceration or necrosis, cold extremities ± colour changes	Dry skin, rash (e.g. erythema multiforme, cutaneous vasculitis, urticaria, purpura, subacute cutaneous lupus), ulcer, Raynald's phenomenon
Pulmonary	Husky voice, breathlessness, persistent non-productive dry cough, chest pain	Pleural rub, crepitations, reduced breath sound, percussion dullness
Renal	Muscle weakness, bone pain, fatigue, renal colic	(Inappropriately) alkaline urine, hypercalciuria, urinary stone, proteinuria, haematuria
Muscular	Myalgia, weakness	Weakness
Peripheral nervous system	Paraesthesia, sensory deficit, weakness, ataxia, multiple sclerosis-like syndrome	Sensory changes, motor deficit, ataxia, mononeuritis multiplex
Central nervous system	Multiple sclerosis-like syndrome, cognitive impairment, seizures, headache	Optic neuritis, transverse myelitis, cranial neuropathy, meningism
Haematological and biological	Fatigue, easy bruising	Anaemia, bruises

Box 128.2 Management strategies for oral manifestations of Sjögren's syndrome

Preventive measures

◆ Regular dental visits (every 3–4 months, alternate between dentists and hygienists)

◆ Optimal oral hygiene (guidance from oral health professionals)

◆ Topical fluorides and remineralizing solutions

  • Fluoride mouth rinse (0.1%, weekly)

  • Neutral sodium fluoride gel (depending on the level of oral hygiene and residual level of salivary flow: from weekly to every second day; the gel is preferably applied with a custom-made tray)

    ◆ Avoid professional or over-the-counter fluoride gels as many of them are acidified which reduces patients' compliance (sore oral mucosa) and may damage the teeth (no saliva present to remineralize teeth)

◆ Diet modifications

  • Avoid cariogenic food and beverages

  • Minimize chronic use of alcohol and caffeine

  • Use non-fermentable sweeteners (xylitol, sorbitol, aspartame, or saccharine) whenever possible

◆ If possible, avoid drugs that may worsen sicca symptoms (e.g. anti-depressants, anti-histamines, anti-cholinergics, anti-hypertensives, neuroleptics)

◆ Optimize treatment of other medical conditions that result in xerostomia (e.g. endocrine disorders, metabolic diseases, viral infections)

◆ Avoid other exacerbating factors

  • Low-humidity atmospheres (e.g. air-conditioned buildings, windy locations)

  • Irritants such as dust and cigarette smoke

Salivary gland stimulation

◆ Masticatory stimulation (e.g. sugar-free gums, lozenges, or pastilles)

◆ Combined gustatory and masticatory stimulatory

  • Lozenges, mints, candies

  • Water, with or without a slice of lemon

◆ Parasympathomimetic secretogogues

  • Pilocarpine (5–7.5 mg, 3–4 times/day)

  • Cevimeline (30 mg, 3 times/day)

Saliva replacement and other symptomatic treatments

◆ Relief of oral dryness (non-responders to systemic salivary stimulation)

  • Increase humidification (e.g. air moisturizers, humidifiers)

  • Frequent sips of water

  • Oral rinses, gels, and mouthwashes

  • Saliva substitutes

Treatment of complications

Oral candidiasis

◆ Topical anti-fungal drugs:

  • Nystatin oral suspension (100,000U/1 ml, 4 times/day)

  • Clotrimazole cream (1%, 2 times/day)

  • Ketoconazole cream (2%, 1–2 times/day)

  • Amphotericin B lozenge (10 mg, 4 times/day) or 100 mg/ml, 4 times/day)

  • Systemic anti-fungal drugs:

  • Fluconazole tablets (50–200 mg/day for 7–14 days)

  • Itraconazole tablets (100–200 mg/day for 1–2 weeks)

◆ Dentures should be soaked in chlorhexine mouth rinse (0.2%) or a proprietary hypochlorite-containing denture soak at night

Angular cheilitis

◆ Usually a mixed infection with candidosis and *Staphylococcus aureus*. Therefore miconazole oral gel (24 mg/mL, 4 times/day for 7 days and continue for at least 2 days after clinical resolution of the lesions)

◆ Daktacort hydrocortisone cream (miconazole plus hydrocortisone; 1–2 times/day)

acinar fluid-producing cells are replaced by non-fluid-producing connective tissue cells which do not respond to stimulation.

◆ Masticatory and gustatory stimulation is the easiest to implement with few side effects. The combination of chewing and taste (e.g. sugar-free gums, mints, lozenges, candies) can be very effective in relieving symptoms. Special gum bases are available if regular chewing gums frequently sticking to the dry oral mucosa. If an acid is added, malic acid is preferred as it is less harmful to tooth substance and oral mucosa.

◆ Pilocarpine and cevimeline are muscarinic agonists which induce a transient increase in salivary output. Frequent but rarely severe or serious side effects include sweating, flushing, urinary urgency, and gastrointestinal discomfort. Parasympathomimetics are contraindicated in patients with uncontrolled asthma, narrow-angle glaucoma, or acute iritis and should be used with caution in patients with significant cardiovascular disease, Parkinson's disease, asthma, or chronic obstructive pulmonary disease. The recommended doses for pilocarpine are 5–7.5 mg 3–4 times daily but should be titrated for individuals to achieve the right balance between therapeutic benefits and adverse effects. The duration of action is 2–3 hours. Cevimeline (30 mg three times daily) has a longer duration of secretogogue activity (3–4 hours) but the onset of action is slower. Cevimeline is available in the United States, Canada, and Japan but not yet licensed in Europe.

Symptomatic treatment

Water, although less effective than natural saliva, is the most important fluid supplement for dry-mouth individuals. Sipping water and swishing it around the mouth throughout the day will help to moisten the oral cavity, hydrate the mucosa, and clear debris from the mouth. Careful water-drinking with meals will enhance taste perception, ease the formation of food bolus, and improve mastication and swallowing. It will also help prevent choking and aspiration.

However, aqueous solutions produce only transient relief from oral dryness, because the mucous membrane of xerostomic patients is inadequately coated by a protective glycoprotein layer and therefore its moisture is not retained.

Many oral rinses, mouthwashes, and gels are available for dry-mouth patients. Products containing alcohol, sugar, or strong flavourings which may irritate the sensitive, dry oral mucosa should be avoided. Saliva replacements are not well tolerated long-term, particularly when not instructed properly. To choose the best substitute for a SS patient, we recommend the following approaches:

◆ **Mild hyposalivation**: saliva substitutes are unlikely to be beneficial. Try gustatory or pharmacological stimulation.

◆ **Moderate hyposalivation**: if gustatory or pharmacological stimulation is ineffective, use saliva substitutes with low viscoelasticity, such as those containing carboxymethylcellulose, hydroxypropylmethylcellulose, mucin (porcine gastric mucin), or low concentrations of xanthan gum as base. During the night or other periods of severe oral dryness, oral gel can be helpful.

◆ **Severe hyposalivation**: a saliva substitute with gel-like properties should be used during the night and when daily activities are at a low level. During the day, use saliva substitutes with properties resembling the viscoelasticity of natural saliva, such as substitutes which have xanthan gum and mucin (particularly bovine submandibular mucin) as base.

Secondary infection of the oral mucosa with *Candida albicans* is common. A high index of suspicion for fungal disease should be maintained, and appropriate anti-fungal therapies instituted as necessary. Prolonged treatment may be needed to eradicate oral fungal infections. Avoid wearing dentures overnight and soak dentures in 0.2% chlorhexidine solution to prevent reinfections of the oral cavity by candida species living in the denture material.

Ocular manifestations

Most SS patients experience ocular surface irritation without long-term effects, although if it is left untreated, ocular surface damage and even visual impairment may ensue.

Overall, treatments aim at increasing ocular surface lubrication, stimulating secretion of or conserving tears, and targeting the associated ocular surface inflammation.[24] Treatments should be tailored to address the individual patient's needs and the severity of dry eye. Most treatments are palliative and do not treat the underlying condition. Management strategies are summarized in Box 128.3.

Preventive measures

If possible, patients should avoid dry, windy, or dusty environments which can exacerbate dry-eye symptoms. Similarly, the use of hair-dryers, central heating, air conditioning, or fans should be minimized, especially when these devices are directed towards the eyes.

Box 128.3 Management strategies for ocular manifestations of Sjögren's syndrome

Preventive measures

◆ Avoidance of exacerbating factors:
  • Avoid/restrict low humidity, dusty or windy environment
  • Avoid irritants such as dust and cigarette smoke

  • Avoid restrict and take regular breaks during activities that reduce blinking or provoke tear film instability (e.g. prolonged reading or computer use)

◆ Avoidance of drugs that may worsen sicca symptoms (e.g. anti-depressants, anti-histamines, anti-cholinergics, anti-hypertensives, neuroleptics)

◆ Optimized treatment of other conditions (e.g. ectropion, meibomian gland disease, lagophthalmos) that result in/aggravate dry eyes.

◆ Use of air moisturizers or moisture glasses

Improved ocular surface lubrication

◆ Tear substitution therapy (preservative-free preparations if frequent use is needed)
  • Low-viscosity eye-drops (e.g. cellulose derivatives) as frequently as needed
  • Medium- to high-viscosity eye-drops (e.g. carbomer gel 940) 3-4 times/day in more severe cases
  • Ophthalmic gels and ointments (at night)

◆ Mucolytic agents for sticky eyes or mucous threads/corneal filaments on eye examination
  • *N*-acetylcysteine 5% eye-drops (preservative-free, 2–3 times daily)

◆ Autologous serum eye-drops

◆ Systemic parasympathomimetic secretogogues
  • Pilocarpine (5–7.5 mg, 3–4 times/day) or cevimeline (30 mg, 3 times/day)

◆ Tear retention measures
  • Lacrimal punctum plugs/occlusion (moderate to severe dry eyes)

Reduction of ocular surface inflammation

◆ Topical immunomodulatory agents
  • Pulsed topical non-preserved corticosteroids (e.g. dexamethasone 0.1% eye-drops, 4 times daily twice daily for up to 8 weeks, taper dose or discontinue drops based on clinical findings and eye pressure)
  • Ciclosporin eye-drops
  • Dietary supplements: essential fatty acids (omega-3 and linoleic acid)

Other measures

◆ Treatment of blepharitis
  • Daily eyelid rubs with warm water and diluted baby shampoo, eyelid cleaning solutions, or wipes
  • Warm water compresses 2 times/day for 5 min
  • Topical antibiotics for anterior blepharitis if indicated (e.g. chloramphenicol ointment)

Spectacles, protective goggles, or glasses with lateral protection should be worn when aggravating environmental factors cannot be avoided. Humidifiers and house-plants can add moisture to the environment. Goggles should be used when swimming as chlorinated water and seawater can irritate the eyes.

Prolonged visual tasks with consequent reduced blink rate also aggravate dry eyes. Purposefully blinking, especially during computer use, and frequent resting of tired eyes with additional tear-drops can reduce discomfort.[25] Directing gaze downwards—by lowering computer screens, for example—may be helpful. Avoid rubbing the eyes as it can irritate them further.

Improving ocular surface lubrication

Topical tear supplementation

A key part of managing dry eye symptoms in SS patients is choosing the appropriate form of topical treatments. Most artificial tear substitutes fall into five main categories according to their active ingredients:

◆ cellulose derivatives: carboxymethylcellulose, hydroxyethylcellulose, methylcellulose, ethylcellulose

◆ polyvinyl derivatives: polyvinyl alcohol, polyvinylpyrolidone

◆ viscosity agents: carbomer 940, hydroxypropyl-guar, chondroitin sulphate, sodium hyaluronate

◆ paraffin ointments: white/yellow paraffin

◆ osmoprotection agents.

Hypromellose eye-drops are inexpensive, well-tolerated, first-line treatments which should be used as frequently as necessary to alleviate symptoms. Persistent use of artificial tear-drops can produce a long-lasting improvement in tear stability.

Preservatives in many eye-drop preparations can exacerbate symptoms through direct toxicity to the ocular epithelium or via hypersensitivity. Therefore, preservative-free tear substitutes are recommended for patients who use these drops more than 4–5 times daily. When treatment is initiated patients should be given clear instructions on maintaining a high standard of hygiene and specific instructions regarding early disposal of preservative-free eye-drops, to reduce the risk of eye infections. Preservative-free eye-drops come from different sources which may involve special manufacturing procedures; they are therefore expensive and there can be supply problems at times.

Lubricant gels, with greater viscosity and longer retention time, may be used to supplement artificial tears. Paraffin ointments used before bedtime can help to reduce symptoms of waking up with uncomfortable eyes and minimize any blurring of vision associated with their use. The ointment should be warmed up before use to facilitate its instillation.

Topical mucolytics and autologous serum eye-drops

If mucous threads and/or corneal filaments are present, or if the patient complains of sticky eyes, particularly when waking, mucolytic agents such as acetylcysteine may be useful.

SS patients with severe dry eyes may benefit from autologous serum eye-drops. The therapeutic benefits are likely due to the growth factors and vitamins in the serum. A randomized controlled crossover trial comparing autologous serum eye-drops with conventional therapy demonstrated a significant improvement in conjunctival impression cytology and symptoms at months 3 and 6,

although Rose Bengal staining, Schirmer's test and fluorescein clearance test were not improved.[26]

Stimulating tear production

Secretagogues (pilocarpine, cevimeline) may improve dry-eye symptoms in patients with residual lacrimal gland function.[24] See section 'Salivary gland stimulation' for a detailed description of their use.

Tear retention/conservation

Temporary or permanent punctal occlusion is a useful adjunct treatment in patients with moderate to severe dry eyes by facilitating the retention of residual and artificial tears in the eyes.

Reduction of ocular inflammation

Ocular inflammation is a key pathogenetic factor in dry eyes.[4] Therefore, topical anti-inflammatory agents such as corticosteroids can result in complete symptom relief. Because of the potential risk of glaucoma and cataract, topical corticosteroids should be used only in the short term or as pulsed therapy. In the United States (not in Europe unless produced by local compounding pharmacies), ciclosporin eye-drops have been licensed as a treatment for dry eyes. Topical ciclosporin can ameliorate ocular surface inflammation, improve tear production, and alleviate dry-eye symptoms.[27]

Systemic immunosuppression therapies

These agents are usually reserved for SS patients with extraglandular manifestations and rarely used for ocular manifestations alone. Rituximab may improve ocular symptoms and signs.[28]

Other therapies

Two recent randomized, placebo-controlled clinical trials have shown that oral supplementation of omega-3 and -6 fatty acids improved ocular dryness, Schirmer's test results, and markers of ocular inflammation in patients with dry eye syndrome (some have SS),[29,30] but large-scale studies are needed to confirm these findings.

Meibomian gland dysfunction

Meibomian gland dysfunction (MGD) is defined as a chronic, diffuse abnormality of the meibomian gland, characterized by terminal duct obstruction and/or qualitative and quantitative changes in the glandular secretion, resulting in a defective tear-film lipid layer. Typical symptoms include eye irritation, stinging, and burning with clinically apparent chronic inflammation and ocular surface disease. Furthermore, MGD aggravates dry-eye symptoms through excessive evaporation and exacerbating inflammation. Treatments depend on the severity of MGD which include modulating diet, lid margin hygiene, warm glandular expression, topical emollient lubrication, systemic tetracyclines, and topical anti-inflammatory therapy.

Systemic manifestations

Current therapeutic strategies for the management of systemic manifestations of pSS are largely empirical based on experience from managing other autoimmune rheumatic conditions. They are summarized in Table 128.4.

Constitutional

pSS patients may experience constitutional symptoms such as fatigue, anorexia, pyrexia, and unintended weight loss. If severe, clinicians should consider investigations for underlying malignancy

Table 128.4 Management strategies for extraglandular manifestations of SS

Clinical feature		Management
Constitutional symptoms (severe fatigue, anorexia, weight loss, fever)		Consider investigations for malignancies
		NSAIDs
		Hydroxychloroquine (400 mg/day starting dose, titrate to lowest effective dose thereafter)
Arthralgia or myalgia		NSAIDs
		Consider hydroxychloroquine (200–400 mg/day)
Inflammatory arthritis		NSAIDs
		Hydroxychloroquine (400 mg/day starting dose, individual titration to lowest effective dose thereafter)
		Methotrexate (15 mg/week; max 25 mg)
		Sulphasalazine (2–3 g/day)
		Prednisolone (7.5–10 mg/day; max 15 mg)
Inflammatory myositis		Prednisolone (40–60 mg/day initially)
		Pulsed methylprednisolone or cyclophosamide if severe
		Methotrexate or azathioprine as maintenance
Skin involvement	Mild vasculitis	Analgesics
		Pressure stockings
	Moderate/recurrent vasculitis	Hydroxychloroquine (200–400 mg/day)
		Dapsone (50–100 mg/day)
		Colchicine (100 μg/day)
		Prednisolone (7.5–10 mg/day; max 15 mg)
	Polymorphic erythema	Hydroxychloroquine (400–800 mg/day)
		Prednisolone (7.5–10 mg/day; max 15 mg)
	Xerosis	Moisturizers, emollient
		Avoid alcohol-based or heavy perfumed skin products
Severe vasculitis or cryoglobulinaemia		Pulsed methylprednisolone
		Rituximab
		Intravenous immunoglobulin
Cardio-pulmonary involvement	Pleuritis/pericarditis	NSAIDs
		Prednisolone (15–20 mg/day; max 30 mg)
		Colchicine (100 μg/day)
	Interstitial pneumonitis	Prednisolone (60 mg/day)
		Rituximab
		Cyclophosphamide in resistant cases
Gastrointestinal	Oesophageal reflux	Proton pump inhibitors
	Primary biliary cirrhosis	Ursodeoxycholic acid
Neurological involvement	Pure sensory or 'small-fibre' neuropathy	Gabapentin
		Pregabalin
		Carbemazepam
		Citalopram
		Amitriptylline (beware of exacerbation of dryness)
	Severe PNS	Prednisolone (60 mg/day) or pulsed methylprednisolone
		Cyclophosphamide IV (750 mg/m^2/monthly; 6–12 times)
		Intravenous immunoglobulin
	CNS	Prednisolone (60 mg/day) with or without cyclophosphamide IV (750 mg/m^2/monthly; 6–12 times)
Renal involvement	Interstitial nephritis/renal tubular acidosis	Bicarbonate (personalized dose) ± potassium citrate (personalized dose)
		Prednisolone (15–60 mg/day, depending on severity of proteinuria or renal impairment)
	Nephrocalcinosis	Adequate hydration
		Potassium citrate
	Glomerulonephritis	Prednisolone (60 mg/day) with or without cyclophosphamide

CNS, central nervous system; PNS, peripheral nervous system.

in particularly lymphoma. Constitutional symptoms may respond to corticosteroid or hydroxychloroquine. High-dose or long-term use of corticosteroid should be avoided.

Articular

Analgesics or hydroxychloroquine can be considered for the treatment of musculoskeletal pain. Inflammatory arthritis can be treated with local or oral corticosteroid if transient and disease-modifying therapies such as hydroxychloroquine, methotrexate, or sulphasalazine if persistent.

Cutaneous

Xerosis (dry skin) should be managed symptomatically and photosensitivity dermatitis by avoidance of strong 'midday' sun and effective sun-screen. Mild cutaneous vasculitis is often self-limiting, therefore supportive treatment such as analgesics (e.g. non-steroidal anti-inflammatory drugs, NSAIDs) for pain and anti-histamines for pruritus usually suffice. For more severe or recurrent/persistent vasculitis and subacute cutaneous lupus erythematosus, hydroxychloroquine, dapsone, or colchicine can be used. Low/moderate dose of oral prednisolone and topical tacrolimus may also be considered. For more extensive vasculitis or with skin ulceration or necrosis, high-dose corticosteroid and other immunosuppressants such as cyclophosphamide, methotrexate, azathioprine, or mycophenolate are needed. For patients with resistant cutaneous vasculitis, plasmapheresis and intravenous immunoglobulins may be effective. Rituximab is an alternative, particularly for cryoglobulinaemia.

Pulmonary

Severe pulmonary manifestations such as interstitial pneumonitis require corticosteroid with or without immunosuppressive agents such as cyclophosphamide.

Genitourinary

For renal tubular acidosis, correction of acid–base imbalance with alkalis such as sodium bicarbonate or potassium citrate is usually sufficient to correct other metabolic aberrations such as hypokalaemia, hypercalciuria, and hypocalcaemia. Corticosteroid and other immunosuppressive therapy are needed for more severe cases or for glomerulonephritis or cryoglobulinaemia. Patients presenting with renal stones or nephrocalcinosis should be investigated for underlying renal acidosis. These patients should be advised to maintain adequate hydration. Potassium citrate is particularly effective as the potassium increases solubility of urinary calcium and citrate decreases urinary excretion of calcium. Subclinical renal manifestations such as mild proteinuria or metabolic disturbances can be managed conservatively. Symptoms of 'cystitis' such as dysuria or urinary frequency are not uncommon and may be due to a combination of vaginal dryness and/or vaginal thrush in women, urinary tract infections, autonomic dysfunction, or frequent fluid intake (to relieve oral dryness). Oestrogen cream may alleviate vaginal dryness and vaginal thrush or urinary tract infections should be treated with appropriate anti-microbial agents.

Muscular

Myalgia without myositis is managed conservatively. A slight rise in creatinine kinase without other evidence of overt myositis can be monitored. Prednisolone and methotrexate or azathioprine should be used if myositis is confirmed on electrophysiological studies or muscle biopsy or when associated with objective muscle weakness.

Neurological

Treatment of peripheral neuropathy depends on the underlying causes. Pure sensory neuropathy or small-fibre neuropathy are managed with analgesics or pain-modifying agents such as gabapentin, pregabalin, carbamazepam, or amitriptyline (patients should be warned of potential exacerbation of sicca symptoms). Mononeuritis multiplex is treated with corticosteroid and cyclophosphamide or other immunosuppressive therapies. Recovery can be slow and incomplete, however. Some forms of peripheral neuropathy especially those associated with vasculitis and cryoglobulinaemia, respond well to rituximab.[31] Central nervous system manifestations are extremely rare and usually treated with corticosteroid and cyclophosphamide. Intravenous immunoglobulin or rituximab can be considered in resistant cases.

Haematological or other biological abnormalities

Many isolated laboratory abnormalities that are commonly found in pSS patients, such as hypergammaglobulinaemia, mild lymphopaenia, thrombocytopaenia, or hypocomplementaemia, can be monitored and do not require specific treatment. Hypergammaglobulinaemia may improve with hydroxychloroquine. The presence of new onset or rising levels of paraproteinaemia or development of hypogammaglobulinaemia should prompt further investigations for the development of myeloma or lymphoma. The appropriate initial investigations depend on local practice and should be carried out in liaison with haematology specialists, but may include checking for urine Bence Jones proteins, serum lactate dehydrogenase, skeletal survey, and bone marrow biopsy. Stable levels of paraproteinaemia without evidence of malignant transformation can be monitored and do not normally require treatment.

Gastroinstestinal

Proton pump inhibitors can be used for gastro-oesophageal reflux and ursodeoxycholic acid for patients with coexisting primary biliary cirrhosis.

Miscellaneous

Serositis such as pleuritis, pleural effusion, and pericarditis can be treated with anti-inflammatories. Corticosteroid may be used in more severe cases and in acute settings. Colchicine and hydroxychloroquine may be considered in persistent or recurrent disease.

Management of fatigue

In managing SS patients with disabling fatigue, it is pivotal that all potentially treatable factors that may contribute to the symptoms of fatigue (Box 128.4) are investigated, recognized, and appropriately managed. Sleep disturbance is common among pSS patients,[32–34] and the presence of sleep-disturbing sicca symptoms or pain should be adequately treated. Frequent awakening due to interstitial cystitis and overactive bladder can be alleviated by solifenacin, which is usually well-tolerated despite its anticholinergic effects. Sleep apnoea, if present, must be treated adequately. Depression and anxiety are not uncommon in pSS, and can cause tiredness and poor sleep.[12,34,35] Treatment with appropriate anti-depressive or anxiolytic drugs with low anticholinergic potential is indicated. Peripheral neuropathy and restless leg syndrome are common in pSS. Anaemia, thyroid dysfunction, and coeliac disease are other treatable causes associated with pSS, which may contribute to the

> **Box 128.4** Potential contributory factors to fatigue in primary Sjögren's syndrome
>
> - Systemic inflammation and immune dysregulation
> - Disturbed sleep (due to dryness, pain, irritable bladder, depression, anxiety, restless legs, nocturia from overhydration during the day)
> - Anxiety and depression
> - Secondary fibromyalgia
> - Hypothyroidism
> - Anaemia
> - Coeliac disease
> - Vitamin deficiencies (B_{12}, D)
> - Pulmonary and renal dysfunction (rare!)
> - Reduced physical capacity due to inactivity/sedentary lifestyle/kinesiophobia

symptom of fatigue. Reduced pulmonary and kidney function are less common, but should also be considered.

Some SS patients may experience the typical disabling feeling of exhaustion despite having all the above-mentioned treatable causes been either excluded or treated. Some may also suffer from secondary fibromyalgia-like symptoms with widespread musculoskeletal pain. For such patients, behavioural and psychological factors, such as a sedentary lifestyle with physical inactivity and low physical capacity, often accompanied by kinesiophobia and an exaggerated focus on bodily symptoms, should be explored and discussed. Coaching, behavioural therapy, regular physical activity, and learning of coping strategies may be useful in such cases.[36]

For patients with evidence of inflammation, considerable immune system activation and concomitant systemic disease activity from other organ systems, treatment with rituximab to reduce fatigue may be justified.[37,38]

Pregnancy in pSS

The main issue with regard to pregnancy in pSS patients is the risk of neonatal lupus syndrome with intrauterine fetal atrial ventricular (AV) heart block being the most severe complication. Women with antibodies to SSA (mainly antibodies to Ro-52) or SSB are at an increased risk with 2% of the pregnancies affected,[39,40] and up to 15–20% in patients who had a baby with neonatal lupus syndrome. pSS mothers may give birth to babies with lower birth weight and may have more frequent complications during deliveries compared to women in the general population.[41]

Pregnant pSS women with antibodies to SSA/SSB should be closely monitored by obstetricians with weekly assessment of the fetal heart rate between 14–30 weeks of gestation during which fetal heart blocks most commonly occur. Reduction or irregularity of the fetal heart rate may suggest intrauterine AV block and should be fully investigated promptly. First-degree AV block may resolve spontaneously, while second- and third-degree AV blocks usually persist or worsen. No evidence-based treatment is available, but high-dose dexamethasone or betamethasone (which cross the placenta, unlike prednisolone) has been used successfully and without serious harm to the baby.[42,43] Babies with intrauterine AV block should be delivered at units where a cardiac pacemaker can be implanted immediately postpartum.

Management of lymphoma

Approximately 5–10% of pSS patients will develop lymphoma.[44–46] It is difficult to predict who will be affected and when and where the lymphoma will develop. Several risk factors have been identified, namely hypocomplementemia, cryoglobulinemia, cutaneous vasculitis, peripheral neuropathy, monoclonality in serum electrophoresis, and recurrent or persistent SG swelling.[45–47] More recently, cytopenias, especially CD4+ T-lymphocytopenia,[46,48] and the presence of germinal centre-like structures in the SG biopsies[48] have been linked with increased risk for lymphoma in pSS. Clinicians should give SS patients information on the risk and symptoms and signs that may be associated with malignancy, and advise them to seek prompt medical attention if these symptoms or signs occur. In addition, regular physical examinations of accessible structures such as lymph nodes and SGs should be performed and appropriate investigations arranged if signs and symptoms indicative of possible lymphoma are present. Despite improved awareness and clinical vigilance, lymphomas are frequently detected by chance. Effective screening programmes have not been developed.

Mucosa-associated lymphoid tissue (MALT) lymphomas, marginal zone lymphomas, and diffuse large B-cell (DLBC) lymphomas are the main types of lymphomas in pSS.[49] DLBC lymphoma, an aggressive high-grade malignancy, is associated with premature mortality in pSS.[50] Lymphoma can develop at any time between diagnosis and up to 30 years afterwards; MALT lymphomas usually develop earlier than the more aggressive types.[49]

Management of lymphoma is usually provided by haematologists or oncologists, and is tailored to individual patients depending on the site, grade, stage, and extent of the lymphoma. Some low-grade MALT lymphomas can be monitored without treatment. Localized MALT lymphomas may be excised surgically with or without radiotherapy. More aggressive or extensive lymphomas require treatment with chemotherapy, often in combination with rituximab (Figure 128.1).

Emerging therapies

Improved understanding of pSS pathogenesis and the development of biological therapies have led to potential new therapeutic strategies.[52–55] Neither infliximab nor etanercept is an effective treatment for pSS. Several case series and small randomized placebo-controlled clinical trials have demonstrated the efficacy of rituximab in the treatment of fatigue as well as other systemic manifestations of pSS. Rituximab can also improve oral and ocular dryness both subjectively and objectively especially in early pSS, and appears to be effective as a treatment for pSS-associated lymphomas. Nevertheless, large phase 3 clinical trials are needed to confirm these findings. Controlled trials with other B-cell targeted therapies such as epratuzumab, atacicept, and belimumab are underway.

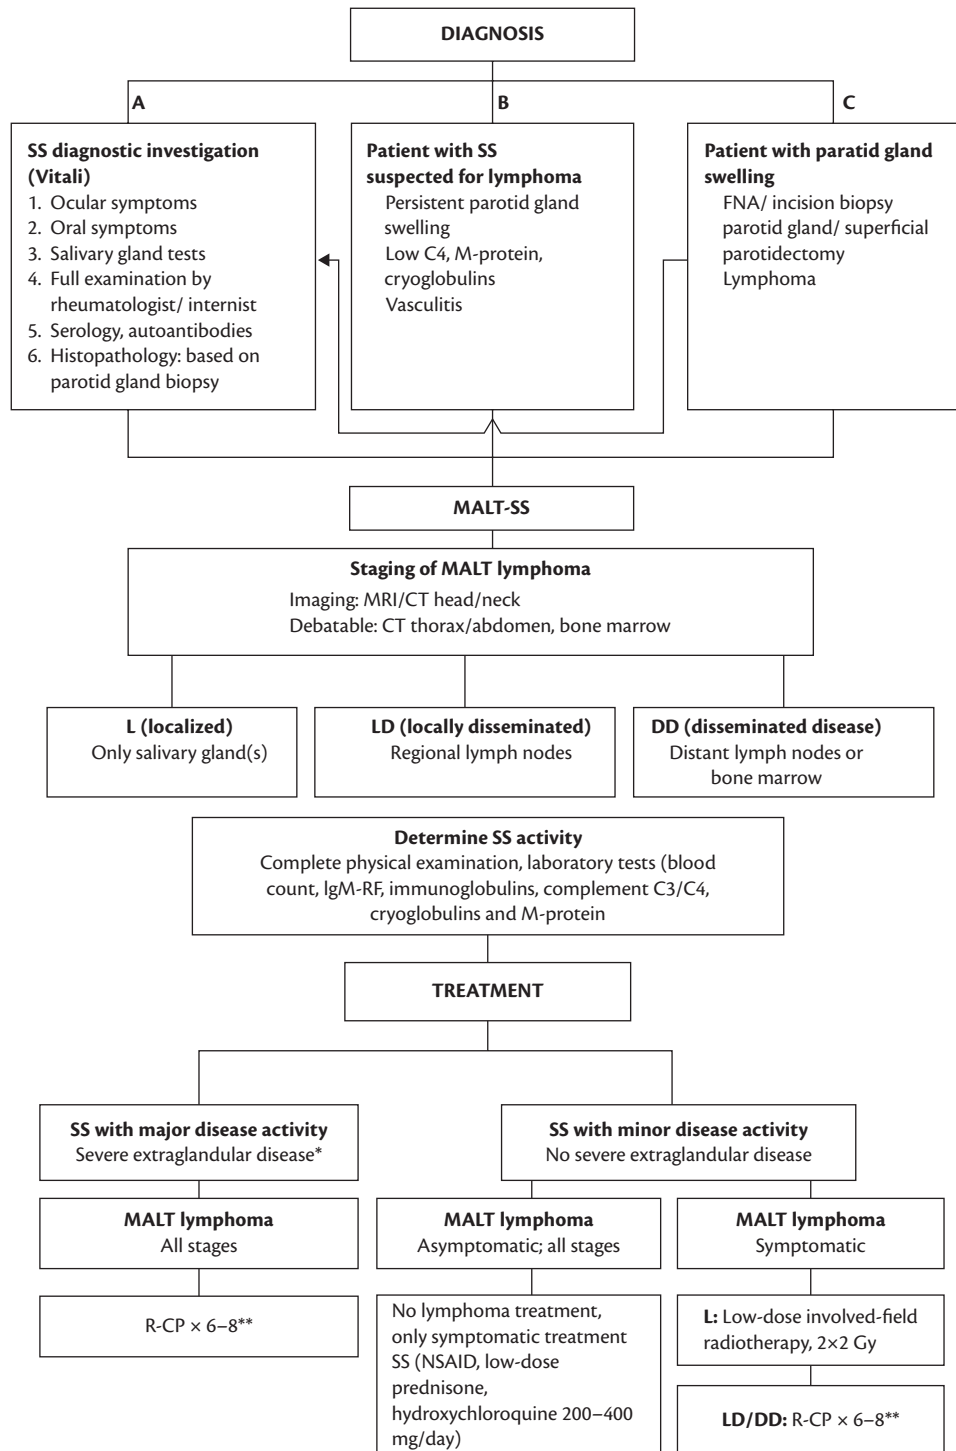
Biological therapies targeting other immune pathways that have been implicated in pSS may also represent useful therapeutic strategies. For instance, blockade of interferon-α, interleukin (IL)-1 or IL-6 may be an attractive approach given their link with pSS pathogenesis and fatigue.


Fig. 128.1 Management of mucosa-associated lymphoid tissue-type lymphoma of parotid gland and associated Sjögren's syndrome (MALT-SS). FNA, fine needle aspiration; R-CP, rituximab with cyclophosphamide and prednisone; NSAID, non-steroidal anti-inflammatory drugs. *Extraglandular disease: polyarthritis/myositis, glomerulonephritis, nervous system involvement, cryoglobulinemic vasculitis, other severe organ involvement, serological abnormalities.

Challenges

Effective management of SS remains a formidable challenge with several key obstacles yet to be overcome (Table 128.5). Success in improving the care for SS patients can only be achieved with a collaborative effort between clinicians, researchers, healthcare policy-makers, and the pharmaceutical industry.

Conclusion

SS is a multisystem disease of unknown aetiology. Dryness, fatigue, and bodily pain are prominent symptoms which although not life-threatening are debilitating and associate with poor quality of life and substantial health economic cost. The AECG classification criteria are the current gold standard for SS; whether the recently

Table 128.5 Challenges in management of Sjögren's syndrome

Challenges	Underlying obstacle	Possible solutions
Diagnosis		
Avoid diagnostic delay	Lack of simple, reliable test for detecting early disease	Biomarker discovery (e.g. saliva proteomics?)
	Poor awareness of SS from the public and healthcare professionals	Increase public and healthcare professionals' awareness of SS
Disease assessment		
Predicting outcome	Heterogeneity of long-term outcome	Biomarker discovery
	Inadequate knowledge on the natural history of SS	Establish patient cohort or registry
		Epidemiological studies
Disease staging (e.g. disease reversibility)	Inadequate understanding of SS pathogenesis	Further basic science and clinical research
Treatment		
Improve the quality of saliva and tear substitutes	Saliva/tears are complex substances containing many different molecules which serves different functions	Further pharmaceutical research
Better treatment for fatigue	Poor understanding of the mechanistic basis of this symptom	Further basic science and clinical research
		Establish multidisciplinary clinic dedicated to fatigue management
Monitor progression of disease (e.g. lymphoma)	Inadequate understanding of SS pathogenesis	Further basic science and clinical research
Effective communication between different healthcare providers	Diversity of health problems of SS requiring different specialist care	Combined clinics
		Multidisciplinary meetings
		Develop local databases
Service provision and drug development		
Improve service provision in primary and secondary care	Poor awareness from healthcare professionals and policy-makers of the health economic impact of SS	Improve education of healthcare professionals including dentists and opticians
		Active engagement between policy-makers and clinicians
Encourage new drug development and clinical trials	SS is perceived to be a condition with high risk but low return by pharmaceutical industry	Active engagement between pharmaceutical industry, research funding bodies, researchers, and clinicians

introduced provisional American College of Rheumatology (ACR) classification criteria will replace the AECG criteria in research and in clinical practice is unclear at present. Assessment of SS patients should include glandular and extraglandular manifestations and lymphoma risk evaluation. The use of standardized instruments such as ESSDAI and ESSPRI is recommended. Optimal management of SS requires a multidisciplinary team consisting of specialists in oral medicine, ophthalmology, and rheumatology as well as other healthcare professionals depending on the clinical presentation. Both pharmacological and non-pharmacological interventions have a role in the management of SS. Replacement therapy and preventative measures are the mainstay of treatment for sicca symptoms but are only partially effective. The use of muscarinic receptor agonists is limited by side effects and poor efficacy in patients with severe glandular damage. Tear duct blockade and ciclosporin eye-drops may improve symptoms of ocular dryness and discomfort. Disease-modifying therapy for SS remains elusive but emerging biological therapies such as rituximab hold promise, especially for those with early disease.

Effective management of SS requires a better understanding of SS pathogenesis, development of more effective therapy as well as an increase in awareness of SS and its health economic impact among healthcare professionals, policy-makers, research funding bodies, the pharmaceutical industry, and the general public.

Overlap/undifferentiated syndromes

Ariane Herrick

Introduction

'Undifferentiated connective tissue disease' (UCTD) and 'overlap syndromes' are difficult to define. Their existence in a separate chapter is justified by the clinical reality that many patients do not fit into the neat boxes of defined connective tissue diseases. First, we introduce the two terms.

Undifferentiated connective tissue disease

UCTD describes the situation when a patient has clinical and/or serological features which point to an underlying connective tissue disease, but there is insufficient evidence to make the diagnosis of any one specific connective tissue disease. If the patient is observed over time, then a defined connective tissue disease may evolve and if so, then this is usually within the first 5 years of disease, although it can be much later.

A complicating factor is that classification criteria for defined connective tissue diseases may change. For example, it is well recognized that the American College of Rheumatology (ACR) criteria for systemic sclerosis (SSc)[1] are insensitive to (especially early) limited cutaneous disease, and other criteria have therefore been proposed.[2,3] Until new classification criteria are validated and accepted, inevitably some clinicians will define disease on the basis of the proposed criteria, whereas others will not. The result is that one clinician's early SSc (using the proposed criteria) will be another's UCTD. This situation is analogous to the new classification criteria for rheumatoid arthritis (RA), which should lead to fewer diagnoses of 'undifferentiated arthritis'.[4,5]

Overlap syndromes

The term 'overlap syndrome' describes situations when a patient has features of more than one defined connective tissue disease. While many connective tissue diseases may overlap, the commonest to do so are systemic lupus erythematosus (SLE), SSc, inflammatory muscle disease (for the purposes of this review termed 'myositis') and Sjögren's syndrome (Figure 129.1). Each of these may also overlap with RA, and less frequently with other illnesses with an autoimmune component, for example vasculitis, and primary biliary cirrhosis.

If, despite overlapping clinical and/or serological features, the phenotype of one particular connective tissue disease predominates (or evolves over time), then a patient is often categorized (or recategorized)

as having that disease rather than an overlap syndrome. A problem is that there is no recognized hierarchy in which a defined connective tissue disease 'supersedes' the diagnosis of an overlap syndrome, or vice versa. For this reason (for example) one clinician's SSc with myositis is another clinician's SSc/myositis overlap.

Mixed connective tissue disease

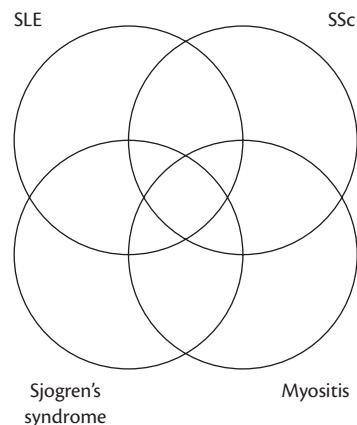
Adding to the complexity of overlap syndromes is the diagnosis of 'mixed connective tissue disease' (MCTD). On the one hand this is sometimes considered the 'prototype' overlap syndrome, on the other hand some rheumatologists have debated whether it is a separate entity.[6] Most clinicians agree that a patient can only be assigned this diagnosis when positive for anti-U1 ribonucleo-protein (RNP) antibodies. However, U1 RNP antibody can also be positive in patients with SLE, SSc, and polymyositis, although most patients with high titres of U1 RNP antibodies have some 'overlap' connective tissue features. A further element of complexity is the suggestion that the term 'MCTD' should be dropped and 'undifferentiated autoimmune rheumatic disease' substituted.[7] The reality is that some patients diagnosed as having MCTD fulfil the criteria of one (or more) defined connective tissue disease but others do not.


Fig. 129.1 Diagrammatic representation of overlap syndromes between systemic lupus erythematosus (SLE), systemic sclerosis (SSc), myositis, and Sjögren's syndrome. As shown, patients may overlap between two, three, or four defined diseases. The diagram does not illustrate how patients can overlap between SSc and Sjögren's syndrome alone, or between SLE and myositis alone.
Fig. 129.2 The interrelationships between mixed connective tissue disease (MCTD), undifferentiated connective tissue disease (UCTD) and overlap syndromes.

If overlap syndromes are defined on the basis that the criteria for at least one defined connective tissue disease are met, then it could be argued that some patients with MCTD are 'undifferentiated' and some are 'overlaps' (Figure 129.2).

In this chapter, UCTD and overlap syndromes are considered separately, although it must be recognized that this is a somewhat false separation: both form part of the spectrum of multisystem connective tissue disease.

Undifferentiated connective tissue disease

Epidemiology

The incidence and prevalence of UCTD have not been studied, most likely reflecting the problems with definition (see next section). In the larger case series reported, the majority of patients are female (at least 90%) with a mean age of onset in the fourth to fifth decades.[8–11]

Definitions, classification criteria, and diagnostic criteria

LeRoy et al.[12] in 1980 first proposed the term 'undifferentiated connective syndromes' for those patients in the early stages of connective tissue disease, and who often presented with Raynaud's phenomenon and puffy fingers. These authors suggested that while many patients evolved into a defined connective tissue disease it was possible that some might remain 'undifferentiated', or remit.[12] As discussed below, it is now well recognized that many patients remain undifferentiated.

Thirty years later, different investigators have used different definitions for UCTD (summarized in Mosca et al.[13,14]). For example, some investigators require the presence of a non-organ-specific autoantibody, usually a positive anti-nuclear antibody (ANA),[8,11] others not.[15] The current situation is that there are no ACR or European League Against Rheumatism (EULAR) criteria for UCTD and therefore diagnosis depends largely on clinical judgement. A dilemma is that all connective tissue diseases 'have to start somewhere' and so a high proportion of patients with defined connective tissue disease at the time of first evaluation at a rheumatology clinic might have been diagnosed as having UCTD had they been assessed at an earlier stage of their disease. Therefore Mosca et al.[8,16] included in their cohort only patients with disease duration of at least 1 year. However, even in the cohort of patients with early connective tissue disease (disease less than 12 months' duration) described by Alarcon et al.[15] the majority of patients with undifferentiated disease remained undifferentiated or remitted.[17,18]

Mosca et al.[13,19] suggested the following preliminary classification criteria for stable UCTD:

- Signs and symptoms suggestive of a connective tissue disease, but not fulfilling criteria for defined connective tissue diseases
- Positive ANA
- Disease duration of at least 3 years (although patients with a shorter follow-up could be diagnosed as 'early UCTD').

Some investigators consider undifferentiated polyarthritis within the definition of UCTD. Although Williams et al.[17,18] and Bodoley et al.[10] included in their series patients with undifferentiated arthritis and with 'isolated' Raynaud's phenomenon, they conducted subanalyses of patients with other 'true' UCTD. For the purposes of this chapter, undifferentiated types of inflammatory arthritis are not included.

Aetiopathogenesis

As for the defined connective tissue diseases, this is unknown and has been less studied. While it is likely that there is a genetic component, this is an area requiring to be researched.

Clinical features

Essentially these are the clinical features of any of the connective tissue diseases, so long as the combination of clinical and serological features does not suffice to make a diagnosis of any one (or more) defined disease. Table 129.1 summarizes the clinical and laboratory features included in the classification criteria for SLE,[20,21] SSc,[1] myositis,[22] and Sjögren's syndrome.[23] It is very possible for a patient to present with one or more (sometimes several) of the features listed in the different classification criteria for these four diseases but remain 'undifferentiated' on the basis that no single set of classification criteria[1,20–23] is fulfilled. For example, a patient with arthralgia, tiredness, Raynaud's phenomenon, pulmonary fibrosis, leucopenia, and a positive ANA (titre 1/1000) does not fulfil any one set of criteria and so is 'undifferentiated'. Patients falling within the definition of UCTD may also have features of inflammatory arthritis (as long as they do not fulfil the criteria for RA) or of a connective tissue diseases other than SLE, SSc, myositis, or Sjögren's syndrome (again, as long as criteria of this are not fulfilled).

Raynaud's phenomenon is a very common presentation of UCTD, as originally described by LeRoy et al.[12] However, because UCTD may present with almost any clinical feature, some non-specific (e.g. fatigue) others organ based (e.g. pulmonary fibrosis, trigeminal neuralgia), patients may present to a number of different specialties. Some key clinical features/presentations (this is not a comprehensive list) include:

- **Raynaud's phenomenon**, with or without puffy fingers. This is a common presentation, reviewed by Mosca et al.[19] and reported in 33–56% of patients. Some clinicians seldom make the diagnosis of UCTD in the absence of Raynaud's phenomenon.
- **Fatigue**. Although this symptom is very common and non-specific, in the presence of a positive ANA (especially in high titre) it may indicate an underlying connective tissue disease (often undifferentiated).
- **Arthralgia (sometimes arthritis) and myalgia**. Again, these are non-specific, but especially if these occur with Raynaud's phenomenon and a positive ANA, may indicate UCTD.

Table 129.1 Clinical, haematological, and immunological features included in the classification criteria for systemic lupus erythematosus (SLE), systemic sclerosis (SSc), myositis, and Sjögren's syndrome (SS)

	SLE	SSc	Myositis	SS
Clinical features				
Mucocutaneous	Malar rash Discoid rash Photosensitivity Oral ulcers	Sclerodactyly (with or without more proximal skin thickening) Digital pitting	Rash of dermatomyositis	Dry eyes Dry mouth (criteria include a number of diagnostic tests for these[23])
Musculoskeletal	Arthritis		Proximal muscle weakness	
Other	Serositis—pleuritis or pericarditis Renal disorder—proteinuria or casts Neurologic disorder—seizures or psychosis Haematologic disorder—haemolytic anaemia, leucopenia, lymphopenia, thrombocytopenia	Pulmonary fibrosis	Raised muscle enzymes Abnormalities on electromyography Characteristic abnormalities on muscle biopsy	
Serological features				
	Anti-DNA Anti-Sm Antiphospholipid antibodies Abnormal titre of ANA			Anti-Ro Anti-La

- **Dry eyes and/or mouth**. These are common complaints in undifferentiated as well as other connective tissue diseases.

- **Interstitial lung disease**. This diagnosis should always prompt a search for an underlying connective tissue disease, which may be undifferentiated. Large series and review articles have reported low prevalences of pulmonary fibrosis in patients with UCTD.[9–11,19,24] Conversely, a substantial proportion of patients with interstitial pneumonia may have underlying autoimmune/connective tissue disease and the term 'lung-dominant connective tissue disease (CTD)' has been proposed.[25] Whether or not a patient with interstitial lung disease has an associated UCTD is clinically relevant because if so, then prognosis is improved.[26]

- **Leucopenia**. This is common, reported in 11% of the cohort of 213 patients with early disease reported by Alarcon et al.[15]

- **Serology**. Most patients with a diagnosis of UCTD have a positive ANA. In the cohort of patients described by Clegg[27] seen within 12 months of disease onset, 59% were ANA positive and as stated earlier, the presence of a non-organ specific antibody (usually ANA) has been required by some authors for diagnosis. A proportion of patients have other non-organ specific antibodies, for example anti-Ro, anti-La, or anti-U1 RNP.[27] Anti-thyroid antibodies may also be present (13% of 64 patients with 'stable' UCTD in the cohort of Mosca et al.[16] had autoimmune thyroid disease). In practice, often it is the finding of a positive ANA which alerts the clinician to the possibility of connective tissue disease, which may be undifferentiated.

Outcome

As first suggested by LeRoy et al.,[12] there are three possible outcomes of UCTD (Figure 129.3):

- evolution to a definite connective tissue disease
- persisting features of UCTD
- resolution.

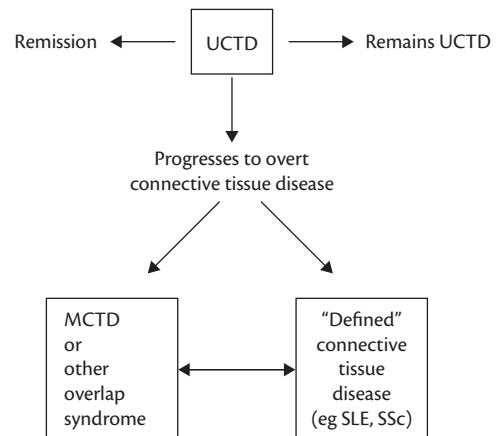
Several case series have described these clinical outcomes in patients with UCTD. Table 129.2 summarizes some of the larger studies. A key point is that the majority of patients, especially those with disease duration of more than 1 year, never progress to a defined connective tissue disease but remain undifferentiated. Of these patients who remain undifferentiated, most have mild disease but some (e.g. those with lung fibrosis) may have severe even life-threatening disease.


Fig. 129.3 Possible outcomes of undifferentiated connective tissue disease. The figure also illustrates how overlap syndromes and defined connective tissue diseases may transition from one to another.

Table 129.2 Clinical outcomes in undifferentiated connective tissue disease—summary table of some of the larger studies

Country	Number of patients	Duration of follow-up	Number (%) evolving into 'defined' connective tissue disease	Number (%) remaining undifferentiated	Number (%) of those remaining undifferentiated who remitted/became symptomatic
USA[a] [18]	115 (47 available for 10 year visit)[2]	10 years (5 year data is reported in [17])	20 (17%): 11 SLE 3 SSc 6 RA	66 (57%) at 1 year of whom 41 remained UCTD at 3 years, 29 at 5 years and 13 at 10 years[3]	10 of those not evolving to a connective tissue disease [c]
Italy[9]	165	5 years	10 (6%): 5 SLE (1 with SS, 1 with APS) 3 other SS, 1 myositis 1 MCTD	155 (94%)	19 (12% of 155)
Italy[16]	83	5 years (1 year data, describing 91 patients, reported in [8])	19 (23%): 18 SLE 1 SS	64 (77%)	0
Hungary[10]	665[b]	5 years	230 (35%): 87 RA 45 SS 28 SLE 26 MCTD 22 systemic vasculitis 19 SSc 3 myositis	435 (65%)	82 (19% of the 435)

APS, anti-phospholipid syndrome; MCTD, mixed connective tissue disease; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; SS, Sjögren's syndrome; SSc, systemic sclerosis; UTCD, undifferentiated connective tissue disease.

[a]Patients were only included if they had early disease (within 12 months of onset).

[b]Excluding patients with isolated Raynaud's phenomenon or unexplained polyarthritis.

[c]Percentages difficult to gauge because of numbers of withdrawals. Numbers do not include patients evolving to isolated Raynaud's phenomenon or to unexplained polyarthritis.

Evolution to a defined connective tissue disease may occur at any point but usually occurs early, within the first 2–5 years.[10,16] In some reported series, SLE was the connective tissue disease most likely to develop (Table 129.2). However, in the series of Bodoley et al.,[10] most 'evolvers' were to RA. The presenting clinical features may predict the pattern of evolution. For example, SSc may be more likely to develop than SLE in those patients presenting with severe Raynaud's phenomenon. The autoantibody profile may also help predict the most likely pattern of disease evolution: patients with anti-Sm patients, anti-double stranded (ds)DNA or ANA with a homogenous pattern are likely to progress to SLE,[28] patients with anti-Ro and anti-La antibodies to Sjögren's syndrome, those with U1 RNP antibodies to MTCD, and those with ANA with an anti-nucleolar pattern to SSc.[10] There is a substantial literature (not discussed in detail here) describing predictors of evolution to a SSc-spectrum disorder in patients with Raynaud's phenomenon[29,30]: abnormalities on nailfold capillaroscopy (Figure 129.4) and SSc-specific autoantibodies are independent predictors of progression (patients with both predictors are 60 times more likely to develop SSc than patients without either predictor).[29]

Management

There is no specific disease-modifying therapy for UCTD. Currently, treatment for any one individual is dictated by their clinical features.

For example, interstitial lung disease and pulmonary hypertension are generally treated similarly as in those with idiopathic disease. Raynaud's phenomenon may be severe, and should be treated as for Raynaud's secondary to SSc-spectrum disorders. Anti-malarials are often prescribed, especially in patients with arthralgia/arthritis, and findings from a retrospective study[31] suggested that anti-malarial therapy in patients with UCTD might delay progression to overt SLE. Although large case series described frequent use of (low-dose) steroids,[10,11] these should only be prescribed when there is clear evidence of an inflammatory component to the illness. Management is multidisciplinary and should have a strong emphasis on patient education: for example, patients with Raynaud's phenomenon should be told to report any persistent discolouration (suggesting a risk of critical ischaemia) or digital ulceration.

A key challenge is whether, in the future, early identification of underlying UCTD will allow early intervention to prevent disease progression, or at least to allow inclusion into clinical trials aimed at testing effectiveness of possible disease-modifying agents. For example, in the patient with Raynaud's phenomenon, early identification of nailfold capillaroscopic abnormality and/or disease-specific autoantibodies (predictive of an underlying SSc-spectrum disorder[29]) might in the future allow early commencement of vascular remodelling therapies. Early identification of interstitial
Fig. 129.4 (A) Normal nailfold capillaries in a healthy control subject compared to (B) abnormal capillaries in a patient with SSc, showing capillary enlargement, areas of avascularity, and loss of the normal nailfold architecture.

pneumonitis might similarly allow early intervention. However, first we need to identify effective disease-modifying agents.

Summary statement on UCTD

UCTD is difficult to define. A proportion of patients evolve to a defined connective tissue disease, and it will never be possible in all patients to separate completely the early stages of a defined connective tissue disease from UCTD. The key point for clinicians is to be especially vigilant in the first 3–5 years of disease onset, because evolution into a defined connective tissue disease is usually within this time frame. Therefore clinical stability after 3–5 years is reassuring. Treatment is based on symptoms and which (if any) internal organs are involved.

Overlap syndromes

Epidemiology

Most likely reflecting problems of definition (discussed below), the epidemiology of overlap syndromes has been little studied, similarly to the situation with UCTD. Of all the overlap syndromes, MCTD (a term first proposed in the early 1970s[32]) has been most researched, accepting that, as already mentioned, there has been considerable debate and controversy as to whether MCTD should be considered a separate disease entity.[6,7,33] For the purposes of this chapter, the term 'MCTD' is retained, given that much of the literature on overlap syndromes focuses on this, but MCTD should perhaps be viewed as an ill-defined entity within a broader group of overlap syndromes, with further overlap with UCTD (Figure 129.2). An epidemiological study of MCTD from Norway reported a mean age of adult-onset disease of 38 years, a female to male ratio of 3.3, a point prevalence of 3.8 per 100 000 adults, and an incidence of 2.1 per million adults per year.[34] These prevalence and incidence rates are lower than for SLE, SSc, and myositis.

Definitions, classification criteria, and diagnostic criteria

Definitions

The definition of overlap syndromes is likely to remain contentious. At one end of the spectrum is the viewpoint that most connective tissue diseases are overlaps, at the other end that 'overlaps' are not a useful concept but that most connective tissue diseases are highly heterogeneous, defined on the basis of their most prominent clinical features.

Nonetheless, the pragmatic approach is to state that overlap syndromes are diseases characterized by having features of more than one defined connective tissue disease. Some specific examples are defined as follows:

◆ **Mixed connective tissue disease**. As already mentioned, U1 RNP antibody (Figure 129.5) is generally considered a necessary prerequisite for diagnosis. The 'typical' patient with MCTD has overlapping features of SLE, SSc, and myositis.

◆ **SSc/polymyositis**. Patients with this overlap syndrome have features of both SSc and inflammatory muscle disease. Because myositis is common in SSc, many physicians would not define this as an overlap, but all part of the SSc-spectrum. A proportion of patients with this overlap have antibodies to PM-Scl.[35] However, this is a minority (in the order of 25%).[36] There are two antigens, PM-Scl-75 and PM-Scl-100. In a cohort of 280 patients with SSc, anti-PM-Scl-75/100 was associated not only with muscle involvement but also with lung disease and digital ulcers.[37]

◆ **SLE/RA**. Patients have features of both SLE and RA. For example, they might have erosive polyarthritis, low white blood and platelet counts, positive rheumatoid factor, positive ANA, and high levels of circulating dsDNA antibodies.
Fig. 129.5 Indirect immunofluorescent staining for ANA (U1 RNP antibodies) on HEP-2 cell line slides at 1 in 100 dilution.
Courtesy of Dr Hana Alachkar.

There are several other possible overlap syndromes (Figure 129.6). For example, the anti-synthetase syndrome[38,39] could be considered an overlap syndrome. This chapter confines itself to broad principles rather than describing details of individual syndromes.

Classification and diagnostic criteria

There are no ACR or EULAR criteria for overlap syndromes. Diagnostic criteria for MCTD have been suggested by different investigators.[40] Alarson-Segovia and Villareal[41] suggested that for a diagnosis of MCTD, a patient had to have (in addition to an anti-RNP antibody) three or more of: swollen hands, synovitis, myositis, Raynaud's phenomenon, and acrocyanosis (including one or both of synovitis and myositis). Kahn et al.'s criteria were similar,[42]

although insisting on Raynaud's phenomenon: these criteria stipulated an anti-RNP antibody, Raynaud's phenomenon, and two of: swollen fingers, synovitis, and myositis.

A key point is that a patient with U1 RNP antibodies with features typical of MCTD may evolve over the years into a phenotype more typical of another connective tissue disease (e.g. SLE or SSc) and that conversely a patient with SLE or SSc with positive U1 RNP antibodies may go on develop overlapping features and so evolve into a 'definite' MCTD (Figure 129.3). Neither the clinical nor the serological boundaries are clear-cut.

Aetiopathogenesis

While this is not known, it is likely that (as with the other connective tissue diseases) there are both genetic and environmental components to overlap syndromes. Associations between MCTD (and anti-U1 RNP) and HLA DR4[43–46] and also HLA DR2[45,46] have been reported.

Clinical and laboratory features

These are highly variable between and within individuals, reflecting the enormous heterogeneity of the individual defined connective tissue diseases, a heterogeneity which is further compounded when these occur in overlap. While all the possible 'combinations' constituting overlap syndromes will not be discussed here, the key features of MCTD deserve mention.

Features of mixed connective tissue disease

Common representing features include tiredness, Raynaud's phenomenon, arthralgias, and myalgias. The tiredness can be profound. Although swollen, puffy fingers (Figure 129.7) are said to be characteristic, these occur also in early inflammatory arthritis and in SSc. There is a large number of other possible presenting

Fig. 129.6 Overlap syndrome of SSc and inflammatory arthritis. Hand radiograph showing acro-osteolysis of several of the distal phalanges, consistent with the diagnosis of SSc, and a Z-thumb deformity, consistent with the patient's inflammatory arthritis.
Fig. 129.7 (A) Right and (B) left hands showing puffy fingers (best shown on the left hand) and an ulcer over the right index proximal interphalangeal joint. Copyright Salford Royal NHS Foundation Trust.

features, including rashes and features reflecting the internal organ involvement of the disease. These possibilities include pulmonary arterial hypertension, interstitial lung disease (which can be fulminating),[47] trigeminal neuralgia, and aseptic meningitis. Renal involvement has generally been considered to be rare in patients who are anti-U1 RNP positive, but can occur.[46,48] Any of these clinical features may occur at any point in the time course of the disease, and it may be only after two or more of these features develop, and the U1 RNP antibody is tested, that the diagnosis is made.

Serology

As already stated, a positive RNP antibody (anti-U1 RNP) is a prerequisite for the diagnosis of MCTD, although RNP positivity is not specific for MCTD and, as stated earlier, can occur in patients with a defined connective tissue disease such as SLE and SSc. Anti-U1 RNP should be tested for if there is any clinical suspicion of connective tissue disease, especially in the presence of a high-titre ANA in a speckled pattern. Antibodies to Sm, Ro, and La also produce a speckled ANA pattern although these speckled patterns can be differentiated. It is now recognized that U1 RNP consists of RNA plus three different proteins (A, C, and a 68–70 kDa protein).[49] Most laboratories check for native U1 RNP which contains proteins 70P, A, and C.

Patients with MCTD may have other autoantibodies, including anti-dsDNA, anti-Ro, anti-La, and anti-cardiolipin antibodies.[46] The presence of these antibodies may be associated with specific features—for example, patients with anti-Ro and anti-La antibodies are likely to have features of Sjögren's syndrome. Other common laboratory features are hypergammaglobulinaemia and leucopenia (reported in 80% and 52% respectively of the original description of patients[32]).

Outcome

Outcome of overlap syndromes is highly variable, depending on the phenotype of the individual and whether this is predominantly (for example) of SLE or SSc. As stated earlier, patients with MCTD often evolve to SSc or SLE.[50] It has been suggested that whether

MCTD evolves into SLE or SSc, or remains 'MCTD', is influenced by MHC antigens.[43]

Although it was originally thought that MCTD had a relatively benign course with a low prevalence of renal, cerebral, and pulmonary involvement,[32] this opinion has been revised and it is now recognized that patients with MCTD may have severe disease and that there is a significant mortality.[6,43,46,51] This reflects how a proportion of patients develop pulmonary arterial hypertension and other major organ involvement.[46,51,52] In the cohort of 47 patients described by Burdt et al.,[46] 23% developed pulmonary hypertension as diagnosed at right heart catheterization or at autopsy.

Management

At present there is no drug known to modify the underlying disease process in overlap syndromes in general or in MCTD in particular. This is unsurprising, given the definition issues.

Treatment is guided by experience from SLE, SSc, and myositis. The clinician has to assess which clinical features require specific treatment. Examples of commonly used treatments for some of the musculoskeletal, vascular, and internal organ involvements of overlap syndromes are given in Table 129.3.

Certain general points can be made:

◆ Patients should be kept under regular review, in order to identify any change in disease status which might require further assessment and management. For example, at the outpatient clinic patients should be asked about the development of any cardiorespiratory symptoms, examined for the presence of a loud pulmonary component to the second heart sound and for basal crackles, and investigations arranged as appropriate (ECG, echocardiogram, pulmonary function tests). A dipstick test of urine should be performed at each visit, looking for protein or blood. The blood count, biochemical profile, and acute-phase response should be monitored, and serological tests requested if appropriate (e.g. dsDNA antibodies and complement levels in the patient with an SLE overlap).

Table 129.3 Examples of treatments for some of the different features of overlap syndromes. This is not a comprehensive list

Clinical feature	Specific examples
Myositis	Steroids ± immunosuppression
Arthritis	Analgesics, NSAIDs, DMARDs including anti-malarials and methotrexate
Raynaud's phenomenon/digital ischaemia and ulceration	Conservative (non-drug) measures, vasodilators (e.g. calcium channel blockers), intravenous prostanoids for refractory ulceration or digital ischaemia (usually in combination with antibiotics)
Pulmonary arterial hypertension	Endothelin receptor antagonist, phosphodiesterase inhibitor, intravenous prostanoid therapy
Pulmonary fibrosis	Steroids ± immunosuppression
Renal disease	Steroids and immunosuppressants, depending on histology, ACE inhibitor (for proteinuria or for scleroderma renal crisis)
Gastro-intestinal disease	Proton pump inhibitors, antibiotics for bacterial overgrowth
Haematological involvement—haemolytic anaemia, thrombocytopenia	Steroids

ACE, angiotensin converting enzyme; DMARDs, disease-modifying anti-rheumatic drugs; NSAIDs, non-steroidal anti-inflammatory drugs.

- As with all connective tissue diseases, management is multidisciplinary, often involving different medical specialties as well as physiotherapy, occupational therapy, and podiatry. Patient education is a key aspect of management.

- A key point is to determine the inflammatory 'burden' in any one particular patient. This will be high when there is a strong SLE/myositis component, but may be low when most of the features are those of SSc. Steroids are commonly used for many of the inflammatory manifestations of MCTD and of other overlap syndromes.

- Pulmonary arterial hypertension is generally treated as in 'idiopathic' or SSc-related disease. However, if there is thought to be a significant inflammatory component to the overlap syndrome then steroids and/or immunosuppressants should also be considered.

- Pulmonary fibrosis should be treated as in other connective tissue diseases, usually with steroids and/or immunosuppressants accepting that the evidence base is weak, except for SSc-related pulmonary fibrosis when cyclophosphamide has been shown to confer modest benefit.[53,54]

- Caution needs to be exercised when steroids are prescribed for inflammatory features in patients with overlap syndromes which include SSc, especially if the SSc is of the diffuse cutaneous subtype. This is because steroids are a risk factor for scleroderma renal crisis.[55]

Summary statement on overlap syndromes

Patients with overlap syndromes fulfil the criteria of a defined connective tissue disease but in addition have clinical features of at least one other (and may fulfil the criteria for another). MCTD is characterized by overlapping features of SLE, SSc, and/or myositis with antibodies to U1 RNP. Management of overlap syndromes depends on the specific clinical manifestations. For example, a patient with a predominantly SLE phenotype, but with some features of SSc, will be managed mainly along 'SLE lines', but addressing also the SSc components (for example treatment of oesophageal dysmotility and/or of severe Raynaud's phenomenon).

Overall summary

UCTD and overlap syndromes form part of the broad spectrum of connective tissue disease. They are difficult to define, reflecting the heterogeneity of these diseases between and within individuals. Within any one individual the disease may evolve over time: different features of that disease may predominate at different times over the years.

UCTD and overlap syndromes are, at least in most patients, chronic conditions which range from the very mild (in some patients with UCTD) to the life-threatening. The key point for the clinician is early recognition of clinical features which require specific treatment. A major challenge over the next 10 years is to better understand the natural history of UCTD, in order to establish whether we can predict those patients who progress to severe disease and whether early immunosuppression and/or vascular remodelling agents might favourably influence prognosis.

Vasculitis—classification and diagnosis

Richard A. Watts and David G. I. Scott

Introduction

The word vasculitis means inflammation of blood vessels; the blood vessel is the primary site of inflammation. The pathological consequence of such inflammation is destruction of the vessel wall, seen histologically as fibrinoid necrosis; hence the term 'necrotizing vasculitis'. Vasculitis may be localized to a single organ or vascular bed and be clinically insignificant, but more commonly it is generalized. Muscular arteries may develop focal or segmental lesions and these may be life threatening. Focal lesions, affecting part of the vessel wall, may lead to aneurysm formation and possible vessel rupture; segmental lesions (affecting the whole circumference) are more common and lead to stenosis or occlusion with distal infarction. The classification of vasculitis has been an area of controversy for many years, with specific classification criteria only relatively recently introduced. The early diagnosis of vasculitis is particularly important because of the significant morbidity and mortality of untreated disease. Appropriate use of immunological tests including anti-neutrophil cytoplasmic antibodies (ANCA) has proved to be most helpful in the assessment and diagnosis of small-vessel systemic vasculitides.

Classification of vasculitis

Kussmaul and Maier[1] are generally accepted as providing the first description of 'periarteritis nodosa' when they described a patient with a systemic illness characterized by numerous nodules along the course of small muscular arteries. Earlier descriptions suggest that the formal recording of this condition is at least 200 years old (reviewed by Matteson[2]).

Zeek[3] reviewed the literature relating to vasculitis and periarteritis nodosa and used the generic term 'necrotizing angiitis' to indicate the specific damage to the blood vessel wall rather than the presence of inflammation alone; she classified these into five distinct entities: (1) hypersensitivity angiitis, (2) allergic granulomatous angiitis, (3) rheumatic arteritis, (4) periarteritis nodosa, and (5) temporal arteritis. Most modern classifications are based on Zeek's work, which essentially combined histological changes and clinical features. Notable omissions from Zeek's classification were Wegener's granulomatosis (WG), microscopic polyangiitis (MPA), and Takayasu's arteritis (TA). Microscopic polyangiitis (originally called microscopic polyarteritis) had been described by Davson[4] in 1948, but was not generally recognized until the 1990s following the description of its association with ANCA. WG, now renamed granulomatosis with polyangiitis (GPA),[5] and TA were not fully recognized in the English literature until after 1953.

The most widely accepted classification systems are still based on Zeek's original groupings, which reflect dominant vessel size but also an association with ANCA. There is considerable overlap in the size of vessels involved so it is important to define exactly what is meant by large-vessel, medium-vessel, and small-vessel vasculitis. This is reflected by the legend of Figure 130.1 which stresses 'more often' for large-vessel vasculitis and 'predominantly' for medium- and small-vessel vasculitis definitions. The most current classification system (Table 130.1 and Figure 130.2) recognizes that the small-vessel vasculitides can be differentiated by immunological testing into a group of ANCA-associated and a group of immune-complex-associated diseases. This classification also broadly reflects the therapeutic approaches that are applied to the different groups (Table 130.2). The small-vessel group associated with ANCA respond well to immunosuppression with cyclophosphamide and corticosteroids (and more recently to rituximab), whereas the large-vessel group require moderate to high-dose steroids and the small-vessel group associated with immune complexes usually require low-dose corticosteroids. Also, the ANCA-associated small-vessel group are those most likely to develop glomerulonephritis and renal failure. The medium-sized vessel group are not associated with ANCA and may respond to anti-viral therapy and plasma exchange (hepatitis B PAN) or intravenous immunoglobulin with or without corticosteroids (Kawaski). Biological drugs are being used with increasing frequency in these diseases and B-cell depletion using rituximab may be particularly helpful for early treatment of the ANCA-associated (replacing cyclophosphamide)[6] and some immune-complex-associated small-vessel diseases.

American College of Rheumatology (1990) criteria

In 1990 the American College of Rheumatology (ACR) proposed criteria for the classification of seven different vasculitides—giant cell arteritis (GCA), TA, granulomatosis with polyangiitis (Wegener's granulomatosis; GPA), eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome; EGPA), polyarteritis

Large Vessel Vasculitis   **Medium Vessel Vasculitis**   **Small Vessel Vasculitis**

Vasculitis affecting large arteries more often than other vasculitides. Large arteries are the aorta and its major branches. Any size artery may be affected.

Necrotizing arteritis predominantly affecting medium-sized arteries defined as the main visceral arteries and their branches. Inflammatory aneurysms are common.

Vasculitis predominantly affecting small vessels, defined as small intraparenchymal arteries, arterioles, capillaries and venules. Medium sized arteries and veins may be affected.

Fig. 130.1 Definitions of vessel size for classification of vasculitis.

Table 130.1 Classification of the vasculitides by vessel size

Dominant vessel	Idiopathic (primary)	Probable aetiology (secondary)
Large	Takayasu	Syphilis
	Giant cell arteritis	Tuberculosis
		Aortitis—RA, AS
Medium	Polyarteritis nodosa (classical)	HBV associated polyarteritis nodosa
	Kawasaki's disease	
Small		
ANCA	Microscopic polyangiitis	Drugs (propylthiouracil, hydralazine)[a]
	Granulomatosis with polyangiitis	
	Eosinophilic granulomatosis with polyangiitis	
Immune complex	Anti-GBM disease	Cryoglobulinaemic (HCV)
	Cryoglobuinaemic vasculitis (non-HCV)	RA, SLE, Sjögren's syndrome
	IgA vasculitis	Serum sickness
	Hypocomplementaemic vasculitis	Drug induced[b]
Variable	Behçet's	
	Cogan's	

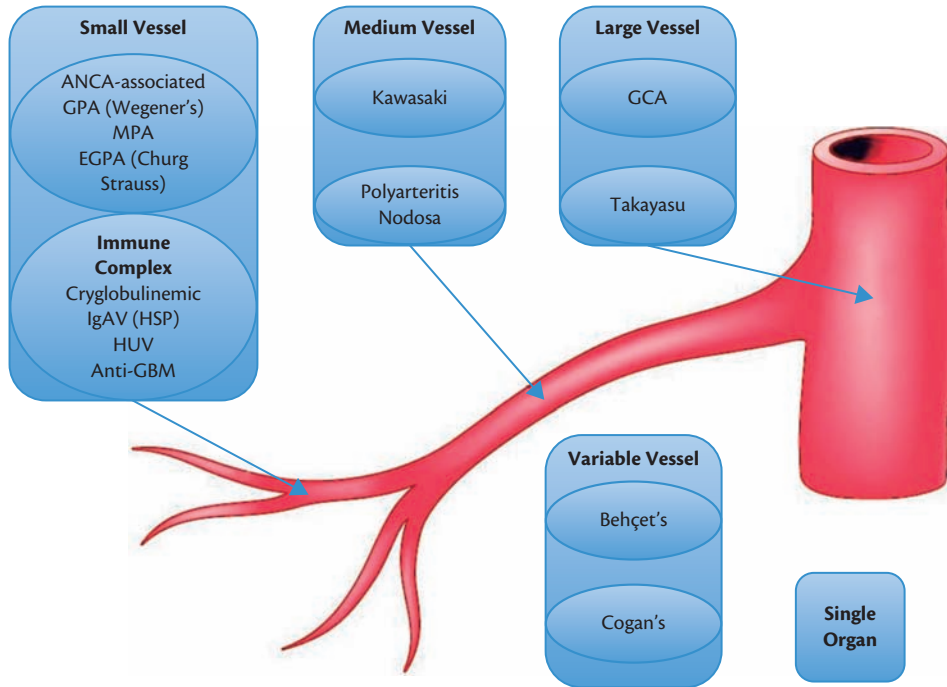
AS, ankylosing spondylitis; HBV, hepatitis B virus; HCV, hepatitis C virus; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus.
[a]Most commonly induce MPO-ANCA.
[b]E.g. sulfonamides, penicillins, thiazide diuretics and many others.


Fig. 130.2 Classification of vasculitis by vessel size.

Table 130.2 Relationship between vessel size and response to induction treatment

Dominant vessel	Corticosteroids alone	Cyclophosphamide and corticosteroids	Rituximab	Other treatments
Large arteries	+++	−	−	+
Medium arteries	+	++	−	++[a]
Small vessel (ANCA-associated)	+	+++	+++	+
Small vessel (immune complex)	++	+/−	+	++[a]

[a]Includes plasmapheresis, anti-viral therapy for hepatitis B-associated PAN and HCV-associated cryoglobulinaemia, and IVIg for Kawasaki disease.

nodosa (PAN), IgA vasculitis (Henoch–Schönlein purpura; IgAV), hypersensitivity vasculitis (HSV)—with sensitivities varying from 71.0% to 95.3% and specificities of 78.7–99.7%.[7–16] The most sensitive and specific criteria were found in EGPA, GCA, and TA; hypersensitivity (leucocytoclastic) vasculitis was the least well-defined condition. This development was important because it allowed epidemiological and clinical studies to be performed using established criteria. The ACR criteria have a number of drawbacks. The criteria were developed before the widespread introduction of ANCA testing, which now plays a key role in the diagnosis of many patients with GPA, MPA, EGPA (and also in PAN, because of its absence). In some circumstances ANCA may be used in place of tissue biopsy. The criteria also do not include MPA, which was not a term in common use during the 1980s. The criteria were established by comparing the clinical features of patients with established vasculitis, and identifying those features that contrasted between the different types of vasculitis. They were not established in an unselected group prior to the diagnosis of vasculitis or with other systemic diseases such as systemic lupus erythematosus (SLE) or other connective tissue diseases. The reliability of these criteria when used in patients in whom vasculitis is suspected but not yet diagnosed is poor.[17,18] However, it is important to stress that they were designed as classification criteria and not diagnostic criteria.

Chapel Hill Consensus definitions

In 1994, the Chapel Hill Consensus Conference (CHCC) produced definitions for vasculitis.[19] These included MPA, but they were not intended as either classification or diagnostic criteria. They recognized that histological data would not be available for all patients, especially when the clinical condition of the patient might preclude obtaining appropriate biopsies or the sample might not be representative and miss salient histological features. The concept of surrogate markers of vasculitis was therefore introduced. In addition, the importance of ANCA in diagnosis was recognized. However, neither surrogate markers nor ANCA were included in the definitions.

The CHCC definitions have recently been modified following an international consensus meeting held in 2011 to reflect changes in our understanding of the aetiopathogenesis of vasculitis.[20] A new tree hierarchy was developed which recognized that some conditions cannot be simply classified by vessel size (Table 130.3). ANCA-associated vasculitis (AAV) was recognized as a specific type of small-vessel vasculitis along with immune-complex-mediated vasculitis. The hierarchy was expanded to include vasculitis affecting vessels of variable size, single-organ vasculitis, and vasculitis associated with either systemic disease or specific aetiologies. A new nomenclature was adopted, with a move away from eponyms towards names reflecting pathology or aetiopathogenesis following the introduction of the term GPA for WG. The name 'eosinophilic granulomatosis with polyangiitis' (EGPA) was adopted for

Table 130.3 Revised Chapel Hill definitions

Name	Definition
Large-vessel vasculitis	Vasculitis affecting large arteries more often than other vasculitides. Large arteries are the aorta and its major branches. Any size artery may be affected
Takayasu's arteritis	Arteritis, often granulomatous, predominantly affecting the aorta and/or its major branches. Onset usually in patients <50 years
Giant cell arteritis	Arteritis, often granulomatous, usually affecting the aorta and/or its major branches, with a predilection for the branches of the carotid artery. Often involves the temporal artery. Onset usually in patients >50 years and often associated with polymyalgia rheumatica
Medium-vessel vasculitis	Vasculitis predominantly affecting medium-sized arteries defined as the main visceral arteries and their branches. Any size artery may be affected. Inflammatory aneurysms and stenoses are common
Polyarteritis nodosa	Necrotizing arteritis of medium-sized or small arteries without glomerulonephritis or vasculitis in arterioles, capillaries, or venules; and not associated with ANCA
Kawasaki's disease	Arteritis associated with the mucocutaneous lymph node syndrome and predominantly affecting medium-sized and small arteries. Coronary arteries are often involved. Aorta and large arteries may be involved. Usually occurs in infants and young children
Small-vessel vasculitis	Vasculitis predominantly affecting small vessels, defined as small intraparenchymal arteries, arterioles, capillaries and venules. Medium-sized arteries and veins may be affected
ANCA-associated vasculitis	Necrotizing vasculitis, with few or no immune deposits, predominantly affecting small vessels (i.e. capillaries, venules, arterioles and small arteries), associated with MPO-ANCA or PR3-ANCA. Not all patients have ANCA. Add a prefix indicating ANCA reactivity, e.g. PR3-ANCA, MPO-ANCA, ANCA-negative
Microscopic polyangiitis	Necrotizing vasculitis, with few or no immune deposits, predominantly affecting small vessels (i.e. capillaries, venules, or arterioles). Necrotizing arteritis involving small and medium-sized arteries may be present. Necrotizing glomerulonephritis is very common. Pulmonary capillaritis often occurs. Granulomatous inflammation is absent
Granulomatosis with polyangiitis (Wegener's)	Necrotizing granulomatous inflammation usually involving the upper and lower respiratory tract, and necrotizing vasculitis affecting predominantly small to medium-sized vessels (e.g., capillaries, venules, arterioles, arteries and veins). Necrotizing glomerulonephritis is common
Eosinophilic granulomatosis with polyangiitis (Churg–Strauss)	Eosinophil-rich and necrotizing granulomatous inflammation often involving the respiratory tract, and necrotizing vasculitis predominantly affecting small to medium-sized vessels, and associated with asthma and eosinophilia. ANCA is most frequent when glomerulonephritis is present
Immune complex small-vessel vasculitis	Vasculitis with moderate to marked vessel wall deposits of immunoglobulin and/or complement components predominantly affecting small vessels (i.e. capillaries, venules, arterioles and small arteries). Glomerulonephritis is frequent
Anti-GBM disease	Vasculitis affecting glomerular capillaries, pulmonary capillaries, or both, with basement membrane deposition of anti-basement membrane autoantibodies. Lung involvement causes pulmonary haemorrhage, and renal involvement causes glomerulonephritis with necrosis and crescents
Cryoglobulinaemic vasculitis	Vasculitis with cryoglobulin immune deposits affecting small vessels (predominantly capillaries, venules, or arterioles) and associated with cryoglobulins in serum. Skin and glomeruli are often involved
IgA vasculitis (Henoch–Schönlein)	Vasculitis, with IgA1-dominant immune deposits, affecting small vessels (predominantly capillaries, venules, or arterioles). Often involves skin and gut, and frequently causes arthritis. Glomerulonephritis indistinguishable from IgA nephropathy may occur
Hypocomplementaemic urticarial vasculitis (anti-C1q vasculitis)	Vasculitis accompanied by urticaria and hypocomplementemia affecting small vessels (i.e. capillaries, venules, or arterioles), and associated with anti-C1q antibodies. Glomerulonephritis, arthritis, obstructive pulmonary disease, and ocular inflammation are common.
Variable-vessel vasculitis	Vasculitis with no predominant type of vessel involved that can affect vessels of any size (small, medium, and large) and type (arteries, veins, and capillaries)
Behçet's disease	Vasculitis occurring in patients with Behçet's disease that can affect arteries or veins. Behçet's disease is characterized by recurrent oral and/or genital aphthous ulcers accompanied by cutaneous, ocular, articular, gastrointestinal, and/or central nervous system inflammatory lesions. Small-vessel vasculitis, thromboangiitis, thrombosis, arteritis and arterial aneurysms may occur

(Continued)

Table 130.3 (Continued)

Name	Definition
Cogan's syndrome	Vasculitis occurring in patients with Cogan's syndrome. Cogan's syndrome is characterized by ocular inflammatory lesions, including interstitial keratitis, uveitis, and episcleritis, and inner ear disease, including sensorineural hearing loss and vestibular dysfunction. Vasculitic manifestations may include arteritis (affecting small, medium or large arteries), aortitis, aortic aneurysms, and aortic and mitral valvulitis
Single-organ vasculitis	Vasculitis in arteries or veins of any size in a single organ that has no features that indicate that it is a limited expression of a systemic vasculitis. The involved organ and vessel type should be included in the name (e.g. cutaneous SVV, testicular arteritis, central nervous system vasculitis). Vasculitis distribution may be unifocal or multifocal (diffuse) within an organ. Some patients originally diagnosed with SOV will develop additional disease manifestations that warrant re-defining the case as one of the systemic vasculitides (e.g. cutaneous arteritis later becoming systemic polyarteritis nodosa, etc.)
Vasculitis associated with systemic disease	Vasculitis that is associated with and may be secondary to (caused by) a systemic disease. The name (diagnosis) should have a prefix term specifying the systemic disease (e.g. rheumatoid vasculitis, lupus vasculitis, etc.)
Vasculitis associated with probable aetiology	Vasculitis that is associated with a probable specific aetiology. The name (diagnosis) should have a prefix term specifying the association (e.g. hydralazine-associated microscopic polyangiitis, hepatitis B virus-associated vasculitis, hepatitis C virus-associated cryoglobulinemic vasculitis, etc.)

From Jennette et al.,[20] with permission.

Churg–Strauss syndrome and 'IgA vasculitis' (IgAV) for Henoch–Schönlein purpura. Definitions were developed for new categories of conditions including single-organ vasculitis, vasculitis associated with specific aetiologies including systemic disease (RA, SLE) and aetiologies such as infection (cryoglobulinaemia, hepatitis B and C), or drugs (e.g. propylthiouracil) (Table 130.3).

EMEA algorithm for classification of ANCA-associated vasculitis

In order to address the issues of lack of compatibility between the ACR (1990) criteria and the 1994 CHCC definitions for AAV and PAN; a consensus method of applying the two systems to facilitate epidemiology studies has been developed.[21] An algorithm was developed incorporating the key features of both systems. It is important to recognize that the algorithm was developed and validated for epidemiological studies rather than for clinical trials,[22] and its use in the latter setting requires validation. It also requires reassessment in light of the changes to the CHCC definitions made in 2011.

Polyarteritis nodosa and microscopic polyangiitis

One of the main problems with the ACR criteria is that they do not include MPA and consequently the ability to distinguish between PAN and MPA is poor. Henegar and colleagues recently conducted a detailed study of 949 patients with systemic vasculitis in the French Vasculitis Study Group database with the aim of developing better criteria for PAN.[23] They introduced the concept of negative predictive parameters in addition to positive ones. Of the original 10 ACR criteria they retained only 3 (hepatitis B virus antigen, arteriographic abnormalities, and polyneuropathy). They introduced 5 negative criteria including negative indirect immunofluorescence detection of ANCA. These criteria had 70.6% sensitivity against all vasculitis controls with 92.3% specificity. When compared against MPA there was 89.7% sensitivity and 83.1% specificity. The discriminant ability of this set of items performs better than the ACR (1990) criteria in all settings. These criteria remain to be validated as diagnostic criteria.

EULAR/PReS criteria for childhood vasculitis

A EULAR/PReS working group has recently developed classification criteria for childhood vasculitis (see Chapter 136) using a Delphi technique.[24] There was agreement to classify childhood vasculitis according to vessel size, with small-vessel diseases subdivided into granulomatous and non-granulomatous. Classification criteria were developed for IgAV (Henoch–Schönlein purpura), Kawasaki's disease (KD), childhood PAN, GPA, and TA. These criteria have not yet been validated.

In conclusion, the classification of vasculitis both for studies and for diagnostic purposes remains a considerable challenge. The new CHCC definitions are a useful step forward, but the development of validated criteria for both classification and diagnosis is urgently needed.[25]

Diagnosis of vasculitis

The diagnosis of vasculitis is often difficult, especially in early disease because of the heterogeneity of presentation and organ involvement. There are no diagnostic criteria, but classification criteria designed to differentiate one vasculitis from another rather than making the diagnosis. Vasculitis is an important diagnosis because of the potential consequences of untreated disease. The spectrum ranges from a minor rash to life-threatening systemic disease and vasculitis needs to be considered within the differential diagnosis of any multisystem disorder. Particularly severe consequences of vasculitis which must be avoided where possible include blindness or stroke in patients with GCA; renal failure leading to dialysis and possible death, especially in AAV; heart disease with coronary aneurysm formation in patients with KD prior to effective treatment. Granulomatosis with polyangiitis (Wegener's) historically had a very poor prognosis with a life expectancy of only 5 months from diagnosis in patients with renal involvement.[26] This was prior to the introduction of immunosuppressive treatment with cyclophosphamide and corticosteroids which have dramatically improved the outlook to a mortality of 11% at 1 year.[27] Early diagnosis and early treatment are therefore essential.

Vasculitis can affect the whole age spectrum from infancy (KD) through to the very elderly (age >90 years). Age has a very clear influence on the clinical phenotype. KD is entirely a disease of infancy occurring chiefly in children aged less than 2 years and very rarely after 5 years of age. IgAV (Henoch–Schönlein purpura) is mainly a disease of childhood and adolescence, but occurs infrequently in adults. At the other end of the spectrum GCA is uncommon before the age of 60 years but there is a rapid increase in age specific incidence peaking in those aged over 80 years. The AAV can occur at all ages but are most common in those aged 65–75 years.[28]

Increased diagnostic awareness over the past two decades especially has been associated with increased recognition of most vasculitides. This is particularly true for the AAV where introduction of ANCA testing in the 1980s greatly increased the recognition of the disease and decreased the diagnostic delay from 17 to 4 months.[29] Diagnostic delay is still a major problem, however, particularly for the rarer conditions. In GCA widespread recognition of the importance of quick introduction of glucocorticoid therapy in patients presenting with new-onset headache has reduced the risk of visual loss.[30]

A number of other diseases can mimic systemic vasculitis (Table 130.4). These mimics usually present with multiorgan illness or evidence of vascular damage or a combination of both. Simple blood tests such as the acute-phase response—erythrocyte sedimentation rate (ESR), C-reactive protein (CRP)—can be misleading as they may be elevated as a consequence of tissue damage rather than an underlying inflammatory process; tissue biopsy is still essential to identify non-inflammatory vascular changes such as embolism or thrombosis. Angiography shows aneurysms typically in PAN, but they have also been described in patients with atrial myxoma and subacute bacterial endocarditis.

A careful drug history is important, as many drugs have been associated with vasculitis. Most of these drugs have been described as causing a small-vessel vasculitis in the skin. Propylthiouracil and hydrallazine are associated with development of a systemic small vasculitis and the presence of MPO-ANCA. It is likely in these cases that the drugs act as a trigger for the vasculitis and withdrawal of the drugs may be sufficient to suppress the disease.[31] These patients may also require conventional immunosuppressive treatment, especially if there is significant organ- or life-threatening disease.

There are six essential components for making a diagnosis of vasculitis:

1. recognition that the patient might have vasculitis
2. a compatible clinical phenotype
3. consistent serology (e.g. ANCA) or radiology (e.g. angiography)
4. confirmation by histology
5. exclusion of mimics and secondary causes of vasculitis (see Table 130.4)
6. the increased certainty of diagnosis with time.

Presenting symptoms and signs

Presentation is often non-specific with features including low-grade fever, weight loss, and malaise which may last several months. Where the prodromal phase is short, reactive vasculitis such as IgAV (Henoch–Schönlein purpura) or a secondary vasculitis is more likely. Constitutional symptoms vary in intensity and may

not be present in patients with organ-limited disease (e.g. cutaneous PAN). Kidney involvement can also present with relatively few systemic symptoms or signs, stressing the importance in all patients of repeated urinalysis for protein and blood.

Because of the widespread and different organ involvement in the various diseases, the clue to diagnosis is often the combination of involvement of one or more organs together with compatible blood tests. For example, the combination of proteinuria/haematuria with arthralgia and weight loss will make vasculitis particularly likely if accompanied by any one of the following: skin lesions such as purpura; chronic or persistent ENT symptoms such as nose bleeds/crusting; eye inflammation, particularly iritis/scleritis; neuropathy, particularly an acute motor neuropathy.

The range of organ involvement and the range of symptoms and signs is variable. Suggestive involvement of the skin includes palpable purpura, deep cutaneous ulcers in unusual sites, and skin infarction; ENT symptoms include epistaxis, crusting, sinusitis, and acute deafness; respiratory symptoms include non-productive

cough, haemoptysis, shortness of breath, and wheezing; neurological symptoms range from mild sensory to widespread motor neuropathy, but the acuteness of onset is more indicative of an underlying vasculitis; gastrointestinal symptoms are often non-specific but include mouth ulcers, bloody diarrhoea, and non-specific abdominal pain. Although cardiac involvement is not uncommon, symptoms are usually non-specific such as chest pain and palpitations associated with arrhythmia. An acutely painful red eye suggesting iritis or scleritis associated with a multiorgan disease is also an important combination often indicating vasculitis. In patients with suspected larger-vessel vasculitis (TA or GCA) pulses should be assessed in four limbs together with blood pressure. Absence of pulses or differential blood pressure between limbs is suggestive of vasculitis.

An assessment tool developed for clinical trials in vasculitis is the Birmingham Vasculitis Score (BVAS). This is a useful aide mémoire for assessing patients with vasculitis and the detailed different organ involvement provide a useful reminder of the widespread nature of vasculitis and the more likely symptoms and signs associated with it. For large-vessel vasculitis, jaw claudication, visual disturbance, and temporal artery tenderness are particularly important features of GCA whereas for TA the absence of peripheral pulses or bruits over large arteries and tenderness over large arteries, particularly the carotid artery, are useful clinical findings.

Laboratory investigations

These may be divided into screening investigations of non-specific nature indicating inflammation, tests to identify specific organ involvement, and diagnostic investigations including serology (Box 130.1).

A patient with suspected systemic vasculitis should be assessed urgently, as the prognosis may be adversely affected by diagnostic delay. Renal involvement should be assessed with urinalysis as the presence of blood and protein with casts is indicative of glomerulonephritis. A poor long-term prognosis is associated with a raised serum creatinine at diagnosis.[27]

The non-specific investigations can sometimes provide useful clues to diagnosis. A full blood count will often reveal anaemia and in some cases this can be severe due to blood loss. If the white cell count reveals significant eosinophilia, the most likely diagnosis is EGPA (Churg–Strauss syndrome) or a drug reaction. A mild eosinophilia can be a feature of GPA (Wegener's). Leucopenia is unusual in systemic vasculitis and more likely to represent either severe sepsis or autoimmune diseases such as SLE, but has recently been described in vasculitis induced by levamisole-contaminated cocaine.[32] The acute-phase response (ESR and CRP) is almost always high in all types of vasculitis. Serum creatinine/eGFR are important screening tests but it is important to remember that significant renal impairment has to occur before there is a major change in these. Severe abnormalities of liver function is seen particularly in patients with hepatitis B or C associated disease but mild changes in the alkaline phosphatase or gamma-glutamyl transferase frequently just indicate low-grade inflammation. A thrombophilia screen is important to look for mimics such as a thrombotic tendency and plasma protein electrophoresis for systemic diseases such as myeloproliferative disorders.

Serology

ANCA testing is a vital part of vasculitis assessment, being associated particularly with a group of small-vessel vasculitides—GPA,

---

Box 130.1 Investigation of suspected vasculitis

General

- FBC anaemia, leucocytosis, eosinophils (eosinophilia suggestive of EGPA)
- Acute-phase response (ESR and CRP)
- Liver function

Assessment of organ involvement in all patients

- Urinalysis (proteinuria, haematuria, red cell casts), should be performed urgently in all patients in whom systemic vasculitis is suspected
- Renal function (creatinine clearance, quantification of protein leak if present using either 24 hour protein excretion or urine protein/creatinine ratio).
- CXR may show infiltrates, haemorrhage, granuloma (especially GPA, EGPA, MPA).
- Liver function.

Where appropriate

- Nervous system (nerve conduction studies in all four limbs, biopsy)
- Cardiac function (ECG, echocardiography)
- Gut (coeliac axis angiography)
- Biopsy of an affected organ should be obtained where possible to confirm diagnosis prior to treatment

Serological investigations

- ANCA: A cANCA pattern on indirect immunofluorescence and PR3 by ELISA are together strongly associated with GPA(>90%). pANCA and MPO is suggestive of MPA or EGPA. Both indirect immunofluorescence and ELISA for PR3/MPO should be performed in all patients
- ANA: ENA profile if positive ANA
- RF (may be positive in cryoglobulinaemic vasculitis or systemic rheumatoid vasculitis)
- Anti-cardiolipin antibodies (usually negative, but if positive consider anti-phospholipid syndrome and B2GPI antibodies).
- Complement (C3, C4 low in cryoglobulinaemic vasculitis)
- Cryoglobulins (suggestive of cryoglobulinaemic vasculitis)

Differential diagnosis

This is from vasculitis mimics (e.g. malignancy, cholesterol embolism, atrial myxoma, calciphylaxis—see Table 130.4) or infection (especially subacute bacterial endocarditis).

- Blood cultures
- Viral serology (HBV, HCV, HIV, CMV)
- Echocardiography (two-dimensional and/or transoesophageal)

ANA, anti-nuclear antibodies; ANCA, anti-neutrophil cytoplasmic antibodies; CMV, cytomegalovirus; CRP, C-reactive protein; CXR, chest radiograph; EGPA, eosinophilic granulomatosis with polyangiitis; ENA, extractable nuclear antigens; ESR, erythrocyte sedimentation rate; GPA, granulomatosis with polyangiitis; HBV, hepatitis B virus; HCV, hepatitis C virus; MPA, microscopic polyangiitis; RF, rheumatoid factor.

MPA, and EGPA. A negative ANCA is an important feature of classical PAN. ANCA testing needs to be undertaken carefully as non-specific ANCA staining on immunofluorescence can be associated with a range of systemic illnesses including infection and inflammatory bowel disease. Screening is frequently undertaken by immunofluorescence; with cytoplasmic staining being associated with proteinase-3 (PR3) specificity and GPA, and perinuclear staining with myeloperoxidase specificity and MPA and EGPA. However, reliance on indirect immunofluorescence (IIF) pattern alone is insufficient for diagnosis as this is less specific and ELISA testing for PR3 and myeloperoxidase (MPO) specificity is essential in all cases.[33] The combination of cANCA and PR3 is has a specificity of 90% for GPA and pANCA-MPO 75% for MPA.[34] ANCA titres may be influenced by treatment and ANCA can be negative in early mild or limited disease, particularly GPA. Other autoantibodies are also important for diagnosis. The presence of anti-nuclear antibodies (ANA) and DNA antibodies are highly suggestive of SLE, and specific ENA antibodies such as anti-Ro and -La are associated with Sjögren's syndrome as well as SLE. Rheumatoid factor is frequently present in low titre but anti-CCP antibodies are more specific for RA and likely to indicate the vasculitis being associated with RA. Complement levels (C3 and C4) are usually elevated in patients with systemic vasculitis as part of an acute inflammatory response: low levels usually indicate immune complex vasculitides (Table 130.1) such as SLE, hypocomplementaemic urticarial vasculitis, and cryoglobulinaemic vasculitis. Anti-cardiolipin antibodies are associated with the anti-phospholipid antibody syndrome—a mimic of systemic vasculitis causing skin or digital infarction as a consequence of thrombosis. Cryoglobulins are most frequently seen in cryoglobulinaemic vasculitis (often associated with hepatitis C infection) but low levels of cryoglobulins are not uncommon in other systemic vasculitides.

Organ-specific investigations

Assessment of kidney function such as eGFR, urinalysis, and urine protein excretion are important to identify that the kidney is involved and the function of the kidney. However, the most useful tissue for diagnostic assessment and prognosis is renal biopsy, particularly in the AAV. The characteristic change in AAV is a focal segmental necrotizing glomerulonephritis but the presence of crescents indicates more severe disease and the present of significant scarring reflects more chronic disease associated with a worse prognosis. Any significant organ involvement should trigger a specialist review which itself is an important part of investigation. Chest radiography may reveal a wide range of features; for example, nodules/fixed infiltrates in GPA, flitting shadowing in EGPA, and widespread changes indicating pulmonary haemorrhage in MPA. CT, bronchoscopy, and lung biopsy may be considered in some cases, again alongside specialist review. Orbital assessment is now highly specialized and investigations include orbital CT and MRI scanning. Subtle nerve involvement may only be detected by nerve conduction studies; nerve biopsy (sural and radial) are useful diagnostic tests if other tissue is not available for biopsy. The widespread nature of neurological involvement may require cerebrospinal fluid (CSF) examination, cerebral MRI and angiography (especially for isolated central nervous system vasculitis). Cardiac assessment includes ECG, echocardiography, and in some cases specialist cardiac MRI scanning and coronary angiography.

Investigations are also essential to exclude vasculitis mimics and secondary vasculitis. These include blood culture, viral screen, and echocardiography (to exclude rarities such as atrial myxoma and bacterial endocarditis as well as assessing possible cardiac involvement).

Coeliac axis and mesenteric angiography may be needed to diagnose PAN. The extent of large-vessel involvement in TA and GCA should be assessed using MR angiography; this enables assessment of inflammation as well the anatomical extent. Patients presenting with multisystem illness with no histological evidence in whom malignancy is suspected may be investigated by [18]FDG-PET scan. This is useful for demonstrating inflammation of large vessels in GCA and TA. Temporal artery biopsy is still the most useful diagnostic test for GCA; however, this must be performed within 10 days of the introduction of high-dose glucocorticoids, beyond this time the rate of positive biopsies decreases.

Conclusion

The diagnosis of systemic vasculitis depends on the presence of a pattern of supportive clinical features, supported by specific investigations (serology, radiology, etc.) and almost always confirmed by biopsy. It is also important to exclude other causes, particularly mimics of vasculitis and 'secondary' causes for vasculitis. Investigations can be inconclusive and vasculitis may be suspected and under these circumstances observation over time with repeat investigations and possibly a therapeutic trial of immunosuppressive drugs including corticosteroids. There are no current diagnostic (as opposed to classification) criteria. The development of diagnostic criteria is eagerly awaited and the evolution of Chapel Hill 1994 to Chapel Hill 2012 with updated definitions and descriptions of vasculitis have helped improve our understanding and classification of the different vasculitic diseases.

Clinical features of ANCA-associated vasculitis

Wolfgang L. Gross and Julia U. Holle

Definitions, classification criteria, disease stages, and epidemiology

The vasculitides are categorized according to the 1990 classification criteria of the American College of Rheumatology (ACR) and the 1994 Chapel Hill Consensus Definition (CCHD), which have recently (2012) been revised (Table 131.1).[1–4] The common feature of all ANCA-associated vasculitides (AAV) is small- to medium-size vessel vasculitis. Granulomatosis with polyangiitis (GPA, Wegener's) and eosinophilic granulomatosis with polyangiitis (EGPA, Churg–Strauss syndrome) are characterized by additional clinical and histological findings such as granulomatous lesions of the upper and/or lower respiratory tract in GPA and asthma, hypereosinophilia, and eosinophilic organ infiltration in EGPA. Recently, a four-step algorithm has been developed to distinguish between the vasculitides on the basis of the ACR criteria, the Chapel Hill Consensus Conference Criteria (CHCC) definitions, and the Lanham criteria for EGPA/CSS (Figure 131.1).[5] Importantly, these classification criteria and consensus definitions do not represent diagnostic criteria although they are often used as such in clinical practice. Yet, classification criteria and disease definitions should only be applied if the diagnosis of vasculitis is already established, to distinguish between the distinct forms. Diagnostic criteria in vasculitides are currently being developed.

The overall incidence of AAV is estimated at 10–20 million per year and the peak onset is from 65 to 74 years.[6] Most of the studies report stable incidence rates for the AAV over the past two decades (e.g. in the United Kingdom and Germany).[6] Incidence rates of 2.95–12 per million per year have been reported for GPA in Europe with lower rates in southern Europe (e.g. 2.95 per million per year in Spain[6]) compared to central and northern Europe (United Kingdom, Germany, and Norway[6]). In contrast, incidence rates of MPA are higher in Spain (11.6 per million per year) compared to other European countries (2.6–5.8 per million per year in Germany, Norway, and the United Kingdom).[6] Interestingly, a similar overall incidence rate was reported for GPA/MPA in Japan and the United Kingdom, but in Japan MPA was the predominant entity (83%) whereas GPA is more frequent in the United Kingdom (66%).[6] These findings suggest that GPA and MPA are genetically different diseases and linked to different ethnic backgrounds. EGPA

is generally rarer than the other AAV with an incidence of 1.0–3.0 per million per year.[6]

The AAV, particularly GPA, follow a stagewise course which has been formally defined by the European Vasculitis Study Group (EUVAS) in order to facilitate clinical studies and develop evidence-based treatment regimens for the different disease stages(Table 131.2).[7] Disease manifestations are restricted to the upper and lower respiratory tract in the localized disease stage. Importantly, there are no clinical signs of vasculitis and no constitutional symptoms in this stage. Typical initial nasal manifestations are bloody nasal discharge and crusting. Localized disease in GPA may be complicated by granulomatous inflammation and mass formation in sinuses, orbit and lungs (see below) which can lead to destruction of cartilage and bony structures.[8] Early systemic disease is defined as non-organ-threatening or life-threatening vasculitis and is characterized by manifestations such as episcleritis or purpura; the generalized stage corresponds to full-blown disease with organ-threatening vasculitis manifestations (e.g. crescentic necrotizing glomerulonephritis, pulmonary capillaritis). Acute organ failure is consistent with the severe disease stage (e.g. creatinine >500 μmol/litre).[7]

Organ manifestations of the AAV can be categorized according to disease extent index (DEI),[9] which is widely used in clinical practice to give an overview of organs involved. Disease activity and chronic organ damage induced by vasculitis or its treatment can be determined by validated scoring instruments such as the Birmingham Vasculitis Activity Score (BVAS) and the Vasculitis Damage index (VDI), respectively.[10–12]

Pathogenesis

Environmental and genetic risk factors

Occupational exposures such as to silica from specific farming tasks related to harvesting have been suggested to be associated with AAV in case-control studies,[13] but the data is controversial.[14] Furthermore, drugs have been implicated in the induction of ANCA and AAV (see below).

Anti-asthmatic medications such as leukotriene receptor antagonists, inhaled glucocorticoids such as fluticasone, inhaled β_2-mimetics such as salmeterole and omalizumab and other drugs such

Table 131.1 American College of Rheumatology (ACR) classification criteria and Chapel Hill Consensus Conference Criteria (CHCC) definitions of ANCA-associated vasculitides

	American College of Rheumatology criteria	**Chapel Hill Consensus Conference criteria (2012)**
Granulomatosis with polyangiitis (Wegener's)	Nasal or oral inflammation Abnormal chest radiograph: nodules, fixed infiltrates, or cavities Abnormal urinary sediment: microhaematuria/red cell casts Granulomatous inflammation on biopsy *At least 2 of 4 criteria must be present*	Necrotizing granulomatous inflammation usually involving upper and lower respiratory tract, and necrotizing vasculitis affecting predominantly small to medium vessels (e.g. capillaries, arterioles, arteries and veins). *Necrotizing glomerulonephritis is common*
Microscopic polyangiitis	No criteria	Necrotizing vasculitis with few or no immune-deposits, predominantly affecting small vessels (i.e. capillaries, venules, or arterioles). Necrotizing arteritis involving small and medium arteries may be present. *Necrotizing glomerulonephritis is very common, pulmonary capillaritis often occurs*
Eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome)	Asthma Blood eosinophilia (>10% on white cell count) Mono- or polyneuropathy Pulmonary infiltrates, non-fixed Paranasal sinus abnormality Extravascular eosinophils in biopsy *At least 4 criteria must be present*	Eosinophil-rich and necrotizing granulomatous inflammation often involving the respiratory tract, *and* Necrotizing vasculitis predominantly affecting small to medium vessels, associated with asthma and eosinophilia. *ANCA is more frequent when glomerulonephritis is present*

Criteria according to references 1–4.

as carbamazepine, macrolides, and quinine[15,16] have been suggested to be associated with the development of EGPA in asthma patients. The occurrence of EGPA in patients using anti-asthmatic medications is often associated with the tapering of glucocorticoids which then may lead to a demasking of EGPA,[16] which could explain the association seen between the use of anti-asthmatic drugs and EGPA; however, in spite of this data it cannot be excluded that these drugs may have a direct triggering role in EGPA.[16]

A first genome-wide association study (GWAS)[17] confirmed single-nucleotide polymorphisms (SNPs)/alleles of the protease inhibitor 1 (also referred to as α_1-antitrypsin) gene,[18] the *HLA-DP* allele,[19–20] as risk factors for proteinase 3 (PR3)-ANCA vasculitis/GPA. These genes had been implicated as genetic risk factors by candidate gene studies.[17] Interestingly, the genetic associations were stronger with respect to the ANCA status (PR3-ANCA) than to the clinical syndrome (GPA). Furthermore, a SNP within the *PR3* gene and a *HLA-DQ* allele was associated with PR3-ANCA vasculitis and myeloperoxidase (MPO)-ANCA vasculitis, respectively.[17] The first GWAS clearly points out that GPA and MPA are genetically distinct diseases. With respect to a possible pathophysiological relevance, deficiency of α_1-antitrypsin may lead to an increased presence of the autoantigen PR3 in the circulation and thereby contribute to the initiation of an autoimmune response against PR3. Mutations within the PR3 itself may lead to an altered (e.g. enhanced) presentation of this autoantigen to antigen-presenting cells, which may be further facilitated by certain HLA alleles. Other risk factors which had been implicated by candidate gene studies, such as the *620W* allele of *PTPN22* and *CTLA-4*,[21] were not replicated in this GWAS.[17] *PTPN22* encodes lymphoid tyrosine kinase (LYP), and the *620W* allele is associated with reduced T-cell receptor signalling and is probably related to impaired negative selection of T cells in the thymus or a reduction of regulatory T cells.[22] Only a few candidate gene studies are available for EGPA: HLA genes have been implicated as risk factors for Churg–Strass syndrome (CSS), such as *HLA DRB1, DRB3, DRB4*.[16,20] Moreover, a distinct haplotype of the *IL10* gene (IL-10.2 haplotype) has been associated with EGPA, in particular with ANCA-negative EGPA, but not with GPA,[20] which may be linked to the finding of increased serum levels of IL-10 in EGPA.

Main target antigens and induction of an adaptive immune response

PR3 and MPO are recognized as main target antigens in AAV. Immunity against PR3 is more likely to induce the phenotype of GPA[23] characterized by formation of granulomatous lesions and vasculitis. MPO-ANCA is rather associated with the phenotypes of MPA and EGPA.[24,25] Whereas induction of ANCA frequently occurs in the generalized disease stage of GPA and MPA, only around 40% of CSS patients develop ANCA.[16] The reasons for these findings are unclear. Factors that may contribute to the induction of an adaptive immune response may be an increased presence of the autoantigen itself and cofactors that may induce the activation of autoreactive immune cells, such as bacterial stimuli that provide a proinflammatory environment or function as molecular mimics, or such as drugs that may modify the autoantigen to render it immunogenic: the polymorphonuclear cells (PMNs) of GPA patients have increased percentages of membrane PR3 expression, and a higher percentage of mPR3 expression has been detected in relapsing patients compared to non-relapsing patients. Additionally, infectious stimuli functioning as triggers may contribute to an increased membrane expression of PR3 or MPO, e.g. in septic states or in bacterial endocarditis. Nasal carriage of *Staphylococcus aureus* is associated with increased relapse in GPA.[26]

In vitro, PR3 is able to raise an adaptive immune response by inducing maturation of dendritic cells and subsequent activation of Th1 cells of GPA patients but not of healthy controls.[27] Th1-type CD4+ CD28− T cells have been shown to be expanded in GPA and represent a major source of Th1-type cytokines, such as tumour necrosis factor alpha (TNFα) and interferon (INF)-γ. Therefore they have been assumed to play a role in granuloma formation. Recently, it was shown that expansion of CD4+ CD28− T cells is related to latent cytomegalovirus (CMV) infection and is associated with an increased risk of infection and mortality.[28] Moreover, stimulation of peripheral blood monocytes from GPA patients induced IL-17, suggesting that Th17 cells play a role as effector cells in GPA, as they do in many other autoimmune diseases.[29] There is also evidence for a disturbance of Fox P3-positive Tregs which have been shown to be increased during remission but are functionally deficient.[30]

LAMP-2 (lysosomal membrane protein 2) has been proposed as another ANCA target antigen, as human LAMP-2 antibodies were detected in the circulation of patients with pauci-immune glomerulonephritis, 50% of whom also had antibodies against PR3 or MPO in one study.[31] In a rat model, induction of LAMP-2 antibodies and glomerulonephritis was induced by the bacterial antigen FimH, suggesting that bacterial agents may represent molecular mimics for ANCA antigens and are capable of inducing an adaptive immune response in AAV. The significance of these findings is not clear, as LAMP-2 antibodies were not prevalent in another cohort.[32]

Drugs such as propylthiouracil (PTU), hydralazine, sulphasalazine, and cocaine have been associated with induction of ANCA and vasculitis.[33] Induction of MPO-ANCA by PTU is frequent, with a prevalence of 20–64%, but only a few patients develop PTU-induced vasculitis.[33] The mechanism of ANCA induction by drugs is not known. Modification of ANCA target antigen by the drug and/or its metabolites may render the target antigen immunogenic, as suggested for PTU.[33] Furthermore, cocaine and immunodeficiencies such as TAP-2 deficiency may play a role in inducing vasculitis-like syndromes and midline destructive lesions.

Vasculitis

In-vitro and in-vivo evidence suggests that ANCA play a central role in mediating small-vessel vasculitis. ANCA are more frequent in the systemic disease stages of GPA compared to the localized disease stage when there is no evidence of clinical vasculitis.[34] In EGPA, ANCA-positive patients have more frequently classic vasculitic manifestations such as glomerulonephritis compared to ANCA-negative patients.[25] Targeting B cells as precursors of ANCA-producing B cells is highly effective in ANCA depletion and the induction of remission in AAV.[35] ANCA induces neutrophil activation in vitro by engagement to the target antigens PR3 or MPO.[36] Animal models further support the role of ANCA in inducing vasculitis. Successful animal models have been developed using MPO for immunization which led to features of MPA in immunized immunodeficient mice.[37,38]

The induction of PR3-ANCA-associated vasculitis in rodents (as a model for GPA) has been less successful, which may be in part due to a lack of PR3 expression on the murine neutrophil surface and different Fc receptor affinities between rodents and humans.[39] Immunization of rats and mice with chimeric human/mouse PR3 induced autoantibodies to mouse PR3 and rat granulocytes, but did not cause vasculitis.[40] The injection of PR3 into PR3-deficient mice induced antibodies to mouse PR3, but passive transfer of anti-mouse PR3-antibodies did not induce vasculitis. Only after injection of TNFα into the skin of PR3-immunized mice could a local infiltrate of inflammatory cells be detected.[41] Injecting human haematopoetic stem cells into immunodeficient mice and challenging them with lipopolysaccharide (LPS) and human PR3-ANCA induced alveolar haemorrhage in all of the mice, but pauci-immune glomerulonephritis was detected in only 17% of them.[42]

No animal model of EGPA is available to date. There is a mouse model of eosinophilic skin vasculitis which is induced by an IgE-mediated cutaneous reverse passive Arthus reaction, but this model provides no evidence for systemic vasculitis, ANCA production, and extravascular granuloma.[43]

Role of granulomatous lesions in granulomatosis with polyangiitis

GPA is characterized not only by ANCA-associated small-vessel vasculitis but also by ill-defined granulomatous lesions. It has been hypothesized that GPA may be initiated within the upper and lower respiratory tract, characterized by granulomatous lesions, and progresses to ANCA-associated small-vessel vasculitis later.[44] Whether granulomatous lesions represent the place of autoantibody production remains to be proven. Within the granulomatous lesions, PR3+ cell clusters of neutrophils and monocytes, B cells

with an immunoglobulin gene repertoire with potential affinity to PR3 in lymph-follicle like aggregates, antigen-presenting cells, and Th1-type T cells have been found.[8] There is some evidence that granulomatous tissue has a destructive potential, as transplantation of inflamed human nasal mucosa into immunodeficient mice induces local invasion and destruction of human cartilage.[45]

Role of eosinophils and T cells in eosinophilic granulomatosis with polyangiitis

Severe eosinophilia (>10%) is a hallmark of EGPA. Factors contributing to eosinophilia are growth factors such as IL-3, IL-5, and granulocyte-macrophage colony-stimulating factor (GM-CSF). In particular, the increased IL-5 secretion by stimulated T cells may substantially contribute to eosinophilia as IL-5 is the most potent stimulator of eosinophil production.[46] Elevated levels of IL-5 have been demonstrated in the serum of EGPA patients,[46] and targeting IL-5 has been successful in two small open-label studies.[47,48] Furthermore, an increased level of soluble CD95 was found in sera of EGPA patients, which may be related to decreased apoptosis of CD95L-expressing eosinophils, as soluble CD95 competes with CD95L on eosinophils with their ligand CD95 49.

Eosinophils of GPA patients display an activated phenotype (CD69 +).[46] Furthermore, elevated levels of eosinophilic proteins such as eosinophilic cationic protein (ECP) have been found in the serum, tissue, and bronchoalveolar lavage (BAL) fluid of CSS patients, indicating the activation of eosinophils.[50] ECP and eotaxin-3 have been associated with active EGPA,[51] and eotaxin-3 has been reported not to be elevated in other eosinophilic conditions such as asthma and hypereosinophilic syndrome (HES).[16]

T cells have been implicated in the pathogenesis of EGPA due to increased levels of sIL2-R which is produced by activated T cells.[16] Clonal expansion of T cells has been demonstrated in EGPA,[49,52] partly displaying an effector memory phenotype. T-cell lines from EGPA patients produce both Th1 (IFN-γ) and Th2 (IL-4, IL-5, and IL-13) cytokines, with a predominance of the Th2 cytokines. Importantly, eosinophils enhance T-cell activation by producing IL-25, which has a crucial role in promoting Th2 cytokine response in T cells. IL-25 correlates with disease activity in EGPA and induces production of IL-4, IL-5, and IL-13 in peripheral blood mononuclear cells (PBMC), probably via engagement with its receptor IL-17RB on T cells; expression is increased in vasculitic lesions of EGPA.[53] Furthermore, EGPA patients display reduced regulatory T cells (CD4+ CD25+ Tr1, producing IL-10) and responder T cells (CD4+ CD25−, producing IL-2) at disease onset and relapse compared to patients with asthma and chronic eosinophilic pneumonia (CEP).[54] The proportion of IL-10- and IL-2-producing T cells increased in EGPA patients in remission, suggesting that regulatory T cells and responder T cells, and the cytokines IL-10 and IL-2, may protect from, and/or control, EGPA.

Clinical features

Clinical features of granulomatosis with polyangiitis (Table 131.3)

GPA (formerly Wegener's granulomatosis, WG) was first described by Friedrich Wegener in 1939 as 'a rhinogenic granulomatosis with distinct involvement of the blood vessel system and the kidneys'.[55] GPA has been proposed as an alternative name for WG, in order to

move away from eponyms to disease-descriptive nomenclature, but partly triggered by Wegener's political background.[56]

GPA is characterized by both granulomatous inflammation, which predominantly occurs in the upper and lower respiratory tract, and vasculitis manifestations with a predilection for kidney (crescentic glomerulonephritis) and lungs (pulmonary capillaritis). GPA is associated with ANCA which are usually directed against PR3. Around 50% of patients are ANCA-negative in the localized stage of GPA whereas more than 90% of patients with generalized disease are positive for PR3-ANCA.[23,57]

Involvement of the upper respiratory tract is the most frequent manifestation in GPA. Rhinosinusitis leading to nasal bloody discharge and crusting is a typical complaint which has been described in 75% to over 90% of patients at diagnosis and up to 99% during the disease course.[23,57] Conductive hearing loss may be induced by inflammation of the middle ear mucosa or by dysfunction of the eustachian tube as a result of mucosal involvement of the nasopharyngeal mucosa. Granulomatous inflammation, which may be associated with sinus and orbital masses (granulomatous sinusitis, orbital and pulmonary masses or granuloma), is a hallmark of localized disease.[34] Orbital mass ('granuloma') formation occurs in up to 15% of patients[58] and is characterized by proptosis and impairment of bulbus motility. It is often associated with severe pain and/or visual loss due to compression of the optic nerve. Trachea and bronchi can be affected either by ulcerating lesions or by tumorous inflammation leading to stenosis. Stenosis most frequently develops in the subglottic area (subglottic stenosis) in 12–15%.[23,58]

Granulomatous inflammation can lead to mucosal, cartilage and bony destruction causing substantial chronic damage to the ENT tract, such as sinus or orbital wall destruction, orbitonasal fistulas, nasal septal perforation, saddle nose deformity, subglottic scar formation, and optic atrophy with subsequent blindness (Figures 131.2 and 131.3) Orbital socket contracture is a complication induced by scar formation within the orbit which may occur after treatment of orbital masses.[59]
Fig. 131.2 Retraction of right orbit due to bony destruction of the orbital base and orbitonasal fistula in the corner of the eye in a patient with granulomatosis with polyangiitis.

While the localized stage is not associated with constitutional symptoms (i.e. fever, weight loss) they represent a characteristic finding of systemic disease and are present in at least one-half of patients during the disease course.[58,60] Musculoskeletal symptoms such as myalgia, arthralgia, and arthritis are also frequent in the systemic disease stages (up to 80% during the disease course).[23,57,60–63]
Fig. 131.3 Orbital mass in a patient with granulomatosis with polyangiitis. MRI, gadolinium-enhanced.

Fig. 131.4 High-resolution CT showing multiple cavitating pulmonary masses in a patient with granulomatosis with polyangiitis.

Pulmonary manifestations can be found in 60–85% of GPA patients.[57–63] Apart from granulomatous manifestations such as pulmonary nodules and masses in up to 60% of patients on chest radiograph,[58] diffuse alveolar haemorrhage (DAH) due to pulmonary capillaritis (7–45%) and neutrophil or T-lymphocytic alveolitis can occur.[23,57–64] DAH is a potentially life-threatening manifestation and its mortality is estimated at around 60%.[65] Patients frequently present with dyspnoea and a drop in haemoglobin levels due to blood loss into the alveolar space; haemoptysis is present in only 30% of patients and is there for not a reliable sign of DAH. Bleeding may be severe and cause hypovolaemic shock and the requirement for mechanical ventilation. Alveolar haemorrhage causes uni- or bilateral shadowing on chest radiographs and a ground-glass infiltrate on CT. DAH can be confirmed by fibre-optic bronchoscopy revealing diffuse bleeding arising from the pulmonary parenchyma and resulting in increasingly bloody lavage fluid during the BAL procedure. Alveolitis and pulmonary masses can be visualized by chest radiographs and/or CT (Figure 131.4). CT scanning is helpful to identify the exact diameters of masses during the disease course. Diameter greater than 3 cm and parenchymal opacification are considered to indicate active lesions.[66] Alveolitis is related to diffuse or interstitial infiltrates on radiograph and to a ground-glass pattern on CT.[64] An increased neutrophil count in the BAL fluid seems to correspond to active disease.[66]

Necrotizing glomerulonephritis is—as in MPA—the hallmark of generalized disease and is reported to develop in 38–70% of patients during the course of the disease.[23,57–63] The spectrum is variable and ranges from asymptomatic erythrocyturia to rapid progressive renal failure with oligo-/anuria. The initial renal function documented at diagnosis may predict renal survival,[61] and patients with renal involvement and/or impairment have poorer prognosis in terms of survival.[67] Around 10–20% of GPA patients develop end-stage renal disease requiring haemodialysis.[23,60–61] A renal biopsy should be performed in order to confirm renal involvement. The histological findings are indistinguishable in GPA and MPA and consist of focal necrotizing, pauci-immune glomerulonephritis with glomerular crescents.

Peripheral nervous system (PNS) involvement and eye and skin manifestations are frequent features of GPA. PNS involvement develops in 3–40%, in the form of either distal symmetric sensory or sensimotor polyneuropathy or mononeuritis multiplex.[23,57,58,63] Furthermore, a significant proportion of patients develop a chronic neuropathy without any active vasculitic process during active disease.[68] The aetiology of chronic neuropathy in AAV is unknown but is has been shown that active PNS involvement and chronic neuropathy is associated with a male predominance, age, and more severe disease (i.e. a higher BVAS and larger DEI).[68,69] Only 35% of patients with an active vasculitic neuropathy who were treated in EUVAS trials were found to have complete resolution of neuropathy within 6 months, suggesting that the chronic damage is frequent. Importantly, PNS manifestations may represent the first signs of the disease, not only in GPA but also in MPA.[68] Ocular involvement (52–61%) manifests most commonly as (epi)-scleritis and conjunctivitis.[58–62] Dacryocystitis, which may lead to obstruction of the lacrimal duct and consecutive superinfection, and orbital masses are rare but associated with serious complications (see above). Palpable purpura (30–40%) is indicative of skin involvement and corresponds to leukocytoclastic vasculitis.[23,58] Digital ischaemic lesions and necrosis may develop but are rare. Ulcers, stomatitis, and hyperplastic gingivitis (in up to 10%) are rare but typical mucosal manifestation of GPA within the oral cavity.[58]

Less common but severe manifestations of GPA are central nervous system (CNS), heart, and gastrointestinal involvement. With respect to CNS manifestations, three pathogenic mechanisms can be distinguished: invasion of granulomatous masses from sinuses/orbits into CNS structures; granulomatous manifestations originating from the CNS itself (i.e. pachymeningitis, granulomatous inflammation of the pituitary gland); and small-vessel vasculitis which also develops within the CNS and can lead to white matter

lesions.[70,71] Overall, CNS involvement occurs in 7–11% of GPA patients.[57,58,62,63,70,71] Invasion of granulomatous tissue can affect the optic nerve (by invasion of orbital masses), the cranial nerves, the meninges, or the pituitary gland. Pachymeningitis can arise primarily as a CNS manifestation and can be completely asymptomatic or manifest as severe headache. Meningismus, cranial nerve or sensimotor palsies, seizures, or encephalopathy may develop in conjunction with pachymeningitis.[70,71] Meningitis of the spinal cord can occur rarely and can lead to paraplegia. Vasculitis can be accompanied by either haemorrhage (i.e. subarachnoid haemorrhage) or ischaemia (i.e. transient ischaemic attacks, strokes, ischaemic myelopathy).[70,71] From 4% to 20% of patients are affected by symptomatic heart involvement such as coronary vasculitis and ischaemia,[57,58,62,72] granulomatous myocarditis with subsequent cardiomyopathy, pericarditis, and rarely valvulitis. Autopsies suggest that non-apparent heart involvement is much more frequent, with coronary vasculitis being present in 50%.[73] Gastrointestinal manifestations have been reported at a frequency of 2–12%,[57,62,63] and arise from either granulomatous inflammation of the gut or mesenteric vasculitis.

Clinical features of microscopic polyangiitis (Table 131.4)

MPA may be recognized as 'pure' small to medium-size vessel ANCA-associated vasculitis. ANCA are present in more than 70% of patients and usually target MPO.[24] Necrotizing glomerulonephritis and pulmonary capillaritis are hallmarks of MPA as described in the CHCC definition.[3,4] MPA was originally described as a novel form of polyarteriitis nodosa by Friedrich Wohlwill in 1923.[74] Zeek realized that this novel form often spared medium-sized vessels and had a preferential involvement of small-size vessels of visceral organs including lungs.[75] It was therefore recognized as a different disease entity,[76,77] and was eventually defined as microscopic polyangiitis by the CHCC in 1994.[3,4] There are no ACR classification criteria for MPA, as the ACR criteria were established in 1990—4 years before the first version of the CHCC definitions and the definite acknowledgement of MPA as a separate disease entity. Importantly, MPA can be distinguished from GPA by the lack of granulomatous inflammation in biopsy specimens and the absence

of mass formation such as pulmonary granuloma. Small- to medium-sized vessel vasculitis accounts for all disease manifestations in MPA. The clinical appearance of these vasculitic manifestations is the same as in GPA and EGPA. Furthermore, MPA has no distinct localized or prodromic phase as described for GPA and EGPA but is characterized by systemic stages only.

Most patients present with constitutional symptoms (up to 90%) and musculoskeletal involvement such as myalgia/arthralgia and arthritis.[24,77,78] Glomerulonephritis and pulmonary capillaritis represent the major clinical features and have been described to occur in 80–100% and 25–55% of patients, respectively.[24,77–80] Endstage renal disease is reported in 12–34% of patients.[24,81] Apart from pulmonary capillaritis, alveolitis, pleural effusions, and interstitial lung disease (ILD) are pulmonary manifestations of MPA. ILD seems to occur mainly in MPA (and not, or very rarely, in the other AAV) with a prevalence of 7.2%.[82] Of note, ILD can occur before, at, or after disease onset and progress in spite of quiescent systemic vasculitis.[83] The cause of ILD in MPA is not known but has been associated with subclinical alveolar haemorrhage (Figure 131.5).

PNS involvement in MPA is also common (19–58%) and manifests as acute mononeuritis multiplex or distal symmetrical sensimotor neuropathy.[24,78] As in GPA, there is a chronic form of polyneuropathy.[68] Skin manifestations are frequent (palpable purpura in 30–40% of MPA patients; Figure 131.6), whereas gastrointestinal involvement (abdominal pain, ischaemia, and bleeding) and CNS manifestations (vasculitis with ischaemic infarction or bleeding) are rare in most of the reported cohorts.[24,78,80]

Clinical features of eosinophilic granulomatosis with polyangiitis (Table 131.5)

Originally termed Churg–Strauss syndrome, EGPA has been renamed as a result of the 2012 Chapel Hill Consensus Conference.[4] It was first described by Jacob Churg and Lotte Strauss in 1951 as a clinical syndrome consisting of asthma, hypereosinophilia (in blood and tissue), and evidence of vasculitis occurring in extrapulmonary organs.[84] Histological features include necrotizing small- to medium-sized vessel vasculitis as well as an eosinophil-rich granulomatous inflammation found in the respiratory tract.[2–4] Since the original description by Churg and

Strauss, several disease definitions and classification criteria have been developed[2,3,85] (Table 131.6) referring to the histological and clinical manifestations of EGPA. EGPA can also be classified as one form of HES. ANCA, usually with anti-MPO specificity, can be detected in around 40% of patients.[25,86] The sinuses (allergic rhinitis/sinusitis, polyps), the PNS (mononeuritis, peripheral sensimotor neuropathy), and the heart (myocarditis) are characteristic organs involved in EGPA.[25,85–88,101-102] Organ manifestations including cardiac, gastrointestinal, CNS, and kidney involvement have been related to increased mortality and are listed in the Five Factors Score (FFS) to estimate the risk of mortality.[89] Lanham et al.[85] proposed distinct disease phases or stages for EGPA similar to GPA: a prodromic phase with asthma (typically late-onset asthma) and other allergic manifestations is followed by a phase of eosinophilic organ infiltration of tissues (e.g. eosinophilic myocarditis) and eventually by a systemic vasculitis phase with typical

Table 131.6 Classification criteria and definitions of EGPA/CSS

vasculitis manifestations as in GPA/MPA. While the last two phases seem to be largely overlapping, the history of a late-onset asthma and allergic disposition is typical. Of note, two different phenotypes of EGPA can be distinguished, one with predominant vasculitis manifestations and positive ANCA status and one with predominant eosinophilic organ infiltration which often remains ANCA-negative.[90]

Asthma is one of the hallmarks of EGPA and occurs in nearly every EGPA patient (93–100%).[24,85–88,101–102] Typically, the asthma manifests late, gets worse over time, and often takes a course refractory to inhalative treatment with the need for oral glucocorticoids to achieve asthma control. Asthma is often associated with upper and lower respiratory tract manifestations such as allergic rhinitis (in around 50–90%), allergic sinusitis (in around 60–80%) and/or polyps.[24,85–88,101–102] Pulmonary manifestations are found in 38–77% of patients[24,85–88,101–102] and mainly occur as patchy, asymmetric, or diffuse infiltrates on plain radiograph or ground-glass infiltrates on CT. BAL usually reveals eosinophilic alveolitis. DAH as a result of pulmonary capillaritis may occur but is rarer than in GPA/MPA and occurs in 7%.[25,86] Furthermore, nodules have been described to occur but seem to remain small and do not cavitate[91]; pleural effusion is seen in 20–30% of patients.

Cardiac and PNS involvement are characteristic for EGPA and occur more frequently in EGPA than in the other AAV. Myocardial involvement has been found in more than 50% by autopsy in the cohort of 13 patients initially described by Churg and Strauss.[84] In large EGPA cohorts, clinically apparent cardiac manifestations have been described in 16–47% of patients.[25,85–88,101–102] The spectrum of cardiac manifestations ranges from eosinophilic myocarditis (with or without granulomatous inflammation), to intraventricular thrombus formation, vasculitic lesions of the coronary arteries (coronariitis), and pericarditis.[25,86–88,101–102] Coronary arteritis is supposed to occur rarely[92]; if present, it is painful, leading to cardiac ischaemia and myocardial infarction. Myocarditis is usually not painful, may result in cardiac insufficiency, and can cause scar formation with consecutive restrictive

or dilatative cardiomyopathy. Arrhythmias are a feared complication of both vasculitic lesions and eosinophilic organ infiltration and may lead to sudden death.[25,85–88,101–102] Today, the detection of cardiac manifestations is dependent on the method of investigation: While 24 hour electrocardiogram and echocardiography should be part of the standard work-up in EGPA, new imaging techniques such as cardiac MRI have been suggested as useful in detecting both clinically apparent and non-apparent heart involvement, although the significance of MRI abnormalities such as late enhancement in non-symptomatic patients is uncertain.[92] Peripheral neuropathy occurs in around 46–80% of EGPA patients,[25,85–88,101–102] and manifests as mononeuritis or as distal symmetric sensimotor polyneuropathy. Polyneuropathy typically occurs suddenly (within hours or days) with a foot or wrist drop and accompanying sensory deficits and severe pain. Most commonly, the peroneal nerve is involved, followed by ulnar and radial nerves.[25,85–88,93,101–102] PNS involvement can by confirmed by a biopsy of the sural nerve, yet the classic findings of necrotizing vasculitis and perineural eosinophilic infiltration are only found in around 50% of cases.[25,85–88,93,94] The diagnostic yield of sural nerve biopsies may be significantly enhanced by a combined nerve and muscle biopsy.[94] PNS involvement occurs in both ANCA-positive and ANCA-negative EGPA at a similar frequency, suggesting that both ANCA-associated necrotizing vasculitis and eosinophilic organ infiltration may contribute to PNS inflammation and damage.[25,86] PNS involvement may resolve with small sensorimotor deficits or none if treated promptly, but severe damage may persist if initiation of treatment is delayed.[25,58–88]

Gastrointestinal (GI) involvement and renal involvement have been associated with a poor prognosis and increased mortality in EGPA.[89] While GI involvement (20–60%) is more frequent than in the other AAV, necrotizing glomerulonephritis is rarer and—if present—associated with a positive ANCA status.[25,86,101–102] GI manifestations originate either from eosinophilic tissue infiltration (from oesophagus to colon) or mesenteric vasculitis with subsequent ischaemia and infarction. Patients present with a variety

Fig. 131.7 Purpura in a patient with eosinophilic granulomatosis with polyangiitis.

of symptoms including abdominal pain, nausea and vomiting, diarrhoea. GI manifestations can be complicated by ulcer formation, severe bleeding, perforation, and obstruction.[95] Serositis, eosinophilic peritonitis, pancreatitis, and cholecystitis are rare manifestations.[95]

Other frequent organ manifestations include constitutional symptoms, musculoskeletal symptoms, and skin involvement. Myalgia/arthralgia/arthritis is present in around 30–65% of patients, and myositis (with creatine kinase elevation) are rarer.[25,85–88, 101–102] Palpable purpura is the most frequent skin lesion and occurs predominantly on the lower limbs; urticarial rash, livedo reticularis, and skin infarction may develop (Figure 131.7). The frequency of CNS involvement is only around 6–15%, yet associated with increased mortality.[25,85–88,101–102] Cerebral vasculitis leading to ischaemia or bleeding and cranial nerve involvement including ischaemic optic neuritis account for the majority of cerebral lesions.

Diagnostic procedure

It is recommended to manage vasculitis patients at, or in collaboration with, centres of expertise (level of evidence 3, grade of recommendation D).[96] A systematic diagnostic approach is useful in order to assess the variety of organ involvements fully (Table 131.7). Patients should be interviewed in a standardized way, which can be done with the help of standardized activity scores such as the BVAS. For all AAV, routine blood tests (including blood count, C-reactive protein, creatinine, urea and electrolytes) and urine analysis should be done at the initial assessment and at regular intervals dependent on disease severity and immunosuppression. ANCA testing is a mainstay to ascertain the clinical suspicion of AAV. An immunofluorescence test (IFT) serves as screening method which should be followed by ELISA for the main target antigens PR3 and MPO to confirm a positive IFT result and to identify the target antigen of ANCA.[97] The use of serial ANCA testing to predict relapses and to guide treatment is controversial. While some studies have shown an association between persistent or rising ANCA titres and relapse—especially in patients treated with rituximab —others failed to demonstrate an association between ANCA titre and relapse.[96]

At first presentation a biopsy should be sought in order to confirm the diagnosis of AAV.[96] Taking a renal biopsy is common in suspected renal involvement. Furthermore, nasal mucosal biopsies are frequently taken to confirm the diagnosis of GPA at the initial presentation; however, the diagnostic yield is low and dependent on the disease activity and the experience of the otorhinolaryngologist.[98] Therefore, consecutive biopsies may be necessary to confirm the diagnosis. Transbronchial or transthoracic biopsy may be required in patients with pulmonary masses, especially when malignancy is considered as differential diagnosis. Biopsies of the sural nerve, muscle, and skin represent other options to affirm AAV involvement.[94]

Apart from confirming the diagnosis of AAV, histological findings in biopsies can be of prognostic value. It has been proposed that necrotizing glomerulonephritis in AAV may be classified according to a scheme which is prognostic with respect to 1 and

Table 131.7 Interdisciplinary diagnostic staging to assess disease extent and activity

Organ involvement	Diagnostic procedure
ENT (including subglottic area)	Assessment by ENT specialist, MRI of the head, laryngoscopy, CT of the subglottic region
Lung	Radiograph, high-resolution CT, bronchoscopy, bronchoalveolar lavage
Kidney	Serum creatinine and urea, urinary analysis, assessment for 24 h proteinuria, ultrasound,
Eye	Assessment by ophthalmologist, MRI/CT of the head (assessment of orbital masses)
Heart	ECG, 24 h ECG, echocardiography, cardiac MRI
Skin	Assessment by dermatologist
Gastrointestinal tract	Ultrasound, CT of the abdomen, endoscopy, angiography
Peripheral nervous system	Assessment by neurologist, EMG, ENG, MRI of muscles
Central nervous system	Assessment by neurologist, MRI of the head, analysis of cerebrospinal fluid, angiography, ultrasound of extra-/intracranial blood vessels
Joints/muscles	Ultrasound, MRI
Constitutional symptoms	Clinical assessment: fever >38 °C, weight loss >10% of body weight, night sweats Fatigue (SF-36)

Table 131.8 Classification schema for ANCA-associated glomerulonephritis

Class	Inclusion criteria
Focal	≥50% normal glomeruli
Crescentic	≥50% glomeruli with cellular crescents
Mixed	<50% normal, <50% crescentic, <50% globally sclerotic glomeruli
Sclerotic	≥50% globally sclerotic glomeruli

From Berden et al.,[99] with permission.

Table 131.9 Definition of disease activity in AAV

Activity state	Definition
Remission	Absence of disease activity attributable to active disease qualified by the need for ongoing stable maintenance immunosuppressive therapy. The term 'active disease' is not restrictive to vasculitis only, but also includes other inflammatory features like granulomatous inflammation in GPA or tissue eosinophilia in CSS
Response	50% reduction of disease activity score and absence of new manifestations
Relapse	Recurrence or new onset of disease attributable to active vasculitis
Major	Recurrence or new onset of potentially organ- or life-threatening disease
Minor	Recurrence or new onset of disease which is neither potentially organ- nor life-threatening
Refractory disease	Unchanged or increased disease activity in acute AAV after 4 weeks of treatment with standard therapy in acute AAV, *or* Lack of response, defined as ≤50% reduction in the Disease Activity Score, after 6 weeks of treatment, *or* Chronic, persistent disease defined as presence of at least one major or three minor items on the disease activity score list (e.g. BVAS or BVAS/WG) after ≥12 weeks of treatment
Low-activity disease state	Persistence of minor symptoms (e.g. arthralgia, myalgia) that respond to a modest increase of glucocorticoid dose and do not warrant an escalation of therapy beyond a modest dose increase in the current medication

Adapted from the EULAR recommendations,[7] with permission.

5 year renal outcomes (Table 131.8).[99] With respect to EGPA, other reasons for hypereosinophilia need to be ruled out including parasitic infections, organ-restricted HES, T-lymphocytic HES, myeloproliferative HES, and FIPL1-PDGFRa-associated chronic eosinophilic leukemia (CEL) [100] Therefore, lymphocyte immunophenotyping, analysis of T-cell clonality and molecular analysis for FIPL1-PDGFRa gene fusion should be performed in any patient with unclear hypereosinophilia.

Disease stage and activity should be defined according to European League Against Rheumatism (EULAR) recommendations (Table 131.9).[7] The BVAS is a validated score system which helps to assess disease activity and is particularly used for study purposes. Chronic organ damage (defined as symptom attributable to scar formation, not due to active disease) can be rated by the VDI.[12] Patients should be examined by a rheumatologist on a regular basis every 3–6 months. Routine blood tests in order to monitor disease activity and to detect potential drug toxicity are required depending on disease activity and intensity of immunosuppression according to standard protocols.

CHAPTER 132

Treatment of ANCA-associated vasculitis

David Jayne

Introduction

Prior to the modern therapeutic era, granulomatosis with polyangiitis (GPA, Wegener's) had a mortality of 80% at 1 year, largely due to renal failure.[1] Glucocorticoids were first used in GPA and polyarteritis in the late 1940s and a randomized trial of adrenocorticotropin (ACTH) by the Medical Research Council in the United Kingdom reported better survival of polyarteritis at 1 year.[2] A follow-up report at 3 years found no difference in survival due to an excess of deaths related to drug-induced adverse events, highlighting the balance of benefits and harms that have continued in vasculitis therapy. In a retrospective survey of polyarteritis, mortality was lower with combination azathioprine/glucocorticoid therapy than glucocorticoids alone or no therapy.[3] Cyclophosphamide was first used in GPA by Novack and Pearson in 1967 and subsequently by Fauci and colleagues at the National Institutes of Health (NIH) in the United States.[4] It became apparent that the combination of cyclophosphamide and glucocorticoids resulted in stable remissions in GPA and polyarteritis and permitted reduction or withdrawal of glucocorticoids. The effectiveness of cyclophosphamide was linked to its ability to induce lymphopenia and particularly reduction in B-cell counts.[5] A 1992 retrospective study of the NIH experience in GPA, in 135 patients, confirmed the effectiveness of this approach but highlighted the greatly increased frequency of urothelial and lymphoproliferative malignancy attributed to the high cumulative exposure to cyclophosphamide.[6] With the association of anti-neutrophil cytoplasm antibody (ANCA) with GPA in 1985 and microscopic polyangiitis (MPA) in 1986, and evidence supporting the pathogenesis of ANCA in small-vessel vasculitis, a rationale evolved to combine these disorders in therapeutic studies.[7,8] Along with eosinophilic granulomatosis with polyangiitis (EGPA, Churg–Strauss) they were termed ANCA-associated vasculitis (AAV); however, EGPA was often excluded from AAV trials in view of perceived differences in treatment response and pathogenesis.

The last 20 years has seen attempts to reduce the toxicity of therapy by lowering exposures to cyclophosphamide and glucocorticoids, by the use of alternate immunosuppressives and other therapies, and by adjusting the intensity of therapy to the severity of the clinical presentation.[9] Although therapeutic monoclonal antibodies were first used in vasculitis in 1990 their use has only recently become widespread with the demonstration of the effectiveness of rituximab.[10–12] Over a similar period improved tools have been developed to assess the outcomes of therapy that have, in turn, emphasized the frequently poor current outcomes with respect to organ damage, chronic morbidity, and poor quality of life.[13]

Outcomes

Survival

Despite advances in therapy patients continue to have a higher mortality than a matched background population, as shown by a recent study of long-term outcomes of patients recruited to the European Vasculitis Study Group (EUVAS) studies.[14] The mortality rate ratio was 2.6 compared to a control population, with advanced renal failure, increasing age, and a high disease activity at diagnosis being the main adverse predicators. Several other studies have identified increasing age and worsening renal function as poor prognostic markers. The MPO-ANCA subtype independently predicts worse renal outcomes and survival.[14a] The increase in mortality is highest in the first year with 1, 2, and 5 year survival being 88%, 85%, and 78% respectively. Disease and therapy-related deaths, particularly infection, account for the majority of deaths in the first year. While infection remains an important cause beyond the first year, malignancy and cardiovascular problems become more common with longer follow-up.

Non-healing damage

Ninety-five per cent of patients develop at least one item of irreversible damage as a result of vasculitis or its therapy. Damage of the upper respiratory tract is common in GPA, with deafness and chronic nasal and sinus symptomatology.[15] Twenty per cent of patients develop endstage renal disease (ESRD) by 5 years with more having chronic kidney disease of less severity. Renal survival is associated with serum creatinine at diagnosis and the percentage of normal glomeruli in the renal biopsy.[16] However, even in those presenting with severe histological findings and low numbers of normal glomeruli, treatment should be given as the chance of renal recovery is greater than for therapy-related death.[17] A renal histology score has been developed with four categories associating with a progressively worse renal survival: focal, crescentic, mixed, and fibrotic (Table 132.1).[16]

Table 132.1 Histological classification of ANCA-associated renal vasculitis and correlation with renal outcomes

Subgroup	Definition	Risk of endstage renal disease at 5 years (%)
Focal	≥50% normal glomeruli	0
Crescentic	≥50% glomeruli with cellular crescents	25
Mixed	≥50% cellular and fibrotic crescents	50
Sclerotic	≥50% globally sclerotic glomeruli	78

From Berden et al.[16]

Table 132.2 Factors increasing relapse risk in ANCA-associated vasculitis

Clinical presentation	Serology	Treatment related
Diagnosis of GPA	PR3-ANCA positive at diagnosis	Steroid withdrawal
Ear, nose and throat involvement	Persistent ANCA positivity after induction therapy	Immunosuppressive withdrawal
Serum creatinine <200 μmol/L	Rise in ANCA during remission	Lower cyclophosphamide exposure

GPA, granulomatosis with polyangiitis (Wegener's).

Relapse

Relapse occurs in around 50%, in 40% by 5 years.[18] The predictors of relapse are treatment reduction or withdrawal, diagnosis of GPA, PR3-ANCA subtype, persisting ANCA positivity after induction therapy, respiratory involvement, younger age, nasal carriage of *Staphylococcus aureus*, and absence of severe renal involvement (Table 132.2). Disease with a granulomatous pathology, such as in the nose and sinuses, relapses more frequently and earlier than vasculitic manifestations, such as neuropathy or nephritis.[19] Relapses are categorized as minor/non-severe or major/severe if vasculitic activity threatens vital organ function. Relapse is not a mortality predictor, suggesting that the majority of relapses do not contribute to vital organ dysfunction. However, therapy must be prolonged to prevent relapse and appropriate monitoring instituted to detect relapse at an early stage.[20] A CD8+ T-cell transcription signature, using microarray analysis of purified T cells, has been identified that can predict patients at risk of relapse. The subset of genes defining the poor prognostic group were enriched for genes involved in the IL-7 receptor pathway, T-cell receptor signaling, and genes expressed by memory T cells.[21]

Approaches to therapy

The goals of therapy are to achieve a remission in disease activity, prevent relapse, and minimize drug toxicity. Definitions of disease activity terminology have been agreed by consensus (Table 132.3).[22] Current regimens employ high doses of toxic agents to suppress manifestations of disease activity and achieve a 'remission' in order to avoid further vital organ damage, rescue renal function, and reduce constitutional disturbance. This accepts a higher level of drug toxicity. This induction phase lasts 3–6 months and is followed by a longer remission maintenance phase when less toxic therapy is used. Prolonged follow-up is then required to manage the consequences of vasculitic damage, drug toxicity, and increased cardiovascular and malignancy risks. Future goals are safer regimens, more rapid remission induction to minimize tissue damage, better relapse prevention, and restoration of quality of life.

Following the association of ANCA with GPA and MPA, clinical trials have combined the two subgroups.[9] This is appropriate for renal disease, which is similar in both syndromes in terms of pathology and treatment response, but is a less useful approach for respiratory tract disease and for maintenance therapy due to differences in pathology and outcomes. Attempts have been made to subgroup patients at diagnosis according to disease extent and severity in order to design treatments of ascending strength. The EUVAS group have defined four subgroups and a refractory subgrouping, while American investigators have separated presentations into limited or non-severe, and generalized or severe (Table 132.4).[9,23,24] The French Vasculitis Study Group have identified factors predicting increased mortality to develop the five-factor score and protocols for patients with good or poor prognosis. However, avoiding diagnostic delay and the early institution of therapy are of primary importance in all subgroups. EGPA has been treated separately to GPA and MPA in the few therapeutic trials that have been performed.

Treatment

Induction therapy

The combination of cyclophosphamide and high-dose glucocorticoids, introduced over 40 years ago, remains the 'standard of care' for new patients with AAV.[20] Cyclophosphamide is equally effective as a daily oral or pulsed intravenous (IV) administration for the induction of remission (Table 132.5).[25] However, the IV protocols exposure the patient to a lower cumulative cyclophosphamide dose and permit bladder protection. Leukopenia is more common with daily oral cyclophosphamide and is an important risk factor for severe infection.[26] Weekly monitoring of the full blood count is required to monitor the falling white cell count and appropriate dose adjustment of daily oral cyclophosphamide is required to avoid leucopenia. The leucocyte nadir after IV cyclophosphamide occurs at 10–14 days and leucopenia at this stage is reflected in a reduction in the next cyclophosphamide pulse. Cyclophosphamide is continued for 3–6 months, by which time remission will have

Table 132.3 Consensus disease state definitions

Activity state	Definition
Remission	Absence of disease activity attributable to active vasculitis qualified by the need for ongoing stable relapse prevention therapy. 'Active disease' is not restricted to vasculitis only, but includes other inflammatory features, such as, granulomatous inflammation in GPA or tissue eosinophilia in EGPA
Response	50% reduction of disease activity score and absence of new manifestations
Relapse	Recurrence or new onset of disease attributable to active vasculitis
Major relapse	Recurrence or new onset of potentially organ- or life threatening disease
Minor relapse	Recurrence or new onset of disease which is neither potentially organ- threatening nor life threatening
Refractory disease	1. Unchanged or increased disease activity in acute AAV after at least four weeks treatment with standard induction therapy, *or*
	2. Lack of response, defined as ≤ 50% reduction in the disease activity score, after at least 6 weeks of treatment, *or*
	3. Chronic, persistent disease defined as the presence of at least one major or three minor items on the disease activity score list, after ≥12 weeks of treatment
Low-activity disease state	Persistence of minor symptoms (e.g. arthalgia, myalgia) that respond to a modest glucocorticoid increase and do not necessarily warrant an escalation of other therapies

EGPA, eosinophilic granulomatosis with polyangiitis (Churg–Strauss); GPA, granulomatosis with polyangiitis (Wegener's); MPA, microscopic polyangiitis.

Table 132.4 Disease subgrouping, US and EUVAS systems, according to disease severity and extent

Subgrouping by severity or extent	Organ involvement		Constitutional symptoms	ANCA status	Serum creatinine (μmol/L)
US	**EUVAS**				
Limited or non-severe	Localized	One site, typically the upper respiratory tract in GPA	No	Positive or negative	<120
	Early systemic	Any, except renal or imminent vital organ failure	Yes	Positive	<120
Generalized or severe	Generalized (or renal)	Imminent vital organ failure or renal vasculitis	Yes	Positive	<500
	Severe	Vital organ failure, typically renal	Yes	Positive	>500 (renal presentations)
	Refractory	Progressive disease despite conventional therapy	Yes	Positive or negative	any

Adapted from Rasmussen et al.[9] and Carrington and Liebow.[23]

been achieved in 80–90%. IV methyl prednisolone is widely used for severe presentations at total doses of 1000–3000 mg, without a robust evidence base. Daily oral prednisolone commences at 1.0 mg/kg per day, maximum 80 mg/day, for 1–4 weeks, then reduces in steps to 10–15 mg/day by 12 weeks.[24,27]

Severe presentations

Plasma exchange improves the chances of renal recovery in those presenting in renal failure (creatinine >500 μmol), but it is uncertain whether it also has a role in renal vasculitis with deteriorating, renal function below this level, or in severe non-renal presentations, such as diffuse alveolar haemorrhage.[28] A meta-analysis failed to confirm a significant benefit of plasma exchange on the composite outcome of death and endstage renal disease.[29] The increasing evidence for the pathogenicity of ANCA in renal vasculitis provides a rationale for its use, but removal of coagulation factors, cytokines, or other substances may also be important. Plasma filtration or

centrifugation appear equally effective and, on average, seven daily or alternate-day exchanges of 1–1.5 plasma volumes are used. Double filtration apheresis, selective IgG, and MPO-ANCA selective immunoabsorption have also been employed but until there is better understanding of the mechanisms of plasma exchange, non-selective procedures are preferred. The procedure usually requires central vascular access, and may be complicated by haemorrhage and thrombocytopenia. Volume replacement with albumin is recommended but plasma or coagulation-factor-rich plasma fractions are used in the setting of increased bleeding risk, such as after a renal biopsy or in the presence of alveolar haemorrhage.

Non-severe presentations

Cyclophosphamide substitution by methotrexate, dosed at 20–25 mg/week, for non-severe AAV presentations was found to be effective in the NORAM trial with similar remission rates at 6 months.[30] Enthusiasm for this approach has waned with a higher relapse rate

Table 132.5 Cyclophosphamide dosing for IV pulsed and daily oral regimens as defined in the EUVAS CYCLOPS protocol

Pulsed cyclophosphamide dosing (mg/kg/pulse) with reductions for impaired renal function and age		
Age (years)	eGFR >30 mL/min	eGFR ≤30 mL/min
< 60	15	12.5
60 to 70	12.5	10
> 70	10	7.5
Timing of cyclophosphamide pulses		
Weeks: 0, 2 and 4, then every 3 weeks (weeks 7, 10, 13, 16, 19, 21, and 24)*		
Daily oral cyclophosphamide dosing		
Age (years)	Dose (mg/kg per day)	
<60	2.0	
60–70	1.5	
>75	1.0	

Data from de Groot et al.[25]

following methotrexate induction and higher subsequent glucocorticoid and cyclophosphamide requirement. Also, non-severe patients accrue high frequencies of organ damage and chronic morbidity, so more aggressive strategies are justified.[15] Mycophenolate mofetil has been shown to have potential as an alternative to cyclophosphamide in MPO-ANCA-positive MPA in preliminary studies.[31,32]

Rituximab

B-cell depletion with rituximab is as effective as cyclophosphamide for the induction of remission of in AAV.[11,12] The RITUXVAS trial employed two cyclophosphamide pulses with rituximab 375 mg/m^2 per week × 4, but the results in the RAVE trial, with the same rituximab dose but no cyclophosphamide, were similar. No early benefits of cyclophosphamide avoidance were observed in either trial. The longer-term effects of rituximab, as opposed to cyclophosphamide induction, are not known, especially the relapse risk and need for remission maintenance therapy. Rituximab can be recommended for remission induction when cyclophosphamide is contraindicated, for example by infection, cytopenia, intolerance, malignancy, or fertility protection.[33] A simpler regimen of rituximab 1 g repeated after 14 days appears to be similar in efficacy to the four-dose regimen.[34] T-cell tubulitis predicts a worse renal outcome in rituximab-treated patients but has not been studied with other induction agents; the implications for treatment regimens are unclear.[35]

Assessing response

Improvement in renal vasculitis is judged by improvement or stability of renal function and control of extrarenal vasculitis and normalization of C-reactive protein (CRP). Microscopic haematuria persists for many months after the onset of therapy and proteinuria typically increases during the recovery period, occasionally to levels sufficient to cause the nephrotic syndrome. The level of proteinuria during the recovery phase indicates the degree of glomerular injury and is associated with worse renal outcomes.[36] ANCA levels are not used to guide the duration or intensity of induction therapy although the binding level in certain PR3-ANCA assays at

diagnosis have been predictive of renal outcome. For patients who are dialysis dependent at presentation, if recovery occurs it is usually seen within 2–3 weeks although rarely later renal recovery occurs. If no recovery has been seen after a course of plasma exchange has been completed, a persisting high ANCA level, high CRP attributed to vasculitis or poor control of extrarenal vasculitis suggest that renal vasculitis is likely to be still active and further plasma exchange would be beneficial. However, if there is no recovery by 4–6 weeks further intensive therapy is likely to be unproductive. The severity of the renal histology at diagnosis should not deter the commencement of induction therapy; however, repeat renal biopsy can be useful in refractory cases when the presence of active vasculitis and degree of sclerosis would influence subsequent treatment decisions.

Improvements in respiratory tract disease are accompanied by symptomatic and radiological improvement. Subglottic and endobronchial disease is rarely present at diagnosis but can appear when GPA is clinically inactive or at the time of relapse. It should be considered for persisting exertional dyspnoea, recurrent respiratory tract infections, or radiological opacities and is best defined by CT scanning and bronchoscopy. Pulmonary function tests are useful in monitoring individual patients but can be misleading when used for diagnosis. Changes in ear nose and throat and ophthalmic activity can be harder to assess and regular specialist review with nasoendoscopy and direct laryngeal visualization is recommended. Vasculitic neuropathy recovers to variable degrees but some motor deficiency usually remains. A paradoxical deterioration in symptoms of dysaethesiae during the recovery phase is common and responds to amitriptyline, gabapentin, or pregabelin.

Eosinophilic granulomatosis with polyangiitis

A similar approach to GPA and MPA is adopted with cyclophosphamide and high-dose glucocorticoids for severe disease.[37] Non-severe disease has been treated with glucocorticoids alone but this has led to a high relapse frequency and glucocorticoid exposure, which is probably reduced by using azathioprine or other immunosuppressive.[38] The only randomized trial of severe disease found

a longer course of 12 cyclophosphamide pulses more effective than 6 in achievement of stable remission. Over one-third of EGPA patients suffer persisting steroid-dependent asthma after control of their vasculitis.

Induction treatment in children and the elderly

The approach to therapy and responsiveness to medication is the same in the young and the old as in other age groups, but drug selection and dosing may differ. In view of the fertility and malignancy risks of cyclophosphamide, alternative use of mycophenolate mofetil or rituximab has been suggested. Higher glucocorticoid doses, up to 2 mg/kg per day, are used in children, due to increased rates of elimination. Elderly patients are more likely to present with renal impairment and have a high risk of infective complications. It is important to reduce cyclophosphamide accordingly (Table 132.5). Lower cyclophosphamide dosing, fixed at 500 mg IV pulses, and reduced glucocorticoid exposure with more rapid tapering have been proposed. Glucocorticoid withdrawal in the remission period is desirable to reduce the risk of osteoporosis.

Remission maintenance therapy

Disease relapse occurs in 75% of GPA and 30% of MPA and EGPA cases by 5 years.[39] The goals of maintenance therapy are to prevent disease relapse while minimizing drug toxicity. Cyclophosphamide is withdrawn after 3–6 months and substituted by azathioprine 2 mg/kg per day, or methotrexate, up to 25 mg/week. They were equally effective for remission maintenance with similar safety risks in the WEGENT trial.[40] Methotrexate is excreted by the kidneys and should be avoided in the presence of renal impairment (GFR <50 mL/min). Although rare, concerns over methotrexate pneumonitis complicate its use in the presence of pulmonary vasculitis. Leflunomide, 20 mg/day, was superior to methotrexate for the prevention of relapse in a small GPA study but mycophenolate mofetil was less effective than azathioprine for relapse prevention after cyclophosphamide induction therapy.[41,42]

Prednisolone is either continued in conjunction with an immunosuppressive at doses of 5–10 mg/day or is withdrawn at the end of the induction phase. There is an increased relapse risk following steroid withdrawal which has to be balanced against the toxicity of long-term administration.[43]

There is no clear guidance as to how long remission maintenance treatment should be continued. The IMPROVE trial withdraw therapy 42 months after diagnosis, but withdrawal after 24 months has also been suggested. The various factors that influence relapse risk should be considered (Table 132.2) along with the likely consequences of relapse for the individual patient.[18,19] Most relapses are minor and do not increased the risk of death or organ failure, but delayed relapse diagnosis is a real concern and renal relapse increases the risk of ESRD. The most frequent factors that would support prolonged treatment are PR3-ANCA at diagnosis, ENT involvement, and persisting ANCA positivity.[44] There should be consideration for prolonged low-dose immunosuppression in these cases.

Management of relapse

The symptoms and signs of relapse in an individual patient reflect those present prior to the original diagnosis. The diagnosis of relapse needs to be differentiated from infection or other potential causes, including malignancy. Infection may precede and precipitate relapse and this is a particular issue with bacterial infections in respiratory tract relapse in GPA. Relapse is categorized as minor (non-severe), or major (severe) when vasculitic activity threatens vital organ function. Renal relapse is initially manifested by a return or increase in haematuria with proteinuria with subsequent deterioration in renal function and is usually, but not always, associated with ANCA positivity and rises in erythrocyte sedimentation rate (ESR) and CRP. Repeat renal biopsy is indicated if there is uncertainty as to whether or not renal relapse is occurring.

Minor relapse is treated by optimization of the background immunosuppressive, such as azathioprine or methotrexate, and increase in prednisolone to 0.5–1.0 mg/kg per day with a reducing regimen back to 5–10 mg/day. When the immunosuppressive dose is limited by adverse events, or if minor relapses recur, an alternative immunosuppressive or switch to rituximab should be considered. Major relapse is treated by introduction of cyclophosphamide or rituximab and a similar increase in prednisolone.[20] Data from the RAVE trial showed a higher rate of response to rituximab than to cyclophosphamide in this subgroup.[12]

Refractory disease

Progression of vasculitis despite induction therapy, failure to attain disease remission, and disease relapse while receiving maintenance therapy are defined as refractory disease (Table 132.3).[22] Before therapy is enhanced, causes for refractory disease—including infection, malignancy, and drugs—should be considered, as well as non-concordance with the prescribed regimen. Drug intolerance, especially to glucocorticoids or cyclophosphamide, and reductions in dosing due to intercurrent infection may also lead to primary treatment failure. This situation is associated with a high mortality due to the presence of organ failure and the risks of prolonged therapy.[45]

Progressive or non-responsive disease occurs in 5–10% and is treated with an increase in glucocorticoid, typically IV pulsed methylprednisolone 1000–3000 mg. Relative cyclophosphamide under dosing is indicated by a failure to induce lymphopenia and is more common with IV pulsed administration. A switch to daily oral cyclophosphamide or an increase in IV dosing has been suggested. Changing from cyclophosphamide to rituximab is now more attractive because rituximab is less likely to increase the infective risk. Failure to induce B-cell depletion indicates that rituximab will be ineffective. Where the response to rituximab appears slow, pulse cyclophosphamide can be added until response is seen, but cyclophosphamide is not routinely required with rituximab.

For resistant renal vasculitis or alveolar haemorrhage plasma exchange is used. Intravenous immunoglobulin reduces disease activity in refractory AAV but the effect lasts less than 3 months.[46] This option can be considered if conventional therapy is contraindicated, for example by infection or in pregnancy. A potential mechanism of immunoglobulin, as proposed in Kawasaki disease, is the neutralization of microbial toxins. Blockade of tumour necrosis factor alpha (TNFα) with infliximab or etanercept has led to remission when used also as an additional agent but prolonged use appears ineffective and it may increase the risks of infection.[24,47] Concerns over malignancy risk with anti-TNF therapy in vasculitis have not been supported by longer-term studies.[48]

Patients failing to achieve remission by 6 months, or possibly before, should have their non-glucocorticoid treatment reassessed as for progressive disease. Deoxyspergualin (Gusperimus) is an

immunosuppressive with a range of activity on the innate and cognate immune systems that has demonstrated high response levels in refractory GPA.[49] Leucopenia is common but rapidly reversible and not accompanied by increased infection frequency. There does not appear to be a sustained effect after deoxyspergualin withdrawal when relapses are common. Lymphocyte, eosinophil, and macrophage depletion with the anti-CD52 therapeutic antibody alemtuzumab has led to sustained treatment-free remissions.[50] The profound, transient lymphopenia induced by alemtuzumab is poorly tolerated in those over 60 or with impaired renal function.

Those relapsing are treated as described above with multiple minor relapses or at least one major relapse requiring a change of immunosuppressive. Changing the non-cyclophosphamide immunosuppressive, for example from azathioprine to methotrexate, or vice versa, or switching to mycophenolic acid preparations or leflunomide, can be considered.[51,52] After a major relapse or after a failure of at least one alternative immunosuppressive for minor relapses, rituximab is indicated.

EGPA can pursue a primary progressive course requiring repeated courses of IV steroid; intravenous immunoglobulin and plasma exchange have also been used.[53] However, a more common problem in EGPA is relapse as glucocorticoids are reduced. Such patients are at risk of high glucocorticoid exposure and alternative strategies should be pursued to permit glucocorticoid reduction to conventional maintenance levels. A change in immunosuppressive may be effective in non-severe disease. Rituximab, alemtuzumab, interferon-α and mepolizumab, an anti-interleukin (IL)-5 monoclonal antibody, have been used in this setting.[54]

Management of damage

Ear, nose, and throat disease in GPA has a high risk of causing irreversible damage and chronic symptomatology. Collapse of the bridge of the nose can be corrected by bone or cartilage grafts and restorative procedures should be performed when the disease is thoroughly controlled and glucocorticoid doses at remission maintenance levels. Damage to the nasal mucosa results in nasal crusting, which provides a focus for infection as well as causing nasal obstruction. Regular nasal douching to remove the crusts and use of a topical aseptic cream, such as mupirocin, reduces associated symptoms and risk of infection.[55] Hearing loss is usually caused by eustachian tube obstruction and recurrent otitis media but may also result from damage to the eighth cranial nerve. Although some recovery may occur, chronic hearing loss is frequent. Subglottic, tracheal, or bronchial stenoses can be fibrotic in origin, reflecting previous episodes of vasculitic damage to the airways. They can progress to cause respiratory obstruction or, if at bronchial level, cause segmental or lobar obstruction, infection, and collapse. Physical dilatation by bougie or balloon can restore the lumen and antibiotics are usually required to control secondary infection. Multiple procedures may be required as well as subsequent intermittent surveillance by nasendoscopy or bronchoscopy.

The long-term outcome of alveolar haemorrhage is usually good with stable lung function, but a minority of patients present with overlapping features of ANCA vasculitis and pulmonary fibrosis.[56,57] The lung fibrosis can precede or follow vasculitis and be progressive, leading to respiratory failure despite control of vasculitis. This pattern is more commonly associated with the MPO-ANCA subtype.

Chronic kidney disease resulting from renal vasculitis is managed in a similar way to other causes of renal disease. Proteinuria rises during the recovery phase of renal vasculitis reflecting glomerular damage. Angiotensin converting enzyme (ACE) inhibition has been recommended to improve long-term renal outcomes without direct supporting evidence. Patients with reduced renal function are at high risk of ESRD if they have a further episode of renal vasculitis and need to be monitored with this in mind. Those developing ESRD can be supported by dialysis and their immunosuppressive treatment withdrawn in the absence of extrarenal disease. Peritoneal dialysis carries an increased risk of peritonitis and need for ongoing immunosuppression is a relative contraindication. Patients who develop ESRD should be considered for transplantation, which is a safe and effective option.[58] Adjusted outcomes for graft loss, death, or functional graft loss are at least as good in those patients with GPA compared to other causes of ESRD and vasculitic relapse is uncommon following transplantation. Patients who are transplanted survive better than those remaining on dialysis, when relapse is more frequent and often hard to control. Outcome in those patients who remain on dialysis is similar to other causes of ESRD. It has been conventional to wait at least 6 months after an episode of active vasculitis before transplanting. ANCA positivity at the time of transplantation does not appear to affect graft or patient survival, although an increase in graft vasculopathy was noted in one series.[59]

Adverse events

Improvement in survival has resulted from improved treatment strategies; however, adverse events associated with these treatments are now an important cause of death and morbidity. In the EUVAS studies mortality at 1 year was 11%. The cause of death was related to an adverse event of treatment in 59%, with infection being the most common factor (Figure 132.1).[26] Active vasculitis accounted for only 14% of deaths. This study highlights the burden of using non-selective immunosuppressant agents. Infection is also a common cause of morbidity, with 25% of patients developing infection in the first year, with respiratory tract infections and generalized septicaemia being the most common infections. Glucocorticoid and cytotoxic therapy both contribute to the increased risks of infection. An older study of 158 patients over a median of 8 years, which used prolonged oral cyclophosphamide, found that 50% of serious bacterial, fungal, and opportunistic infections occurred during periods of daily glucocorticoid therapy, with only 21% occurring on alternate-day glucocorticoids, 16% on single-agent cytotoxic therapy, and 12% while therapy-free.[6]

Infections

Those at risk of infection should be identified and interventions undertaken to reduce risk. Factors predictive of infection include age, severity of renal dysfunction, leucopenia, and intensity and duration of immunosuppression. *Pneumocystis jiroveci* infection occurs in AAV with an incidence of 0.85–12% usually within the first few months after diagnosis, when immunosuppressive therapy is most intense. Presentation is more acute than that commonly seen in HIV patients, with 41% having symptom duration of 3 days or less and high fevers with rapid onset of respiratory failure being common. Mortality rates of 47–62.5% are reported. Pneumocystis infection is associated with lymphopenia, oral cyclophosphamide,
Fig. 132.1 Causes of death in 535 patients enrolled at diagnosis into prospective EUVAS trials in the first year, the second to fifth year and after five years.[14]
Reproduced from Annals of the Rheumatic Diseases, Flossmann O, Berden A, de Groot K, et al. 2011;70:488–494 with permission from the BMJ Publishing Group Ltd.

and steroid use. Prophylaxis against *P. jiroveci* with low-dose sul-famethoxaole/trimethoprim is recommended in patients receiving cyclophosphamide.[20] Herpes zoster varicella (HZV, shingles), occurs in AAV with a frequency of 4.5 episodes per 100 patient-years. While viral reactivation is linked to the intensity of immu-nosuppression, infections also occur following the switch to maintenance therapy.

Leucopenia is common, especially in those receiving oral cyclo-phosphamide, and is directly associated with infection and death.[39] It should be avoided with close monitoring. Leucopenic patients can safely be treated with granulocyte colony-stimulating factor (G-CSF). Influenza and pneumococcal immunization was safe and effective in 230 GPA patients and is recommended for AAV patients.[60] Live vaccines should be avoided in all patients taking immunosuppressives or prednisolone doses above 5 mg/day. In those AAV patients on standard maintenance therapy, maintenance of protective levels of antibody to other vaccines such as diphthe-ria, tetanus, and polio may be shorter than in immunocompetent patients and may require more frequent booster vaccinations.[61]

Malignancy

The incidence of cancer in treated AAV patients is 1.6–2.4 times higher than that in the general population. Immunosuppressive drugs contribute to this risk, especially a 4.8–33-fold risk of urothe-lial cancer and a 4.2–11-fold risk of leukaemia or lymphoma, attributed to cyclophosphamide, but proportionally higher rates of lymphoma and non-melanoma skin also occur.[6] Data collected from the EUVAS studies on patients recruited between 1995 and 2003 found an increased risk of all cancers of 1.7, largely driven by non-melanoma skin cancer.[62] The previously observed increased risk of bladder cancer and leukaemia was not seen, reflecting the reduced cyclophosphamide exposure in the EUVAS protocols. The degree of relative risk and bladder cancer frequency may have been a feature of relatively short follow-up; a French cohort study found a fivefold increase in risk for bladder cancer in AAV patients who had received cyclophosphamide. A Danish single-centre cohort study of 293 GPA patients recruited from 1973 to 1999 found an overall increased risk of 2.1, rising to 3.6 for bladder cancer and leu-kaemia, with no increased risk for these cancers in those receiving

a cyclophosphamide exposure below 36 g.[63] It appears probable that the bladder cancer risk is associated with cyclophosphamide exposure and length of follow-up, and strategies, such as IV pulse administration with hydration and mesna will minimize this risk. However, patients who have received cyclophosphamide require lifelong follow-up with prompt investigation by cystoscopy and urine cytology for the new onset or persistence of haematuria. Azathioprine increases the risk of skin malignancy and may con-tribute to lymphoma risk. Increased risks are detectable with more than 3 years' exposure in inflammatory bowel disease but have not been quantified in vasculitis. Patients receiving azathioprine should receive appropriate advice to minimize sun exposure and should be counselled and reviewed with these risks in mind.

Cardiovascular disease

Myocardial infarction rates were increased with a hazard ratio of 3.6 in a retrospective review of GPA patients enrolled in the Danish National Hospital Register. In addition, a retrospective study showed that patients with GPA and MPA, when matched for renal function and other traditional risk factors, had double the rate of cardiovascu-lar events. Of 535 GPA and MPA patients enrolled in the EUVAS tri-als, 74 (14%) had had a cardiovascular event by 5 years, an increased risk of 3.7.[64] Those who were MPO-ANCA positive had higher risk than those with PR3-ANCA. Theories for the increased event rates in AAV include systemic inflammation and endothelial dysfunc-tion, factors associated with increased cardiovascular risk in other inflammatory diseases. AAV patients in remission have impaired endothelial function and increased stiffness of large arteries, which has been reversed by TNFα blockade.[65] Renal dysfunction is an independent predictor of cardiovascular disease. Patients with AAV may also have an increased prevalence of traditional risk factors for atherosclerotic disease due to glucocorticoid treatment, which causes hypertension, dyslipidaemia, diabetes, and weight gain.

Thromboembolic disease

Although microthrombosis is a component of vasculitic pathology, the frequency of deep venous thrombosis and pulmonary embolism is also increased, being highest during periods of disease activity. A rate of 15% was reported in a prospective trial and in retrospective

surveys rates of 1.8%/year for all AAV patients rising to 6.7–9%/year for those with active disease.[66] Autoantibodies to plasminogen and tissue plasminogen activator occur in the sera of 25% and 14% of AAV patients. Their presence has been associated with more severe renal outcomes and increased risk for thromboembolic events. A rate of thromboembolism of 8.1% has been reported in EGPA, which has been related to the thrombogenic potential of eosinophilia. Anticoagulants have been used historically in the treatment of renal vasculitis but thromboprophylactic strategies have not been developed for AAV in the current era. Until further data emerges of the clinical utility of anti-plasminogen autoantibody testing, it is advisable to address conventional risk factors and maintain a high threshold for suspicion of thromboembolism.

Other drug-specific toxicity

Glucocorticoids

Glucocorticoids have a broad adverse event profile, including steroid-associated diabetes, avascular necrosis, and ocular cataract formation. Prophylaxis against osteoporosis and peptic ulceration has become routine, especially in those receiving high-dose glucocorticoids. Reduced bone mineral density is common in patients with AAV; in one study of 99 patients with AAV 57% had osteopenia and 21% had osteoporosis in at least one site; 7 out of 99 patients sustained fractures. Other studies also report high rates of fractures in AAV patients of 2.5–15%. Bisphosphonates are contraindicated in those with a GFR less than 30 mL/min.

Cyclophosphamide

The adverse events specific to cyclophosphamide, other than infection and bone marrow suppression, include hair loss, haemorrhagic cystitis, and infertility. Haemorrhagic cystitis occurs with a frequency of 0.5/100 patient-years and is associated with oral cyclophosphamide use and total exposure. Prevention of haemorrhagic cystitis is important, as an episode increases the risk of bladder cancer 5–7 times. The risk of haemorrhagic cystitis can be reduced by increased hydration and by concomitant treatment with mesna, which binds to the cyclophosphamide toxic metabolite acrolein. Fertility risks are discussed below.

Azathioprine

Myelosuppression is common with azathioprine and can occur early or later during its administration. Mutant polymorphisms in the thiopurine S-methyltransferase ($TPMT$) gene are associated with rapid and profound myelosuppression. Patients can be screened for common $TPMT$ polymorphisms or for the biochemical activity of TPMT before commencing azathioprine. The significance of heterozygous states and borderline low activity levels is less clear, as many such patients tolerate azathioprine well. Azathioprine allergy or intolerance occurs in 5–10% and hypersensitivity reactions can be difficult to distinguish from infection or vasculitic relapse, but their onset within 2–3 weeks of commencing azathioprine is an indicator. Reactions are manifested by fevers, chills and rash, and interstitial nephritis can occur. Hepatotoxicity and cirrhosis are less common.

Rituximab

The use of rituximab is increasing in patients with AAV. No change in infection rates was observed when rituximab was substituted for cyclophosphamide in two induction trials.[11,12] Whether this reflects an infection risk with rituximab similar to cyclophosphamide or the role of concomitant high-dose steroid is unclear. Progressive

multifocal leucoencephalopathy (PML), caused by the JC virus, has occurred in systemic lupus erythematosus (SLE) patients treated with rituximab but it is unclear whether the prevalence of PML is actually increased by rituximab in SLE. There has not been evidence of increased PML risk with rituximab in AAV but patients should be counselled that such a risk might exist. Infusion reactions to rituximab occur in 20% but have been mild without sequelae and have not prevented repeat treatment. Hypogammaglobulinaemia occurs after rituximab in a minority and is related to the use of previous immunosuppressives, cumulative exposure to rituximab, and length of follow-up. While mild reductions of IgG do not appear to influence infective risk, severe deficiency (to <3 g/litre) has occurred and led to recurrent infection and need for immunoglobulin replacement. Rituximab impairs the humoral response to immunizations, and, where possible, these should be administered at least 2 weeks before rituximab, or 4 months after it.

Fertility and pregnancy

Vasculitis activity and its therapy are threats to the fertility of patients with vasculitis. Loss of fertility is an important consequence of the disease, but the risks of this occurring can be considerably reduced with newer forms of treatment. As a chronic disease, vasculitis also causes psychosexual and relationship problems due to effects on self-esteem and mental well-being. Chronic kidney disease is a common consequence of renal vasculitis and depressed kidney function itself affects fertility in both women and men.

The major threat to fertility is cyclophosphamide exposure, which can result in primary ovarian failure. This is related to the total amount of cyclophosphamide administered and the age of the patient. Data from lupus nephritis suggests that a total cyclophosphamide exposure of 14–20 g results in infertility in over 50% of women aged over 32 years. The risk of infertility in those under 32 years is lower, around 10% in one series. Even if infertility is not induced, less severe ovarian damage leads to early menopause. Drugs that temporarily suppress ovarian function, such as goserelin, are used to reduce the risk of cyclophosphamide toxicity. Rituximab has been shown to be as effective as cyclophosphamide and can be used when cyclophosphamide avoidance is desirable. There have been concerns that cyclophosphamide may result in an increase in birth defects through damage to DNA in the unfertilized egg, but this has not proved to be the case. However, it is advisable to wait at least 6 months between stopping cyclophosphamide and attempting to conceive.

Cyclophosphamide directly affects sperm production in men. There is more potential for recovery by the generation of new sperm-forming cells when cyclophosphamide is withdrawn, although prepubertal boys are at greater risk of infertility than girls, with a threshold of 200 mg/kg deduced from nephritis trials. Sperm production does not usually recover to pretreatment levels and healthy sperm counts can remain depressed. It is likely that, in combination with non-specific effects of chronic illness, cyclophosphamide reduces male fertility. An alternative immunosuppressive used in vasculitis, methotrexate, also reduces sperm formation but has a lower risk of sustained effects after withdrawal. Egg preservation in women can be difficult because of the urgency in starting therapy, but semen preservation is quite feasible in men and can be considered before cyclophosphamide is commenced.

Methotrexate and mycophenolate mofetil, damage the fetus and must not be used in pregnant women or those attempting to conceive. Anti-inflammatory drugs and high-dose steroids also reduce fertility. The infective risks of the intrauterine coil are increased in those

receiving immune suppression. Sexually transmitted diseases can be more problematic in immune suppressed patients and *Chlamydia trachomatis* infection results in infertility in women. Drug effects, especially high-dose steroids, vasculitic activity, and chronic illness reduce testosterone levels that can lead to reduced libido and erectile failure. Testosterone levels in the blood are readily measured and testosterone supplementation can correct the problem.

GPA has been diagnosed during pregnancy but this is rare and there is no evidence of an increased relapse risk during pregnancy or the postpuerperal period. The risks of pre-existing damage to the pregnancy, in particular to the kidneys, lungs, or heart, need to be considered before conception, and appropriate changes to medication made. Transmission of ANCA and a self-limiting vasculitis syndrome have been reported in the neonate, but this is probably a rare occurrence. The largest review of 22 pregnancies in AAV reported good fetal outcomes, the adverse events being pre-eclampsia in two pregnancies and one newborn with hypothyroidism and one with a cleft palate.

Future directions

Reducing diagnostic delay will have a major impact on outcomes but requires understanding of where patients present and subsequent referral pathways. Improved education of referring medical specialties and wider use of ANCA testing and urine analysis will facilitate earlier referral. Management in a subspecialist vasculitis clinic with rapid access to associated specialities including ENT and respiratory medicine allows a coordinated approach to patient care and optimal assessment of disease extent and treatment response. Careful supervision of therapy, especially cyclophosphamide and high-dose glucocorticoids, has led to major reductions in severe adverse events over the last 20 years and late treatment-related toxicity. This is likely to be further improved by the availability of rituximab as an alternative to cyclophosphamide.

Glucocorticoids, delayed treatment response, and a high relapse rate are important components of the unmet need of current vasculitis therapies. Potential alternatives to glucocorticoids, such as intravenous immunoglobulin or TNFα blockade have proved impractical or ineffective. Therapies targeted at other cytokine, complement, or immune components may provide an opportunity to reduce glucocorticoids, such as the use of mepolizumab in EGPA. Rituximab has not led to a lower relapse rate than cyclophosphamide and there is uncertainty as to how to prevent relapse after rituximab induction. Other B-cell targeted therapies may be more effective, or B-cell therapies may need to be continued during the remission phase.

The causes of impaired quality of life despite vasculitis remission are not understood, although subclinical disease activity is likely in some patients. Other factors include ongoing treatment toxicity, irreversible damage, and physical deconditioning. Newer therapies may impact on quality of life, but there is currently no evidence for rituximab doing so.

CHAPTER 133

Large-vessel vasculitis

Nicolò Pipitone, Annibale Versari,
and Carlo Salvarani

Introduction

Giant cell arteritis (GCA) and Takayasu's arteritis (TAK) are primary systemic vasculitides mainly involving the aorta and its main branches. GCA was first described by Hutchinson in 1890, but the histological alterations of GCA were reported only in 1932 by Horton et al. TAK was first described by Morgagni in 1761, but is named after the Japanese ophthalmologist Takayasu, who reported a case with ocular involvement in 1908.[1,2]

Epidemiology

GCA affects almost exclusively subjects aged over 50 years at the time of diagnosis.[1,2] The incidence of GCA increases with advancing age, and peaks in the 70–79 years age group.[3] Females are affected two to three times more often than males.[3] GCA occurs predominantly in white people, and it is very rare in blacks and Asians. The highest incidence rates of GCA (>17/100 000 for individuals aged >50 years) have been reported in Scandinavian countries and North American populations of Scandinavian descent.[3] In contrast, the incidence of GCA is lower than 12/100 000 for those aged over 50 years in southern European countries.[3] The incidence of GCA has increased over the past decades, presumably as a consequence of heightened physician awareness.[3] A cyclic pattern in incidence rates of GCA has been observed.[4]

GCA and polymyalgia rheumatica (PMR) occur together more frequently than expected by chance alone. Around 16–21% of patients with PMR have clinical manifestations of GCA, while 40–60% of patients with GCA suffer from PMR.[4] PMR can develop before, simultaneously with, or after the onset of the clinical manifestations of GCA.[1] Furthermore, about 4% of patients with pure PMR (i.e. without clinical features of GCA) have temporal artery biopsy (TAB) lesions consistent with GCA,[5] while nearly one-third of patients with pure PMR have subclinical arteritis on imaging.[6] However, patients with PMR and clinically silent GCA are not at risk for ischaemic complications.

Mortality rates of patients with GCA are comparable to those of the general population.[7] An exception is the subset of GCA patients with thoracic aorta aneurysms, in which mortality is increased mainly due to thoracic aorta dissection.[8]

There is scanty data on the epidemiology of TAK. A population-based study of Olmsted County, Minnesota (USA) found an incidence rate of 2.6 cases/1 000 000 per year,[9] while a United Kingdom population study found an incidence rate of 0.8 cases/1 000 000 per year with a prevalence of 4.7/1 000 000.[10] Studies from East Asia on Asian subjects have reported higher incidence rates than in whites, but estimates are often biased by hospital-based study designs and imprecision in sampling. In Japan, an incidence rate of 1.5 cases/1 000 000/year[11] has been reported.[12] The female:male ratio is approximately 9:1 in Europe and Japan,[13,14] but close to 1.5:1 in India.[15] The typical age of onset is 20–30 years, but onset can also occur at paediatric ages.[13] The 5 year survival rates are in the range of 90–95%.[9] Mortality is increased in patients with severe vascular complications, including aneurysmal rupture, myocardial infarction, heart failure, and cerebrovascular accidents.[9]

Classification criteria

Criteria for the classification of GCA and TAK were published by the American College of Rheumatology (ACR) in 1990 (Tables 133.1 and 133.2).[16] These criteria were developed to distinguish a specific type of vasculitis among patients with various vasculitides, but not to differentiate patients with vasculitis from those without. Therefore, while they are helpful to recruit patients into clinical trials, it is not appropriate to use them to make a diagnosis of GCA or TAK, respectively, in individual patients.

There is also a set of criteria that classifies patients with TAK into five subtypes depending on the vessels involved on angiography (Table 133.3).[14] Typically, in white patients the branches of the aortic arch are most commonly (38–98%) involved, but the renal arteries and the abdominal aorta are also affected in approximately one-third of cases.[13] Involvement of other arteries is less frequent but by no means exceptional. Stenoses are by far the most common lesions, followed by occlusions, but dilatations and frank aneurysms are also recognized complications of TAK.[13]

Aetiology and pathogenesis

Genetics

The *HLA-DRB1*04* allele is associated with susceptibility to GCA.[2,18] Because MHC alleles function as antigen-presenting

Table 133.1 American College of Rheumatology 1990 classification criteria for giant cell arteritis[16]

Criterion	Definition
Age at disease onset ≥50 years	Development of symptoms or findings beginning at age ≥50
New headache	New onset of or new type of localized pain in the head
Temporal artery abnormality	Temporal artery tenderness to palpation or decreased pulsation, unrelated to arteriosclerosis of cervical arteries
Elevated ESR	ESR ≥50 mm/1st hour by the Westergren method
Abnormal artery biopsy	Biopsy specimen with artery showing vasculitis characterized by a predominance of mononuclear cell infiltration or granulomatous inflammation, usually with multinucleated giant cells

ESR, erythrocyte sedimentation rate.

For purposes of classification, a patient with vasculitis is said to have giant cell arteritis if at least three of these five criteria are present. The presence of any three or more criteria yields a sensitivity of 93.5% and a specificity of 91.2%.

From Hunder et al.[16]

Table 133.2 American College of Rheumatology classification criteria for Takayasu's arteritis[17]

Criteria	Definition
Age at disease onset	Development of symptoms or findings related to Takayasu's arteritis at age <40 years
Claudication of extremities	Development and worsening of fatigue and discomfort in muscles of one or more extremity while in use, especially the upper extremities
Decreased brachial artery pulse	Decreased pulsation of one or both brachial arteries
BP difference >10 mmHg	Difference of >10 mmHg in systolic blood pressure between arms
Bruit over subclavian arteries or aorta	Bruit audible on auscultation over one or both subclavian arteries or abdominal aorta
Arteriogram abnormality	Arteriographic narrowing or occlusion of the entire aorta, its primary branches, or large arteries in the proximal upper or lower extremities, not due arteriosclerosis, fibromuscular dysplasia, or similar causes: changes usually focal or segmental

BP, blood pressure.

For purposes of classification, a patient is said to have Takayasu's arteritis if at least three of the six criteria are present. The presence of any three or more criteria yields a sensitivity of 90.5% and a specificity of 97.8%.

From Arend et al.[17]

Table 133.3 Classification of Takayasu's arteritis based on the vessels involved on angiography

Type	Vessels involved
I	Branches from the aortic arch
IIa	Ascending aorta, aortic arch, and branches of the aortic arch
IIb	Ascending aorta, aortic arch and its branches, and thoracic descending aorta
III	Thoracic descending aorta, abdominal aorta, and/or renal arteries
IV	Abdominal aorta and/or renal arteries
V	Combined features of types IIb and IV

From Moriwaki et al.[14]

molecules, the association with the *HLA-DRB1*04* allele suggests that this allele may be implicated in presenting yet unidentified pathogenic antigens. In addition, this allele may be a marker of disease severity.[18] GCA is also associated with the *MHC B*15* allele as well as with the MHC class I chain-related gene A (*MICA*) *A5* allele independently of linkage disequilibrium with *HLA-B*15* and of the association with *HLA-DRB1*04*.[19] Functional polymorphisms of TNFα,[20] but not interleukins IL-6 or IL-12 have been linked to increased susceptibility to developing GCA.

Genetic factors may also play a role in determining susceptibility to TAK. The *HLA B52* and *B39* alleles are found with increased frequency in Japanese patients with TAK, although associations with *HLA* genes in different populations have proved inconsistent.[21] There are also reports of TAK cases in families and monozygotic twins.[21] Furthermore, different patterns of vascular involvement have been described in different ethnic groups.[21]

Aetiology

The aetiology of GCA remains unclear. Its higher incidence in Scandinavian countries and in populations of Scandinavian descent in North America suggest that both genetic and environmental risk factors may be involved. The infectious aetiology would also be consistent with observed cyclic patterns of incidence rates of GCA.[4] However, studies that have searched for evidence of infectious agents in the sera and in temporal artery specimens have provided conflicting results.[22] Such discrepancies do not necessarily rule out a pathogenic role for infection triggers and may be explained by a 'hit and run' mechanism of disease induction, i.e. triggering of the immune response by a microorganism followed by clearance of the offending agent. It is also conceivable that different agents may lead to the development of the same vasculitis in different individuals by activating similar immune pathways.

Traditional cardiovascular risk factors also modulate susceptibility to GCA. In particular, case-control studies have linked susceptibility to GCA to smoking and atherosclerosis.[23,24]

The aetiology of TAK is unknown. A number of infectious agents including *Mycobacterium tuberculosis* have been implicated as triggers, but none has conclusively been proven responsible.[21]

Pathology

Histologically, GCA is characterized by intimal hyperplasia and by a transmural inflammatory infiltrate mainly consisting of CD4+ lymphocytes and macrophages with a variable admixture of neutrophils and eosinophils. In addition, in approximately 50% of cases giant cells can be detected at the intima–media junction (Figure 133.1).[2] The affected arteries typically show 'skip' inflammatory changes most pronounced in the inner portion of the media adjacent to the internal elastic lamina, which appears disrupted.[25,26] However, in some cases the inflammation may be restricted to the vasa vasorum, to the periadventitial small vessels, or both (Figure 133.1).[27] These histological patterns have distinctive clinical correlations. More specifically, patients with inflammation confined to the vasa vasorum have clinical features similar to those of patients with transmural inflammation, whereas patients with periadventitial inflammation have lower inflammatory markers at diagnosis as well as less frequent constitutional and cranial manifestations including headache, scalp tenderness, and abnormalities of the temporal arteries.[27] In contrast, visual loss is equally represented in all patients with GCA regardless of their histological pattern.[27]

It is important to appreciate that marked fibrinoid necrosis is not part of the pathological abnormalities found in GCA. If a biopsy shows extensive fibrinoid necrosis, alternative diagnoses such as anti-neutrophil cytoplasmic antibodies (ANCA)-associated vasculitis (see Chapter 132) should be considered.

The histological alterations found in TAK are similar to, and often indistinguishable from, those observed in GCA.[28] The inflammatory infiltrate is mainly localized around the vasa vasorum in the adventitial layer and comprises B lymphocytes, αβ and γδ T lymphocytes, NK cells, dendritic cells, macrophages, and sometimes giant cells.[28]

Pathogenesis

A variety of cell types are involved in inducing and maintaining inflammation in GCA. Normally, large- and medium-sized arteries harbour dendritic cells located at the adventitia–media junction.[29] These dendritic cells express Toll-like receptors, which are able to stimulate the dendritic cells via their binding to specific ligands, including mediators synthesized or induced by infectious agents.[1] Dendritic cells in the temporal arteries from GCA patients have an activated phenotype, although the mechanisms leading to their activation are still in dispute. Activated dendritic cells release chemokines that recruit CD4+ lymphocytes and macrophages through the vasa vasorum into the vessel wall. In addition, they also
Fig. 133.1 Histological patterns of temporal arteries in giant cell arteritis: (A) Classical histological transmural inflammatory infiltrate with reduction in vessel lumen (H&E, 40×). (B) Vasa vasorum vasculitis (arrow). Note the preserved media and the lymphocytic infiltration around a small adventitial vessel (H&E, 100×). (C) Periadventitial inflammation characterized by small lymphocytic cuffs around periadventitial vessels (arrows). Note the preserved media (H&E, 20×).
Dr Alberto Cavazza, Pathology Department, Reggio Emilia Hospital.

provide costimulatory signals required for lymphocyte activation.[30] CD4+ lymphocytes are stimulated both by unknown antigens and by dendritic cells and, once activated, secrete the proinflammatory cytokines IL-1β, IL-2, IL-6, and interferon-γ.[30] In particular, interferon-γ is produced almost exclusively by a subset of CD4+ lymphocytes found in the adventitia.[30] Interferon-γ is found in most samples from patients with GCA but not in those from patients with PMR, and its expression correlates with the risk of developing GCA-related ischaemic complications.[30] These findings suggest that interferon-γ is critically involved in the pathogenesis of arteritis and of its ischaemic complications.[31] Interferon-γ acts, at least in part, by stimulating macrophages and, more specifically, by inducing the synthesis of platelet-derived growth factor (PDGF) by macrophages at the media–intima junction.[30] In turn, PDGF leads to intimal hyperplasia and thus to luminal narrowing or occlusion, which clinically translates into an increased risk of vascular ischaemic events.[32] Following stimulation by lymphocytes, macrophages (as well as circulating monocytes) also produce other inflammatory molecules, including TNFα, IL-1β, and IL-6.[33] Systemic release of inflammatory cytokines by monocytes plays a role in causing constitutional manifestations in both PMR and GCA.[33] However, IL-6 has not only a proinflammatory action, but also a protective effect against ischaemic events in GCA, since its expression in the temporal arteries and its circulating concentrations are significantly lower in patients with ischaemic complications.[34]

While adventitial macrophages specialize in producing proinflammatory cytokines, macrophages in the media primarily cause damage to the vessel wall and fragmentation of the internal elastic lamina by synthetizing matrix metalloproteinases and oxygen-derived free radicals.[1,33] These destructive processes are counterbalanced by tissue repair mechanisms including neoangiogenesis.[35] Mediators such as PDGF, IL-6, and vascular endothelial growth factor (VEGF) are mainly responsible for inducing tissue repair.[35]

An immune-mediated response also appears to be involved in the pathogenesis of TAK.[28] Because dendritic cells colocalize with lymphocytes, they may be involved in their activation. T-cell receptor (TCR) αβ and γδ gene usage is restricted, which suggests that T cells may target specific, yet unidentified, antigens. A possible target is a 65 kD heat shock protein, which is highly expressed in the media and vasa vasorum in TAK and is known to induce a strong response by γδ lymphocytes.[36] Lymphocytes and NK cells cause vascular injury by direct cytotoxicity, while both lymphocytes and macrophages release proinflammatory chemokines and cytokines, including TNFα, IL-1, and IL-6.[28] In addition, macrophages secrete matrix metalloproteinases and free oxygen radicals, leading to arterial wall damage, and PDGF, leading to intimal hyperplasia. A significant proportion of patients with TAK have circulating anti-endothelial cell antibodies (AECA), which can cause vascular complement-dependent cytotoxicity.[37] However, AECA are not consistently found in patients with TAK.[37]

Clinical manifestations

The onset of GCA is gradual, but can also be abrupt.[2] The most frequent symptom of GCA is new onset of headache (or worsening of pre-existing headache), which affects two-thirds of patients. The headache is predominantly localized to the temporal area, but may also be felt over other sites such as the occipital area.[2] The pain is often unrelenting and responds poorly to common painkillers. One-half of patients with GCA also report dysaesthesia of the scalp worsened by combing the hair, mostly associated with headache.

About one-half of patients have constitutional manifestations including fever, malaise, depression, anorexia, and weight loss.[1] The fever is usually low-grade, but it can reach 39–40 °C in about 15% of cases.[2] In a minority of patients, systemic manifestations can be the only features of GCA.

Partial or complete loss of vision in one or both eyes occurs in up to 20% of patients, most often at disease onset. Visual loss is typically related to anterior ischaemic optic neuropathy (AION) caused by occlusive arteritis of posterior ciliary artery and, less commonly, by retinal artery occlusion. Unilateral visual loss can be followed by visual loss in the other eye within a couple of weeks if the patient is not promptly treated with glucocorticoids. Rarely, posterior ischaemic optic neuropathy (PION) or cortical ischaemia is responsible for visual loss. Amaurosis fugax (transient visual loss) occurs in 10–15% of patients.[1] In nearly one-half of patients, amaurosis fugax heralds permanent visual loss if treatment with glucocorticoids is not started immediately.

Cerebrovascular ischaemic events, including transient ischaemic attacks and stroke, are a rare but recognized complication of GCA. These events are usually precocious and mostly due to vasculitis of the carotid or of the vertebrobasilar arteries. Intracranial vasculitis has been reported in patients with GCA, but only in extremely rare cases.[38] A moderately but not very high erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) at diagnosis, older age at diagnosis, hypertension, a past history of ischaemic heart disease, and the absence of systemic manifestations have been mapped to an increased risk of cranial ischaemic events.[39–41] The development of any ischaemic complication is also associated with the risk of developing subsequent ischaemic manifestations, including visual loss.[41]

Jaw claudication due to ischaemia of the masticatory muscles is noted in about one-half of patients. Jaw claudication is highly suggestive (although not pathognomonic) of GCA. Occasionally, claudication may affect the muscles of the tongue or those involved in swallowing. Severe ischaemia leading to necrosis of the scalp, tongue, or lips is exceedingly rare.[2,42]

Cough occurs in around 10% of GCA patients, presumably as a consequence of ischaemia of the cough receptors. Cough associated with GCA may or may not be associated with sore throat and hoarse voice.[2]

Peripheral neuropathy complicates GCA in approximately one-sixth of patients. Both the upper and the lower limbs may be affected.[1,2]

About 10–27% of patients with GCA develop clinical manifestations related to large-vessel involvement including arm claudication, arterial bruits, and heart murmurs.[2,43] More specifically, thoracic aorta aneurysms, abdominal aorta aneurysms, and large-vessel stenoses (predominantly of the upper limbs) develop in 9.3%, 6.5%, and 13.5% of unselected GCA patients, respectively.[44] These manifestations usually become apparent only 3–4 years after the onset of the symptoms of GCA. However, although overt features of large-vessel involvement are relatively late events in GCA, evidence of large-vessel involvement can be demonstrated early on in the disease course. A sensitive technique such as ^{18}F-fluorodeoxyglucose positron emission tomography (FDG-PET) is able to reveal large-vessel vasculitis in as many as 83% of patients with

early GCA.[45] Other investigations such as colour Doppler sonography (CDS) and MRI are also able to document early large-vessel vasculitis.[46]

Compared to unselected patients with GCA, those with large-vessel vasculitis have less frequently cranial symptoms and a positive TAB,[8,43] while they have an increased risk of developing aortic aneurysms.[44] There also is a slightly increased risk of mortality due to thoracic aorta dissection. Yearly chest radiographs are recommended to screen for thoracic aorta aneurysms, while vascular imaging techniques are useful to study and monitor large-vessel disease.

PMR is the most frequent musculoskeletal manifestation of GCA, occurring in around 40% of patients.[1] Other musculoskeletal manifestations affect approximately 25% of patients and include carpal tunnel syndrome, non-erosive asymmetric peripheral arthritis (predominantly affecting the knees and wrists), and distal swelling with pitting oedema (also known as remitting symmetric seronegative synovitis with pitting edema, RS3PE).[1]

Other infrequent clinical manifestations of GCA include facial swelling, odontogenic pain, chin numbness, glossitis, submandibular swelling, audiovestibular dysfunction, diplopia, Charles Bonnet syndrome (visual hallucinations probably due to ischaemia of the visual pathways), pericardial and pleural effusions, myocardial infarction, female genital tract and breast involvement, syndrome of inappropriate antidiuretic secretion, dysarthria, and noises in the head (e.g. sounding like turbine engines and tree frogs).[1,2,47] These manifestations can usually be reversed by glucocorticoids.

Physical examination in GCA may reveal tenderness, thickening, nodules, and occasionally erythema of the superficial temporal arteries.[2] Temporal artery pulses may be decreased or absent. In patients with large-vessel involvement bruits may be heard, particularly over the epiaortic vessels.

TAK is traditionally considered a triphasic disease, although overlap between stages may occur.[48] Phase 1, or 'pre-pulseless' disease, is characterized by constitutional and musculoskeletal manifestations such as fatigue, fever, weight loss, myalgia, and joint pain. Arthritis proper is uncommon.[49] Vascular abnormalities are absent at this stage. Phase 2 involves manifestations related to vascular inflammation ('pulseless disease'). These include carotidodynia and clinical features due to insufficient vascular supply to limbs and organs, such as Raynaud's phenomenon, limb claudication, dizziness, and hypertension. Finally, phase 3 refers to the final or 'burnt out' stage, when inflammation has abated, but symptoms and signs of vascular insufficiency persist. Table 133.4 summarizes the frequency of the most common clinical manifestations in different countries.

Most patients develop manifestations of vascular insufficiency in the upper limbs, ranging from a feeling of numbness or coldness to claudication, Raynaud's phenomenon or, rarely, distal gangrene.[13,51] The lower limbs are less frequently affected.[51] Physical examination reveals decreased or absent arterial pulses, and arterial bruits consistent with stenosing vasculitis. Bruits are mainly heard over the carotid, subclavian, and abdominal arteries.[13,49] Differences exceeding 10 mmHg in blood pressure readings in the arms are noted in most patients.[13]

Neurological manifestations are reported by approximately one-third of patients and are related to involvement of the carotid or vertebral arteries.[13,51] Neurological features include headache, dizziness, lightheadedness, and less commonly ischaemic events, syncope, or seizures.[13,48]

Ocular disease in TAK can be due to hypoperfusion (typically in the presence of severe carotid stenosis), but can also to unrecognized, untreated hypertension or to glucocorticoid treatment. Blurred vision, often dependent on posture, is described by up to one-third of patients, but fully-fledged ischaemic retinopathy is rare.[49] Signs of ischaemic retinopathy resemble those seen in diabetes mellitus and include microaneurysms and venous beading.[49] Rarely, in advanced disease retinal haemorrhages, arteriovenous anastomoses, optic disk atrophy, and retinal detachment may occur.[49]

Hypertension is associated with renal artery stenosis and is observed in approximately one-half of patients.[13] This complication is more common in Chinese and Indian patients than in whites. Renal artery occlusion leading to renal failure ('Schrumpfniere') can cause refractory hypertension requiring nephrectomy of the

Table 133.4 Frequencies of main clinical manifestations of Takayasu's arteritis in different countries

Clinical manifestations	Country and number (n) of patients studied			
	Japan[50] (n = 52)	USA[51] (n = 60)	India[52] (n = 45)	Italy[13] (n = 104)
Constitutional manifestations	27%	43%	16%	ns

Dizziness	40%	35%	44%	30%
Carotidodynia	21%	32%	4%	ns

ns, not specified.

affected kidney. Blood pressure readings may be unreliable in the presence of vascular stenosis, and should be obtained in all four limbs to minimize the risk of spuriously low values. In patients with diffuse stenoses of all limbs, central blood pressure measurement may be required. There are also scattered reports of renal amyloidosis, glomerulonephritis, and mesangial disease associated with TAK.[49]

Heart involvement occurs in 8–40% of patients and can be multifactorial in origin.[49,51] Coronary artery involvement can cause angina, myocardial infarction, heart failure, and sudden death. Myocarditis has been documented histologically in some patients, while in others arteritis may cause aortic or, less commonly, mitral regurgitation.[48,49]

Pulmonary artery involvement is found in one-half of patients, although it remains subclinical in many of those affected.[48,49] Interstitial lung disease has also been occasionally noted.[49]

Intestinal involvement in TAK is seen in approximately 10% of patients.[53] It is often due to an associated Crohn's disease, but ulcerative colitis has also been reported.[53]

A variety of skin changes have been described in TAK, including erythema nodosum, pyoderma gangrenosum, panniculitis, facial lupus, and erythema multiforme.[49,53] Some of these changes may reflect an underlying inflammatory bowel disease.

There are no established criteria to assess disease activity in TAK. The National Institute of Health (NIH) criteria consider the disease active if a patient has new onset or worsening of at least two out of the following items: raised ESR, systemic features, manifestations of vascular ischaemia, and typical lesions on angiography.[51] However, the sensitivity of these criteria is only 39%.[51]

A newer tool is the Indian Takayasu Activity Score (ITAS), which assesses disease activity in six domains (one for systemic manifestations and five for organ involvement). Physician global opinion and inflammatory markers are also recorded. TAK is considered active if there is evidence of disease activity in at least one domain. However, false-negative results have been obtained using the ITAS in 31% of patients with active TAK.[54]

Investigations

Laboratory tests

Inflammatory markers, in particular the ESR and CRP, are usually raised at diagnosis before the onset of glucocorticoid treatment in GCA patients. Normochromic normocytic anaemia, thrombocytosis, hypoalbuminaemia, and raised α_2-globulin may also be present as part of the systemic inflammatory process. In a minority of cases the ESR and, less frequently, CRP may be normal at diagnosis.[2,55] Elevated inflammatory markers are useful to assess disease activity. The CRP is more specific than the ESR in measuring inflammation, and is thus better suited to assess disease activity and guide therapeutic decisions.[1,2] Flares and relapses are often heralded by an increase in inflammatory markers, but an increase in ESR or CRP does not necessarily portend worsening of disease activity.[1,2] Therefore, treatment decisions should not be based solely on the behaviour of markers of inflammation. A possible exception is ocular GCA (GCA affecting the eye only), where monitoring of inflammatory markers is the only way to assess disease activity, since by definition patients with ocular GCA have no symptoms or signs of GCA except for ocular involvement.

Approximately one-quarter of GCA patients with active disease have a raised alkaline phosphatase, which normalizes following the onset of glucocorticoid treatment.[56] Patients with active GCA also test positive for anti-cardiolipin antibodies more often than age- and gender-matched controls, but the presence of anti-cardiolipin antibodies is not associated with an increased risk of thrombosis.[57] Anti-cardiolipin antibody levels normalize after treatment onset, but may rise again during flares or relapses.

Occasionally, thyroid function tests may be abnormal.

About 70–80% of patients with active TAK have elevated inflammatory markers such as ESR and CRP.[9,51] Normocytic anaemia as well as moderate leucocytosis and thrombocytosis can also occur.[9] However, inflammatory markers have only limited sensitivity and specificity for active disease. In a study from the NIH, the ESR was raised in only 72% of patients with active disease and normal in only 56% of those in remission.[51] IL-6 may be a better indicator of disease activity, but is not routinely measured.[58] Hypergammaglobulinaemia is found in up to one-third of patients, while anti-nuclear antibodies and rheumatoid factor are usually negative.[9] AECA are neither sensitive nor specific and have no role in the diagnostic work-up or in assessing disease activity.

Temporal artery biopsy

TAB is considered the gold standard for the diagnosis of GCA. However, TAB is negative in at least 10% of patients with clinical GCA even when performed accurately 'by the book'.[59] There are a number of reasons why TAB may be negative in patients with GCA. First, inflammatory changes affect the temporal arteries in a segmental fashion, so that a 'sampling error' may occur if the particular vessel segment sampled is not inflamed. Second, in some patients with GCA the temporal arteries may be truly spared by the inflammatory process. Particularly patients with large-vessel involvement have negative TAB findings in a quite high proportion (42%) of cases.[43] Third, inadequate sampling, such as excision of small (<2 cm) vessel segments, may significantly contribute in clinical practice to obtaining false-negative biopsy findings. Finally, glucocorticoids therapy may decrease the rate of positive TAB findings. In newly diagnosed GCA patients treated with high-dose glucocorticoids, TAB is positive in 78% of patients treated for less than 2 weeks, in 65% of those treated for 2–4 weeks, but only in 40% of those treated for longer than 4 weeks.[60] Therefore, while glucocorticoid therapy should be promptly commenced if GCA is strongly suspected, it is preferable to perform TAB within 1 week or so of onset of glucocorticoid therapy.

Fundoscopy

All patients with suspected GCA and visual loss should undergo an ophthalmologic examination including fundoscopy. In most cases, acute visual loss in GCA is due to AION. A chalky white optic disc oedema on fundoscopy is typical of AION, representing infarction of the optic nerve head caused by vasculitis, while fluorescein angiography usually demonstrates extensive choroidal hypoperfusion.[61] Central retinal artery and cilioretinal artery occlusion are less common causes of visual loss[61] that can also been appreciated on ophthalmoscopy, although fluorescein angiography may be required to buttress the diagnosis.

PION is an infrequent cause of ischaemic visual loss in GCA.[61] It differs from AION, in that the optic disc has a normal appearance

on fundoscopy in the acute phase, although optic disk pallor usually ensues 4–6 weeks later.[62] Finally, in extremely rare cases blindness in GCA can be the result of cortical ischaemia, which obviously leaves the optic disc intact.

Imaging techniques

CDS, magnetic resonance angiography (MRA), and contrast-enhanced CT angiography (CTA) can visualize both the vessel wall and the lumen of the aorta and its major branches.[46] All these techniques can aid in diagnosing early large-vessel vasculitis by demonstrating inflammation of the arterial wall before vascular complications develop. Early inflammatory signs are vessel wall thickening as well as the 'halo' sign on CDS (a hypoechoic rim surrounding the lumen of an inflamed artery), vessel wall oedema (on MRA) and contrast enhancement (on MRA and CTA).[46] These techniques are also useful to monitor luminal changes over time and may replace digital subtraction angiography (DSA) in this regard.[46] On a note of caution, it should be pointed out that vessels that appear unaffected on CDS, CT, and MRI may develop vessel lumen alterations later.[63] It should also be appreciated that inflammatory changes depicted by CDS, CT, and MRI may persist for a while despite clinical remission, particularly in the large vessels.[63] PET may be more specific for active vascular inflammation in this regard.[46] Finally, luminal changes need not always be due to active vasculitis. For instance, vessel stenosis may also be to postinflammatory scarring, while aneurysms may grow in size due to intraluminal pressure even after inflammation has abated.[46]

DSA can reveal stenoses or aneurysms of the large vessels, but cannot visualize the vessel wall. PET is very sensitive in revealing inflammation of large vessels, but does not provide anatomical details of the vessels involved. The choice of the particular technique to be used in the individual patient thus critically depends on the vessels to be examined and on the type of information that one wishes to obtain.[46]

All vascular imaging techniques are to some degree operator-dependent and should be performed and interpreted by physicians with an expertise in vasculitis.

MRI and CT

MRI is able to show increased vessel wall thickness and oedema of inflamed large vessels.[46] MRI performed with contrast medium can also show enhancing vascular lesions in inflamed arteries.[46] Because vessel wall thickening and oedema precede the development of stenoses or aneurysms, MRI can aid in diagnosing early large-vessel vasculitis at a stage when conventional angiography (which only depicts the vessel lumen) is still negative. MRI (and CT) are particularly useful in evaluating deep, large vessels such as the thoracic and the abdominal aorta, which are frequently involved in GCA and TAK (Figure 133.2). Both MRI and CT can be combined with angiography to document alterations of the vessel lumen. MRI and CT are overall equally sensitive and specific in assessing large-vessel alterations. Compared with CT, MRI has the advantage of not exposing patients to radiation, although it may spuriously accentuate the appearance of stenoses.[46]

Preliminary data suggests that high-field (1.5–3 T) MRI may be very sensitive and specific in showing temporal artery inflammation.[64] In contrast, lower-field (1 T) MRI of the temporal arteries has poor sensitivity (27.2%) although good specificity (88.9%) for diagnosing GCA defined according to the ACR criteria.[65]
Fig. 133.2 Enhanced CT of a patient with giant cell arteritis involving the descending thoracic aorta (axial section). Note the thickened wall of the thoracic aorta (*).

Colour Doppler sonography

CDS combines imaging of the vessel wall with flow-velocity determination, and can thus assess both vessel anatomy and the lumen. The most specific and sensitive sign for the diagnosis of large-vessel vasculitis is a concentric hypoechogenic mural thickening ('halo' sign), reflecting vessel wall oedema.[66] This sign can be observed early on both in the temporal arteries and in the large vessels affected, and precedes the appearance of alterations of the vessel lumen such as stenoses or aneurysms (Figure 133.3). A recent meta-analysis which used a positive TAB as standard for the diagnosis of GCA demonstrated a sensitivity of 75% and a specificity of 83% for the halo sign in the temporal arteries.[67] The halo sign disappears within a few days to weeks from the temporal arteries following the onset of glucocorticoid treatment, whereas it may persist for longer periods of time in the large vessels involved.[46,66]

CDS has a 10-fold greater resolution than MRI or CT. Other advantages of CDS include its limited cost, the relatively short time required for the examination, and the absence of radiation. However, CDS is more operator-dependent than other imaging techniques. In addition, CDS cannot visualize some arteries covered by bones, such as the thoracic aorta, and may not image the abdominal aorta well when bowel gases and excessive fat tissue are interposed between the probe and the aorta.[46]

FDG-PET

PET (18F-Fluorodeoxyglucose positron emission tomography) is a nuclear medicine technique that is very sensitive in detecting increased uptake of a fluorine-labelled glucose analogue (FDG) by metabolically active cells, including inflammatory cells. PET is very useful in diagnosing large-vessel involvement because of its capacity to reveal inflammatory cell infiltration of the vessel wall, which
Fig. 133.3 Colour Doppler sonography of an inflamed temporal artery from a patient with giant cell arteritis (transverse section). The image shows the classical 'halo' sign, a hypoechoic rim (double arrows) around an inflamed temporal artery. is one of the earliest events occurring in vasculitis (Figure 133.4).[46] In a study on 35 patients with new-onset, untreated GCA increased vascular uptake was observed in 83% of patients, mainly in the subclavian arteries (74%), in the aorta (>50%), and in the femoral arteries (37%).[45] A distinctive advantage of PET is its capacity to reveal both the grade and the extent of inflammation. Furthermore, because of its high sensitivity in revealing inflammation, PET may be a valuable tool in assessing disease activity over time, including response to therapy.[46] Compared with MRI, PET appears to be more sensitive in detecting vascular inflammation in the early stages of large-vessel vasculitis, and may also be superior in monitoring disease activity during immunosuppressive therapy.[46] However, the absence of validated criteria of disease activity hamper a proper assessment of the performance of PET.[68]

PET findings of vascular changes are not invariably due to vasculitis, and in fact may be secondary to atherosclerosis. Differentiating vasculitis from atherosclerosis is not always straightforward, but there are some clues that preferentially point to a diagnosis over the other (Box 133.1).[46] First, vasculitic lesions are usually characterized by more intense vascular uptake of FDG. Second, they have a smooth appearance that extends over long vascular segments, whereas atherosclerotic plaques are more irregular, with areas of high uptake close to others of lesser uptake. Finally, atherosclerosis and vasculitis tend to involve at least in part different types of vessel. Therefore, the pattern of vessels affected may provide some clues to the underlying disorder. Needless to say, vasculitis and atherosclerosis may also coexist in the same patient.

PET is minimally invasive and involves a very small dose of radiation. However, despite its merits, PET has some limitations. An important limitation is the lack of visualization of the temporal arteries, which is due both to the high background signal of the neighbouring brain and to the small diameter of the temporal arteries, which is below the resolution threshold of the PET scanners currently available.[46] Other limitations of PET are the high costs of the procedure, its long duration, and its limited availability.

Digital subtraction angiography

DSA is an excellent technique to document alterations of the vessel lumen such as stenoses or aneurysms in large-vessel vasculitis. Typical

---

Box 133.1 Differential diagnosis of established Takayasu's arteritis

Non-inflammatory vascular diseases
- Fibromuscular dysplasia
- Ehlers–Danlos syndrome
- Marfan syndrome
- Coarctation of the aorta
- Ergotism
- Neurofibromatosis

Diseases associated with large-vessel alterations
- Tuberculosis
- Syphilis
- Mycosis
- Spondyloarthropathies

Vasculitides involving large vessels
- Adamantiades–Behçet disease
- Cogan's syndrome
- Kawasaki's disease

angiographic findings are long, smooth vessel stenoses and, less frequently, occlusions and aneurysms.[46] However, none of these lesions occur early on. On the other hand, vessel wall thickening and mural oedema, which represent early vasculitic lesions, cannot be appreciated on angiography. Therefore, angiography is not useful in diagnosing early large-vessel vasculitis.[46] DSA also involves exposure to radiation and carries a risk of ischaemic complications due to the contrast medium.[46] Despite these limitations, angiography remains a helpful technique for guiding interventional procedures, and may also be used to monitor established lesions by means of serial angiograms.[46]

Management

Glucocorticoids

Glucocorticoids remain the cornerstone of treatment of GCA and TAK. In GCA, an initial dose of 40–60 mg daily of prednisone or its equivalent is adequate in most cases, while patients at high risk of developing ischaemic complications require higher dosages (in the range of 1 mg/kg per day). Pulse glucocorticoid therapy has been advocated for GCA patients with visual loss.[69] However, there is no evidence that pulse therapy is superior to oral glucocorticoids in preventing ischaemic complications including visual loss.[70] Regardless of the route of administration (oral or intravenous), glucocorticoids are very effective in rapidly preventing ischaemic complications, although they usually cannot reverse them.[71] Patients with active large-vessel vasculitis should receive glucocorticoids at appropriate dosages even in the absence of cranial vessel involvement to prevent vascular complications such as stenoses or aneurysms.

Alternate-day administration of glucocorticoids has been proposed to limit the occurrence of glucocorticoid-related adverse events. However, this regimen is associated with a much higher risk of relapses compared with daily treatment (70% vs 20%) and thus cannot be recommended.[72] Treatment with glucocorticoids at lower doses (10–40 mg/day) has also been proposed,[73] but there is insufficient evidence to support this regimen. Currently, the British Society for Rheumatology (BSR) recommends that the initial glucocorticoid dose be given for 3–4 weeks until clinical manifestations and laboratory alterations normalize. Subsequently, the glucocorticoid dose can be reduced by 10 mg every 2 weeks to 20 mg, then by 2.5 mg every 2–4 weeks to 10 mg, and then by 1 mg every 1–2 months provided there is no relapse.[74] Prophylaxis for osteoporosis should be implemented in all patients according to current guidelines.[74] Gradual tapering of glucocorticoids minimizes the risk of disease flares, although flares may still develop in some patients despite cautious tapering.[1,2] Flares are usually milder than clinical manifestations at onset, and can often be easily managed by increasing the glucocorticoid dosage.[75]

The majority of patients with GCA are able to discontinue glucocorticoids within 6 months to 2 years from the onset of treatment.[2] However, patients with PMR and GCA[76] and those with highly elevated inflammatory indices require longer glucocorticoid treatment.[40] A minority (up to one-third) of patients may require low-dose glucocorticoid treatment indefinitely.[77]

Glucocorticoids are also the mainstay of treatment of TAK. Although never formally tested in controlled trials, the NIH experience has shown their efficacy in improving clinical and laboratory parameters and preventing vascular complications.[9] The European League Against Rheumatism (EULAR) recommends that prednisone 1 mg/kg per day (maximum 60 mg/day) be used as induction therapy and slowly tapered after 1 month to a maintenance dose.[78] The vast majority (>90%) of TAK patients respond to glucocorticoids, but over two-thirds of them relapse upon tapering or discontinuation of glucocorticoid therapy.[79]

Immunosuppressive agents

Despite their remarkable efficacy, the use of glucocorticoids is fraught with many potential adverse events. Therefore, in patients with longstanding disease and in those at risk for glucocorticoid-related adverse events, the use of steroid-sparing agents should be considered.

Azathioprine

Azathioprine at a dose of 2 mg/kg per day has modest steroid-sparing properties in GCA. However, the effect of azathioprine becomes apparent only after over a year of continuous treatment.[80]

Azathioprine (2 mg/kg per day) is one of the steroid-sparing agents recommended by EULAR for use in patients with refractory TAK.[78] Azathioprine provides symptomatic benefit and prevents vascular complications.[81]

Cyclophosphamide

Cyclophosphamide can be efficacious in TAK,[78] but concerns about its toxicity limit its use in clinical practice.[52]

Methotrexate

Three randomized controlled trials have assessed the efficacy of methotrexate in recent-onset GCA with conflicting results. A meta-analysis based on the results of these studies has shown that methotrexate used as adjunctive treatment in GCA at a mean dosage of 11.1 mg/week reduced the risk of a first and a second relapse by 35% and 51%, respectively.[82] However, despite a lower cumulative glucocorticoid dose in the group of patients that received methotrexate, the incidence of glucocorticoid-related adverse events was similar in both groups. In addition, the effect of methotrexate was noticeable only after 24–36 weeks. It is unclear whether methotrexate used at a higher dosages could prove more effective and act more rapidly in curbing disease activity in GCA.

Methotrexate (20–25 mg/week) is recommended by EULAR as a steroid-sparing agent in patients with refractory TAK.[78] Methotrexate can improve clinical manifestations and halt progression of vascular complications.[83]

Mycophenolate mofetil

Mycophenolate mofetil ameliorates clinical manifestations and reduces serum levels of inflammatory markers in active TAK.[84]

Rituximab

A single report has described successful treatment of recalcitrant GCA with the monoclonal anti-CD20 (anti-B cell) antibody rituximab combined with cyclophosphamide.[85]

Rituximab also seems to be a useful option for refractory TA. Three patients with disease refractory to previous agents, including TNF blockers, were treated successfully with rituximab.[86]

TNFα-inhibitors

A randomized controlled trial (RCT) has shown that adding infliximab to prednisone provides no significant benefit over and above that provided by prednisone alone in patients with newly diagnosed GCA.[87] Therefore, TNFα inhibitors have no indication for the treatment of new-onset GCA.

In contrast, TNFα blocking agents might have some efficacy in patients with relapsing GCA. An RCT demonstrated that treatment with etanercept 25 mg twice weekly resulted in a lower cumulative prednisone dose after 12 months in patients who were unable to taper the prednisone dose below 10 mg/day.[88] Similarly, a small RCT and uncontrolled observations have shown that TNFα blockade with infliximab or etanercept was effective in reducing glucocorticoid requirements in patients with long-standing, relapsing GCA.[88,89]

The TNFα inhibitors etanercept (50 mg/week) and infliximab (3–5 mg/kg every 6–8 weeks) also induced remission in 60% of patients with TAK refractory to standard treatment.[15]

Tocilizumab

The IL-6 receptor antagonist monoclonal antibody tocilizumab has been used at a dose of 8 mg/kg per month in seven patients with GCA characterized by large-vessel involvement.[90,91] Three patients were treatment-naive and four had refractory GCA. All patients achieved a rapid and complete clinical response and normalization of the inflammatory markers, while the prednisone dosage could be tapered down within 12 weeks. However, it is unclear whether tocilizumab can effectively prevent GCA-related cranial ischaemic events; even more so, as IL-6 may arguably have a protective role against GCA-related ischaemic events.

Tocilizumab has proved effective in four patients with TAK, one of whom was treatment-naive, one resistant to glucocorticoids, and two resistant to multiple drugs.[91,92]

Aspirin

Two retrospective studies have suggested that low-dose aspirin might prevent ischaemic complications related to GCA. In one study, only 8% of the aspirin-treated patients presented with cranial ischaemic complications, compared with 29% of the non-aspirin-treated patients. In patients treated with glucocorticoids, addition of aspirin to glucocorticoids led to lower rates of cranial ischaemic complications (3%) compared to those observed in patients treated with glucocorticoids alone (13%).[93] In another study, only 16% patients on anti-platelet or anti-coagulant therapy suffered a GCA-related ischaemic event, compared with 48% of those not receiving such therapy.[94] However, these putative beneficial effects of aspirin have not been confirmed by other studies.[39,95] A prospective, controlled study is needed to formally assess the efficacy of aspirin for GCA patients, particularly those that are at risk of developing ischaemic complications.

Revascularization procedures

Revascularization procedures are indicated in patients with severe vascular stenoses. Both angioplasty and stenting have high (~90%) success rates, although restenosis may occur.[96,97] Bypass grafts provide the longest-lasting patency rates. Percutaneous balloon angioplasty provides good results for limited lesions. Timing surgery to remission reduces the risk of restenosis from 40–50% to 10%.[96,97] Nephrectomy is indicated if a kidney is non-functional owing to renal artery occlusion.

Differential diagnosis

Visual loss, usually due to AION, is a precocious manifestation, often heralding GCA. In patients with visual loss, diagnosing GCA is easy in the presence of the other typical clinical manifestations. However, some patients can present, at least initially, with isolated visual loss. In these cases, the diagnosis of GCA rests on the demonstration of elevated inflammatory markers and of a positive TAB. AION should be differentiated from non-arteritic AION (NAION). NAION is much more common than AION, affects almost exclusively elderly white patients, and is characterized by unilateral sudden visual loss in the absence of cranial of systemic manifestations suggestive of GCA. Contralateral eye involvement in NAION can occur, but less is less frequent than in AION. Fundoscopy usually shows hyperaemic (less often pale) oedema of the optic disk with a small cup to disc ratio.[62]

Approximately 15% of elderly patients with fever of unknown origin (FUO) are eventually diagnosed as having GCA.[98] In these patients, the diagnosis of GCA can be secured by TAB or, in some cases, by demonstrating large-vessel vasculitis using imaging procedures.

Temporal artery involvement is mostly due to GCA, but in the odd case may also be related to granulomatosis with polyangiitis (Wegener's) or primary systemic amyloidosis. In such cases histological findings point to the correct diagnosis.

A new onset of headache is also the most frequent main presenting symptom of primary central nervous system vasculitis; however, cerebral vasculitis is very rarely observed in GCA.[38]

Early, 'pre-pulseless' TAK should be differentiated from infections, FUO, malignancies, and early arthritis. A high index of suspicion and the use of imaging techniques are required to arrive at a correct diagnosis. Established TAK should be differentiated from other vasculopathies and diseases associated with large-vessel alterations (Box 133.1).[99]

In most cases, a diagnosis can be made by considering the features associated with the diseases and by the appropriate laboratory tests. Non-inflammatory vascular diseases can be distinguished from TAK by imaging. In older subjects, TAK should be differentiated from GCA. Age older than 40–50 years, shoulder stiffness, scalp tenderness and a lower frequency of vascular insufficiency of the upper limbs point away from TAK and towards GCA.[100] However, a subset of GCA patients may have only large-vessel vasculitis virtually indistinguishable from TAK.[99]

Polymyalgia rheumatica

Bhaskar Dasgupta

Introduction

Polymyalgia rheumatica (PMR), a common inflammatory condition of older people, is characterized by bilateral proximal pain and morning stiffness, an acute-phase response involving elevated erythrocyte sedimentation rate (ESR) and/or C-reactive protein (CRP), and a rapid response to corticosteroids. This widely prevalent condition is subject to variations of practice in primary and secondary care[1] and is a common indication for long-term steroid use in the community.[2] Patients are therefore vulnerable to the manifold adverse events associated with prolonged corticosteroid therapy.

Accurate assessment of patient-based outcomes, disease activity, and course of disease are critical to balance the benefits of corticosteroids against the increased risk of adverse outcomes such as diabetic complications and fractures. There is also considerable uncertainty regarding diagnosis and outcomes in PMR.[3] Initial features may be variable, e.g. PMR without an elevated ESR is reported in up to 22% of patients and common mimicking conditions can present with the polymyalgic syndrome. There is no gold standard test and several diagnostic criteria have been used. This may explain the lack of agreement in PMR diagnoses between primary care physicians and rheumatologists and revision of diagnoses in 5–23% of patients on long-term follow-up.

An international initiative to address this diagnostic conundrum has led to classification criteria for the polymyalgic syndrome.[4] Most clinicians consider a rapid resolution of symptoms with corticosteroid therapy a diagnostic hallmark of PMR, though some studies report slower responses in many patients and lack of response may indicate an incorrect diagnosis. However, there is little evidence on what constitutes a typical response and how it relates to longer-term outcomes or revisions of the initial diagnosis.

It is accepted that around one-half of patients have one or more relapses and median duration of corticosteroid treatment around 2–3 years. PMR appears to be a heterogeneous condition. The prognostic factors at presentation that affect this heterogeneity of disease course, clinical outcomes, and duration of treatment are ill understood. This chapter discusses (1) the epidemiology of PMR; (2) the burden of disease, including the economic burden; and (3) the impact of PMR, particularly the initial response to corticosteroid therapy, on clinical and patient-based outcomes (early and long term), and examines the relationship between laboratory measures and clinical outcomes, functional status, and changes in quality of life (QoL),[4] potential medical errors in the diagnosis and management of PMR, occurrence of preventable complications,[5] and guidelines and audit standards for diagnosis and management.

Epidemiology

The epidemiology and population burden of PMR is documented in a limited number of studies.[5] The incidence of PMR varies markedly according to geographical region, with much higher rates in countries in the northern latitudes. In northern United States, the average annual age- and sex-adjusted incidence of PMR per 100 000 population 50 years of age or over is estimated at 58.7.(95% CI 52.8–64.7) with a significantly higher incidence in females (69.8; 95% CI 61.2–78.4) than in males (44.8; 95% CI 37.0–52.6). The incidence in the northern United States is similar to the incidence estimates from Denmark (68.3 per 100 000) and Norway (112 per 100 000), but is substantially higher than the figures reported in Göteborg, Sweden (28.6 per 100 000), Reggio Emilia, Italy (12.7 per 100 000) and Lugo, Spain (18.7 per 100 000).

A recent large primary care database study from the United Kingdom reported an incidence of 84 per 100 000 with a female:male ratio of 2.0.[6] This is the only study that also reported a marked increase in the incidence of PMR throughout the 1990s, from 69 per 100 000 person-years in 1990 to 93 per 100 000 person-years in 2001. A similar temporal increase in incidence was not observed in other studies. It is unclear whether there is a true increase in incidence of PMR, or overdiagnosis or increased recognition of PMR over time.

The prevalence of PMR among individuals over 50 years of age in the year 2000 is estimated at 739 per 100 000, with a higher prevalence in females than in males.[7] The prevalence increases dramatically with age: from 21 per 100 000 for ages 50–54 years to 4213 per 100 000 for ages 90–95 years. With these prevalence estimates, 711 000 Americans are estimated to have PMR. Survival was also examined in various studies and they all indicate that survival in PMR patients is similar to that in the general population. This has been in part attributed to increased medical surveillance during the disease course.

Classification criteria

Difficulties in diagnosing and classifying patients with PMR unrelated to lack of training and expertise are inherent to accepted

definitions of PMR. The proximal pain and stiffness syndrome, the commonly accepted phenotype of PMR, can occur at presentation in many other rheumatological and inflammatory illnesses, especially in older people. About one-half of patients diagnosed with PMR may have distal musculoskeletal manifestations such as peripheral arthritis, distal hand swelling with pitting oedema, and carpal tunnel syndrome. On the other hand, polymyalgic presentation is common, if not the rule, in late-onset rheumatoid arthritis and spondyloarthritis. Polymyalgia is also associated with giant cell arteritis (GCA) in 10–30% of cases. Heterogeneity in the clinical disease course, uncertainty regarding best disease assessment parameters, and the evolution of alternate diagnoses on follow-up complicate understanding and treatment of PMR. For all these reasons, recent guidelines on PMR opt for a safe and specific approach, preferring a relative underdiagnosis to an overdiagnosis of PMR.

A uniform responsiveness to low doses of corticosteroids has been assumed to be a cardinal feature of PMR. It is included in several popular diagnostic criteria and is commonly used by clinicians in both primary and secondary care to make a PMR diagnosis. However, there is little hard evidence to substantiate this assertion and a previous prospective inception cohort study of PMR showed that at 3 weeks after starting prednisolone 15 mg/day more than 55% failed a complete response to therapy as defined by greater than 70% improvement in pain, morning stiffness less than half an hour, and normal inflammatory markers.[10] This also emphasizes that clinical trials of disease-modifying anti-rheumatic drugs (DMARDs) and novel agents are needed to improve treatment efficacy in PMR.

In an international initiative sponsored by the European League Against Rheumatism (EULAR) and the ACR, candidate classification criteria for PMR were defined through systematic literature review, a three-phase consensus process, and a wider survey.[6] These criteria were then evaluated in a 6 month prospective cohort study of 125 patients with new-onset PMR and 169 non-PMR comparison subjects with conditions mimicking PMR. Potential criteria were assessed for their ability to discriminate PMR from other conditions and a scoring algorithm was developed.

New-onset bilateral shoulder pain in subjects aged 50 years or older and elevation of CRP and/or ESR are regarded as essential items for classification as PMR. The clinical scoring algorithm is based on morning stiffness in excess of 45 minutes (2 points), hip pain/limited range of motion (1 point), normal rheumatoid factor (RF) and/or anti-citrullinated protein antibody (ACPA) (2 points), and absence of peripheral joint pain (1 point). A score of 4 or more has 68% sensitivity and 78% specificity for discriminating all comparison subjects from PMR. The specificity is higher (88%) for discriminating shoulder conditions from PMR and lower (65%) for discriminating RA from PMR. The c-statistic for the scoring algorithm is 81%. The positive predictive value was 69% and the negative predictive value was 77%.

Ultrasound was performed in 120 PMR subjects, 154 comparison subjects (46 with RA and 47 with shoulder conditions), and 21 additional controls (not included in our study cohorts) who did not have shoulder conditions. Patients with PMR were more likely to have abnormal ultrasound findings in the shoulder (particularly subdeltoid bursitis and biceps tenosynovitis), and somewhat more likely to have abnormal findings in the hips than comparison subjects as a group (Table 134.1). PMR could not be distinguished from RA on the basis of ultrasound, but could be distinguished

Table 134.1 Polymyalgia rheumatica classification criteria: scoring algorithm. Required criteria: age≥50 years, bilateral shoulder aching, and abnormal CRP and/or ESR[a]

	Points without US 0–6	Points with US[b] 0–8
Morning stiffness >45 minutes	2	2
Hip pain or limited range of motion	1	1
Normal RF or ACPA	2	2
Absence of other joint involvement	1	1
At least 1 shoulder with subdeltoid bursitis and/or biceps tenosynovitis and/or glenohumeral synovitis (either posterior or axillary) AND at least 1 hip with synovitis and/or trochanteric bursitis	Not applicable	1
Both shoulders with subdeltoid bursitis, biceps tenosynovitis or glenohumeral synovitis	Not applicable	1

ACPA, anti-citrullinated protein antibody; CI, confidence interval; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; RF, rheumatoid factor; US, ultrasound.
[a]A score of 4 or more is categorized as PMR in the algorithm without US and a score of 5 or more is categorized as PMR in the algorithm with US.
[b]Optional ultrasound criteria.

from non-RA shoulder conditions and subjects without shoulder conditions. Adding ultrasound criteria of either both shoulders and/or a shoulder and hip showing typical abnormalities, an algorithm score of 5 or more has 66% sensitivity and 81% specificity for discriminating all comparison subjects from PMR. Ultrasound abnormalities at presentation were predictive of a good steroid response.

Pathogenesis

The pathogenesis of PMR is unclear, but one concept is that GCA and PMR are the opposite ends of the same spectrum with the absence of vascular involvement in pure PMR. Synovitis, bursitis, and tenosynovitis around the joints are all seen in PMR. Inflammation is initiated inside the tissue (synovium or bursa) with recognition of putative antigen by dendritic cells (DCs) or macrophages (Figure 134.1).[8] Activated DCs or macrophages secrete inflammatory mediators, including IL-1, IL-6, and tumour necrosis factor alpha (TNFα), which are responsible for the systemic features of the disease. They may then move to the central lymphoid organs, such as the lymph node and spleen, where they present antigen to the T cells. These T cells then migrate back to the synovium, enhance the adaptive immune response, and secrete further cytokines promoting local inflammation. A recent study has shown that vasoactive intestinal polypeptide, a neuropeptide, is locally produced inside the synovium. Vasoactive intestinal polypeptide (VIP) can induce a change in CD4+ T-cell phenotype from Th1 to Th2. Th2-type cells do not secrete interferon (IFN)-γ, which is a key cytokine in GCA pathogenesis. This may explain why most patients with PMR do not develop GCA. Two different T-cell subsets, Th17 (steroid-sensitive acute lesions) and Th1 (steroid-insensitive chronic lesions) may relate to the persistence of disease in GCA.[9] A similar mechanism for disease persistence may be relevant to PMR.
Fig. 134.1 Pathogenesis of polymyalgia rheumatica.
From Ghosh et al Expert Rev. Clin. Immunol. 6(6), 913–928 (2010).

Cytokines in polymyalgia rheumatica

Cytokines are the ultimate products fuelling the pathogenesis of PMR and GCA and are responsible for the systemic inflammatory response seen in these conditions. Therefore, modulating cytokine levels should lead to the amelioration of the disease process. Most studies regarding circulating cytokines focus on IL-6.[10] These studies show high levels of IL-6 in both PMR and GCA. The data on other cytokines (IL-1,IL-2, TNFα, IFN-γ, IL-10, and so on) are too scant to allow us to draw any definitive conclusions. Most studies in PMR have shown that levels of circulating IL-6 decrease significantly with the remission of clinical symptoms. IL-6 blockade could be a potential target for therapy, especially in PMR patients.

Evaluation of the patient with suspected polymyalgia rheumatica and pitfalls in diagnosis

Proximal pain and stiffness, hallmarks of the polymyalgic syndrome, can be features of several systemic inflammatory diseases. The disease usually starts abruptly with pain and stiffness in the shoulder, pelvic girdles, and neck. There may also be systemic features including fever, malaise, and weight loss. Patients may also present with distal features, especially hand arthritis, tenosynovitis, and carpal tunnel syndrome. PMR is present in approximately 50% of GCA patients and approximately 10% of PMR patients develop GCA.

The following are the key steps required:

1. **Establish the diagnosis** by ruling out mimics, considering clues to a non-PMR diagnosis and assessing any overlap with inflammatory arthritis or large-vessel vasculitis. A thorough history-taking, examination, and review of blood results is essential prior to prescription of steroids (see Figures 134.2 and 134.3). A pain diagram indicating the site of pain may be useful in improving accuracy of PMR diagnosis in primary care.

   Clues to a non-PMR diagnoses are: younger age of onset, chronic onset, peripheral arthritis, spinal involvement, pronounced systemic symptoms, neurological signs, very high CRP/ESR, lack of response to 15–20 mg prednisolone.

2. **Assess the severity** of the condition (based on intensity of pain, stiffness, disability, inflammatory markers).

3. **Imaging** with ultrasonography of shoulders, hips, peripheral joints, and temporal arteries may be helpful in establishing the diagnosis and excluding peripheral arthritis and GCA.

4. **Assess comorbidities** which may be relevant to choice of steroid dose.

5. **Make an individualized choice of steroid dose** and other therapy based on the above assessments and patient's preferences.

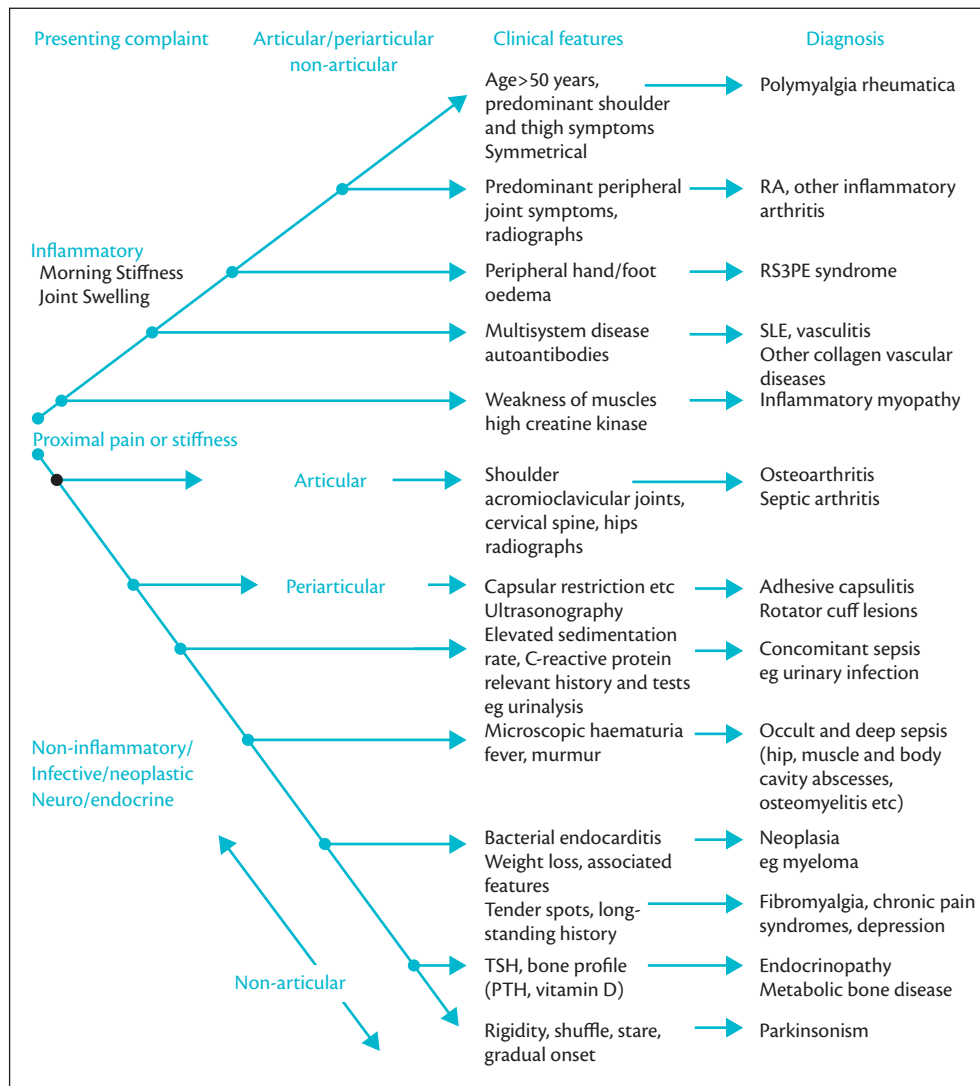
6. **Provide education** on the condition, its treatment, and potential complications, precautions, and monitoring requirements.


Fig. 134.2 A referral pathway for polymyalgia rheumatica (PMR) compatible with these guidelines is suggested in the Map of Medicine. CRP, C-reactive protein; CTD, connective tissue disease; ESR, erythrocyte sedimentation rate; FBC, full blood count; GCA, giant cell arteritis; IM, intramuscular; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; U&E, urea and electrolytes.

7. **Provide advice on range of motion exercises** for the shoulder and pelvic girdle muscles (with referral for physiotherapy if necessary).

Fallacies related to glucocorticoid use in polymyalgia rheumatica

An empirical trial of steroids should in no circumstances be used as an alternative to careful clinical evaluation of PMR. Recent reports show that 3–4 weeks after starting prednisolone 15 mg daily only 55% showed a complete response to therapy. Treatment with a moderate dose of prednisone, 15–20 mg daily as a single AM dose is indicated in PMR.[13,14] Under no circumstances should patients be given a larger dose of prednisone. Higher doses are unnecessary and only contribute to delays in diagnosis of another condition and lead to more corticosteroid morbidity. A 70% patient-reported global improvement with normalization of the ESR and CRP within

3–4 weeks indicates a complete response. If the initial response to treatment is not dramatic, do not continue treatment without considering other possible diagnoses. The corticosteroid dose should not be increased in an attempt to lower persistent elevation of acute-phase reactants without consideration of alternative diagnoses. High doses (often >40 mg/day) often employed as initial treatment for PMR are a source of diagnostic confusion as well as a rocky disease course.[13,14] They may serve to obscure systemic manifestations of potentially life-threatening diseases. Suppression of fever, malaise and weight loss in patients treated with high doses of corticosteroid can delay the diagnosis for example of malignancies or subacute bacterial endocarditis, with potentially life-threatening or life-limiting consequences.

The presence of swelling and early morning or inactivity stiffness of the peripheral joints should point the clinician towards an inflammatory arthritis such as RA or psoriatic arthritis.

A personal or family history of psoriasis or inflammatory bowel disease together with prominent inflammatory hip, back, or buttock

Step 1

Inclusion

Core inclusion criteria
- Bilateral shoulder and/or pelvic girdle pain
- Morning stiffness >45 minutes
- Abrupt onset
- Age >50 years
- Duration >2 weeks
- Acute phase response (raised ESR/CRP)

Step 2

Exclusion

Core exclusion criteria
- Active cancer
- Infection
- GCA

Other inflammatory conditions:
- RA, other arthopathies
- SLE, myopathies, other connective tissue diseases

Non-inflammatory:
- Local shoulder and hip conditions
- Fibromyalgia/pain syndromes
- Osteoarthritis

Endocrine eg thyroid
Drug induced eg statins
Statin-related myalgia/myopathy

Lab tests prior to steroids
- FBC
- ESR/CRP/plasma viscosity
- U&E
- Liver function tests
- Calcium, alkaline phosphatase
- Protein electrophoresis/
  Bence Jones protein
- Thyroid stimulating hormone
- Creatine kinase
- Rheumatoid factor
- Anti-nuclear antibody in cases
- Chest radiograph (in cases eg
  prominent systemic symptoms)
- Dipstick urinalysis

Step 3

Low-dose steroids

Prednisolone 15–20 mg daily
Clinical response in 1 week
- At least 70% global improvement
- Lab resolution of acute phase response in 3–4 weeks

Step 4

Follow up (4–6 weeks)

No alternative diagnoses

PMR

- Gradual steroid tapering
- IM depomedrone in mild cases, or
  contraindications to oral steroids
- Bone protection

Early specialist referral is recommended for:
- *patients with atypical features or features that
  increase likelihood of a non-PMR diagnosis*:
  – younger patients <60 years
  – chronic onset
  – lack of shoulder involvement
  – lack of inflammatory stiffness
  – 'red flag' features:
      prominent systemic features, weight loss,
      night pain, neurological signs
  – peripheral arthritis or other features of CTD/
    muscle disease
  – normal or very high ESR/CRP
- *treatment dilemmas such as*:
  – incomplete or non-response to corticosteroids
  – ill-sustained response to corticosteroids
  – unable to reduce corticosteroids
  – contra-indications to corticosteroids therapy

Symptoms to monitor
- Proximal pain
- Morning stiffness
- Disability related to the PMR
- Adverse events
- Osteoporotic risk
- Symptoms that may suggest
  an alternative diagnosis

**Lab monitoring
(every 3 months)**
- FBC
- ESR/CRP
- U & E
- Glucose

Relapses
- Increase steroids to previous higher dosage first and second relapse
- Consider immunosuppressive eg methotrexate

GCA relapse
- Treat with high dose steroids 40–60 mg prednisolone
- Consider alternative diagnosis with steroid partial or non-response

Fig. 134.3 Recommended approach for the evaluation of proximal pain and stiffness. PTH, parathyroid hormone; RA, rheumatoid arthritis; RS3PE, remitting, seronegative symmetrical synovitis with pitting oedema; SLE, systemic lupus erythematosus; TSH, thyroid stimulating hormone.
Reproduced from: Dasgupta B. Diagnosis and management of polymyalgia rheumatic. Clin Med 2010;10:270–4. Copyright © 2010 Royal College of Physicians. Reproduced with permission.

symptoms should make the clinician consider a late-onset seronegative spondyloarthropathy with sacroiliitis.

Severe back pain **without stiffness** might suggest vertebral metastases or myeloma. This is especially the case if red flag signs such as nocturnal pain, night sweats, anorexia, and significant weight loss are present. Although weight loss is common in PMR, loss of more than 14 lb (6 kg) is unusual and malignancies should be searched for.

High fevers can be caused by PMR, but should be investigated for other sources of infection, both common sources including urine and chest, and deep-seated infections, such as osteomyelitis, septic discitis and endocarditis, particularly if other systemic symptoms are prominent.

The presence of headache, visual symptoms, and jaw claudication should be recognized as GCA (40% of GCA patients have

polymyalgia at onset). The presence of arm or leg claudication and prominence of systemic symptoms would suggest a large-vessel vasculitis.

ANCA-associated vasculitis can also present with the polymyalgic syndrome, and the clinician should enquire about symptoms of mesenteric ischaemia, nasal polyps, crusting, epistaxis, sinusitis, and late-onset asthma. Dipstick urinalysis is essential in the assessment of PMR.

A chronic onset of symptoms inevitably indicates an alternative diagnosis. Patients with fibromyalgia can sometimes be mistaken for PMR due to pain and tiredness, but these patients do not describe true inflammatory stiffness and have a prominence of depressive symptoms and poor sleep patterns with multiple trigger points on examination. Such patients often appear to respond to trial of steroids.

The examination should be focused on the differential diagnoses. All peripheral joints need to be assessed for synovitis. The sacroiliac joints should be examined for evidence of sacroiliitis. The spine should be assessed for tenderness suggestive of fractures/metastases/osteomyelitis/discitis and to check the range of movement to see if there is any evidence of a spondyloarthropathy.

Painless muscle weakness might suggest an inflammatory polymyositis. Features of Cushing's syndrome should be obvious on inspection of the patient. Discoid or photosensitive rashes might suggest systemic lupus erythematosus (SLE). The absence of peripheral pulses, difference in bilateral blood pressures, or presence of arterial bruits suggests a large-vessel vasculitis. The heart, lungs, and abdomen should be examined routinely looking for signs of infection or malignancy.

Neurological examination may reveal Parkinsonian features (which is the only non-inflammatory condition to produce true stiffness). The presence of a sensory or motor neuropathy in the arms points towards a local disorder affecting the neck, such as cervical disc protrusion or cervical abscess. The absence of systemic and lower limb symptoms indicates local shoulder pathology, such as bilateral adhesive capsulitis or osteoarthritis.

As a baseline we suggest that all patients with suspected PMR should have full blood count (FBC), urea and electrolytes (U&E), liver function tests (LFT), bone profile, CRP, creatine kinase (CK), thyroid function tests (TFTs), immunoglobulins and electrophoresis, basic urinalysis, urinary Bence Jones protein, and chest radiograph checked. The rest of the investigations should be tailored to the individual symptoms and patient and may include serum cortisol, prostate-specific antigen (PSA, in men), ANA, RF, anti-CCP antibodies, ANCA, CT chest/abdomen/pelvis, spinal radiographs, MRI of the spine and sacroiliac joints, and echocardiogram.

Imaging

It is recommended that ultrasound should be performed at first presentation. PMR is a heterogeneous disease with heterogeneous outcomes in disease course on follow-up. Patients may show features which are a mix of bursitis, tenosynovitis, synovitis, and large-vessel vasculitis on imaging.

Ultrasound

Ultrasound depicts characteristic pathologic findings of shoulders and hips that can aid in distinguishing PMR from other diseases that may mimic it.[11] Typical findings on ultrasound include subdeltoid bursitis and biceps tendon tenosynovitis at the shoulder, and less frequently synovitis of the glenohumoral joint. In the hips, ultrasound often reveals synovitis and trochanteric bursitis. Inflammatory shoulder lesions were observed even in patients with normal ESR values and it has been suggested that ultrasound may facilitate the correct diagnosis in patients with the typical proximal symptoms of PMR who also have normal ESR.

Technique

For the shoulders, linear probes are necessary that provide a frequency in the 6–10 MHz range. For the hips, linear or curved array probes are necessary that provide a frequency in the 5–8 MHz range. In addition, duplex ultrasonography of the temporal and axillary arteries often detects features of vascular inflammation such as the 'halo', stenosis and occlusions.

MRI

In PMR, MRI scanning also shows up features of subdeltoid/subacromial bursitis.

FDG-PET scanning

Blockmans et al. have detected a significant percentage of PMR patients with vascular uptake on FDG-PET scans.[12] In our experience the following situations justify a FDG-PET scan in the setting of either PMR or GCA: unexplained constitutional symptoms, limb claudication, persistent incomplete response to steroids.

Management

There are no trials comparing different steroid dosing regimens in PMR. The recommendations are based on doses suggested in the British Society of Rheumatology (BSR) guidelines on PMR and are mostly based on level 3 evidence.[13] Low-dose initial corticosteroids with gradual tapering over 1–2 years is the principal therapy. However, owing to heterogeneity in steroid response between patients, treatment should be tailored according to the needs of a particular patient. Initial treatment should start with 15 mg/day prednisolone and should be gradually tapered after disease control. The response should be significant (i.e. >70% global response). A lack of response to 15 mg prednisolone should always make the clinician reconsider the diagnosis and think about arranging other investigations for alternative diagnoses.

Some patients may benefit from a more gradual corticosteroid taper, or a period of treatment at a stable dose, such as 5 mg prednisolone for 3 months. The dose may also need adjustment, due to disease severity, comorbid factors (e.g. diabetes, cardiorespiratory, or renal disease), fracture risk, patient wishes, or adverse events. Intramuscular methylprednisolone may be used in milder cases and may reduce the risk of corticosteroid-related complications.[14] The initial dose is 120 mg intramuscularly repeated at 3–4-week intervals. The dose is then reduced by 20 mg every 2–3 months and given monthly. It is better to avoid non-steroidal anti-inflammatory drugs (NSAIDs), especially in very elderly patients and in those with renal impairment. Bone protection is advised for all patients.

Treatment of relapsing polymyalgia rheumatica

Relapse is defined as recurrence of symptoms of PMR or onset of GCA symptoms, such as headaches, jaw claudication, and visual symptoms, usually with a rise in ESR/CRP. Approximately 50% of

patients relapse.[15] Clinical features of PMR may be mimicked by rotator cuff disease or shoulder osteoarthritis. An isolated rise of ESR or CRP, if not associated with clinical features of relapse, does not require an increase of immunosuppression. Speed of corticosteroid tapering and genetic factors have been postulated to influence the development of relapses in PMR. Initial relapses may be treated with a return to the previous higher dose. GCA relapse requires a high dose (40–60 mg) of prednisolone. Beyond two relapses, steroid-sparing agents such as methotrexate or azathioprine are usually used, but leflunomide has shown promise.[16] Current experience with randomized controlled trials of biological agents, such as infliximab or etanercept, is not generally encouraging.[10] An inability to wean off steroids or the development of new symptoms should make the clinician reassess the diagnosis.

Monitoring

Patients should be monitored for evidence of relapse, for disease-related complications, for steroid-related complications, and for symptoms that may suggest an alternative diagnosis. The best measures of disease activity and treatment response in PMR appear to be patient-reported global pain, hip pain, morning stiffness, physical function (MHAQ), mental function, and an inflammatory marker.[18] Ultrasound may have utility as an outcome measure. There is a need for specific biomarkers of disease activity in PMR. Poorly responsive PMR, persistent raised inflammatory markers, and constitutional symptoms may indicate large-vessel disease. Such patients may need echocardiography, PET, axillary artery ultrasound, and MRI to look for aortitis and large-vessel disease. Bone mineral density measurement may be required.

Conclusion

PMR may be an uncertain diagnosis and needs a stepwise assessment which includes inclusion and exclusion criteria and use of low-dose steroids. Subdeltoid bursitis or tenosynovitis visible on ultrasound appear to be key features. Meticulous monitoring for complications related to treatment and disease are required. The new EULAR/ACR classification criteria will facilitate uniform entry into clinical trials of novel therapies which are so urgently required for the condition. There appears to be an overlap with both GCA and large-vessel vasculitis as well as inflammatory arthritis.

CHAPTER 135

Behçet's syndrome

Sebahattin Yurdakul, Emire Seyahi, and Hasan Yazici

Introduction

Behçet's syndrome is a systemic vasculitis of unknown aetiology with a peculiar geographic distribution. Most cases are clustered around the countries of the Mediterranean basin, the Middle East, and the Far East. Its most dreaded complication, eye disease, is one of the leading causes of blindness in these regions.

In 1937, Behçet described in detail three patients with oral and genital ulceration, erythema nodosum, and hypopyon uveitis and proposed that this was a distinct entity. Subsequently, it was realized that many other clinical manifestations were part of this syndrome.[1] Table 135.1 lists the more important of these manifestations.

Epidemiology

The usual onset of the syndrome is in the third or fourth decade. The onset is rare in children and after the age of 45.

The male/female ratio is approximately equal but the syndrome has a more severe course in men and in young people. Worldwide, Turkey has the highest frequency with prevalence rates ranging from 2 to 42/10 000 based on five field surveys among the adult population.[2] Based on case registries, the prevalence is about 1/300 000 in northern Europe and 1/10 000 in Japan. The disease prevalence also shows ethnic variation in the same region: for example, ethnic Armenians living in Istanbul (Turkey) have a lower frequency of Behçet's syndrome (11/10 000) compared to that found in the general population (42/10 000).[3] Similarly, in a recent cross-sectional study disease frequency was significantly higher in North Africans (3.5/10 000) and Asians (1.8/10 000) compared to the native Europeans (0.2/10 000) living in a suburb of Paris (France). The study also showed that the overall frequency of Behçet's (0.7/10 000) was as frequent as those of other vasculitides (0.9/10 000) including polyarteritis nodosa, microscopic polyangiitis, granulomatosis with polyangiitis (Wegener's), and eosinophilic granulomatosis with polyangiitis (Churg–Straus).[4]

Clinical features

Skin and mucosal involvement

Oral aphthae

Behçet's syndrome only rarely occurs without oral ulceration, frequently also the first and most recurrent manifestation of the

Table 135.1 Clinical findings in Behçet's syndrome

Lesion	Frequency (%)
Aphthous ulcerations	97–100
Genital lesions	80–90
Skin lesions	80
Eye lesions	50
Arthritis	40–50
Thrombophlebitis	30
Neurological involvement	1–15
Gastrointestinal involvement	0–25

syndrome. It may precede the diagnosis by a mean of 8 (± 10) years.[5] Mostly oral ulcers in Behçet's syndrome are indistinguishable from what is seen in recurrent oral ulceration, but tend to be multiple and occur more frequently (Figure 135.1a). Large (major) ulcers are less frequent and herpetiform ulcers are rare. Major ulcers, however, can be very troublesome because they heal with scarring, which can even occlude the oropharynx. The minor ulcers do not as a rule leave scars. The histology reveals non-specific ulceration with necrotic material.

Genital ulceration

In male patients, 90% of genital ulcers occur on the scrotum and rarely on the penile shaft or on the glans penis. Urethritis is not observed, in contrast to reactive arthritis and sexually transmitted diseases. In the female, the labia (major and minor) are commonly affected (Figure 135.1b). As genital ulcers are usually deep and painful they affect the quality of life. Healing time is usually 2–4 weeks. Major ulcers (≥1 cm in diameter) almost always leave scars which are very specific for Behçet's syndrome.[6] Histologically, they are indistinguishable from what is seen in oral aphthae.

Skin lesions

The skin lesions of Behçet's syndrome can be divided into three main types:

- **Nodular lesions** resembling erythema nodosum: these are similar to idiopathic erythema nodosum and those due to other

conditions (e.g. sarcoidosis). However, it has been shown that more elements of vasculitis are observed on histological sections of these lesions than in idiopathic erythema nodosum or to erythema nodosum due to other causes.[7,8] Sometimes superficial thrombophlebitis can be clinically indistinguishable from erythema nodosum.

- **Papulopustular lesions** also called acneiform lesions or simply acne: most papulopustular lesions are histologically very similar to ordinary acne. However, they differ from the latter in their propensity to occur also in the extremities in addition to the face and the trunk. Pustules associated with Behçet's syndrome are usually considered as non-infectious inflammatory lesions. However, a study showed that they were not sterile.[9] The predominant bacteria in pustules of Behçet patients were *Staphylococcus aureus* and *Prevotella* spp., whereas coagulase-negative staphylococci were more common in pustules from ordinary acne patients.

- Others lesions are leucocytoclastic vasculitis, necrotizing arteritis of the small and medium arteries, superficial thrombophlebitis, unclassifiable papules and pustules, and Sweet syndrome.[10]

The pathergy reaction (Figure 135.1c), a curious hyperreactivity of the skin to a needle prick, is peculiar to this syndrome. The only other condition in which it is known to be positive with any consistency is pyoderma gangrenosum. After a skin puncture with a needle, a papule or a pustule forms in 24–48 hours. Pathergy is seldom observed among patients in northern Europe or the United States. In patients from Japan and Turkey the reaction is positive in around 60–70% when tested repeatedly.

The mechanism of the pathergy reaction is still obscure. Surgical cleaning of the skin considerably dampens this reaction, which suggests that more than disrupting the integrity of the epidermis and dermis is operational. Immunophenotypic analysis of skin biopsy specimens of positive pathergy reactions suggest that the reaction consists of a delayed hypersensitivity reaction independent of a specific antigen. Skin biopsy specimens obtained at 48 hours after a needle prick showed marked cellular influxes into the injury site, leading to an exaggerated lymphoid Th1-type response.[11]

The propensity for inflammation in Behçet's syndrome can also be observed in the response to intradermal injections of monosodium urate crystals.[12]

Eye involvement

Eye involvement is one of the most serious manifestations of Behçet's syndrome (Figure 135.1d). Its overall rate is about 50%. Males and those with younger age of onset have an increased frequency. Females are less severely affected. Disease is bilateral in 90% of patients with ocular involvement.[13,14] The onset of eye disease is usually within 2–3 years of the development of the syndrome.[14]

Eye disease in Behçet's syndrome consists of a chronic relapsing posterior and anterior uveitis. Isolated anterior uveitis is found in only 10% of those with ocular involvement.[13] Hypopyon uveitis (Figure 135.1d) is very typical, although occasionally it can be

Fig. 135.1 Skin-mucosa and eye lesions in Behçet's syndrome. (A) Multiple oral ulcers on the mucosal side of the lips. (B) Multiple ulcers on the labia major (black arrow). A large scar on the perineum (white arrow). (C) Pathergy reaction. (D) Hypopyon.

observed in reactive arthritis. It is an accumulation of white cells and debris in the anterior chamber that precipitates to form a layer due to gravity. Hypopyon is seen in 10–20% of patients with eye disease and is almost always associated with severe retinal disease.

The basic retinal lesion is a vasculitis, which can lead to exudates, haemorrhages, venous thrombosis, papilloedema, and macular disease that frequently results in a hole. The pars plana is also involved. During an acute flare there is a marked influx of fibrin, inflammatory cells, and cellular debris into the vitreous. Recurrent inflammatory activity results in late complications such as anterior and posterior synechia, cataract, secondary glaucoma, macular degeneration, and finally phthysis bulbi.[13]

Male gender, posterior involvement, frequent attacks, strong vitreous opacity, and exudates alongside the retinal vascular arcade are poor prognostic factors.[15] The prognosis of the eye disease has been reported to be extremely poor in the past. Nearly three-quarters of patients with eye disease would eventually lose their vision more than 20 years ago, but loss of useful vision ensues in less than one-fifth of patients with Behçet's syndrome and eye involvement under treatment since 1990.[13,16] Severely impaired vision does not always mean an eventual loss of useful vision, and male patients with late-onset eye disease, and female patients overall have an improved visual prognosis.[13–16]

Musculoskeletal system

Involvement of the joints is seen in about one-half of the patients in the form of arthritis or arthralgia. There is usually a mono- or oligoarticular involvement but symmetrical disease of the wrist or elbow, which can be confused with rheumatoid arthritis, may occasionally be seen. Usually lasting a few weeks, it seldom leads to chronic synovitis and deformity. Erythema of the overlying skin is not seen. Erosions are uncommon. The synovial fluid is inflammatory with a good mucin clot and the histological changes are non-specific.

Knees are the most commonly affected joints, followed in frequency by ankles, wrists, and elbows. Back pain is quite rare in Behçet's syndrome and an increased prevalence of sacroiliac joint involvement has not been found in controlled studies. On the other hand, patients with Behçet's syndrome who had arthritis also had more acne lesions compared to controls, suggesting a link with the reactive arthritides.[17] Furthermore, the frequency of enthesopathy was found to be significantly increased among Behçet's syndrome patients with acne–arthritis compared with that among patients without arthritis.[18] These recent studies support the hypothesis that patients with Behçet's syndrome with arthritis and acne form a distinct cluster. Interestingly, this cluster shows also familial clustering.[19]

Local or generalized myositis is occasionally found in Behçet's syndrome. The muscle enzymes are not raised in the local forms and the histological features are indistinguishable from those seen in polymyositis.

Another musculoskeletal manifestation associated with Behçet's syndrome is aseptic necrosis of the bone. This is possibly related to vasculitis and not necessarily to steroid use.

Cardiovascular and pulmonary involvement

Cardiac involvement

Endocarditis, myocarditis, and pericarditis can all occur but are rare. Cases with intracardiac thrombosis, endomyocardial fibrosis, coronary vasculitis and ventricular aneurysms have also been reported. Intracardiac thrombosis is usually located in the right side of the heart and closely associated with pulmonary artery involvement.

Vascular involvement

Vascular disease develops in up to 40% of patients and has a definite male preponderance. Both veins and arteries are affected. However, venous involvement is more common than arterial disease (75% vs 25%). About 30% of the vascular events develop simultaneously at disease onset or before fulfilling the criteria.[20] Lower extremity vein thrombosis, pulmonary artery aneurysms, Budd–Chiari syndrome, and dural sinus thrombosis are reported to occur early. However, both vena cava thrombosis and non-pulmonary artery aneurysms are late findings developing in a median of 5 and 7 years.[5,20]

Venous lesions

Superficial and deep veins of the lower extremity are the most common sites of venous thrombosis, which constitute 60–80% of vascular lesions. The affected veins in descending order of frequency are femoral, popliteal, saphenous, and crural veins. Furthermore, chronic relapsing vein thromboses in the legs tend to precede other sites of major vessel involvement.

Chronic occlusion of the superior and the inferior venae cavae leads to the appearance of prominent venous collaterals on the thoracic and abdominal walls. Thrombotic involvement may extend from hepatic veins to femoral/iliac veins or vice versa. Hepatic vein thrombosis may cause Budd–Chiari syndrome which may lead to liver failure and death. On the other hand, superior vena cava thrombosis has a better outcome, despite its alarming presentation.

Arterial lesions

The frequency of arterial disease in Behçet's syndrome is relatively rare (2.5%).[20]

Pulmonary artery involvement is mainly manifested as aneurysms (Figure 135.2a,b) and, less often, as solo in-situ pulmonary artery thrombosis (Figure 135.2c). Often, both pathologies can be seen together.[21] In-situ pulmonary artery thrombosis has a clinical and prognostic picture similar to pulmonary artery aneurysms. Patients present with fever, chest pain, coughing, dyspnea, and hemoptysis and a high acute-phase response. They may also have mild pulmonary artery hypertension.[22] The involvement is usually bilateral and confined mostly to inferior lobes. In two-thirds of cases aneurysms may disappear with only medical treatment. Both aneurysms and thrombosis may heal without any arterial sequelae or by leaving occlusions or stenosis. Thoracic CT scans of these patients may also show parenchymal nodules (Figure 135.2d), consolidations, and cavities (Figure 135.2b) mimicking opportunistic infections.

Despite the high prevalence of venous thrombosis in Behçet's syndrome, pulmonary thromboembolism is extremely rare since thrombosis develops usually as a complication to the underlying extensive vasculitis and is tightly adherent to the vascular wall.

Pulmonary artery involvement causes significant morbidity and mortality.[21,23] This is usually due to the rupture of an aneurysm into a bronchus. About one-quarter of patients still die even with early diagnosis and intensive treatment.

Non-pulmonary arterial disease is manifested mostly in the form of aneurysms and located in the abdominal aorta, carotid (Figure 135.3), femoral, and popliteal arteries. Occlusions are seldom seen and have a better prognosis than that of the aneurysms.[24]
Fig. 135.2 Several pulmonary lesions in Behçet's syndrome. (A) Bilateral hilar opacities on the chest radiograph. (B) CT scan showing pulmonary artery aneurysm (red arrow) and a cavity (white arrow) in the right middle lobe. (C) Pulmonary artery thrombosis (arrow) in the right descending artery. (D) Nodular lesions in the lung.
Fig. 135.3 Bilateral carotid artery aneurysms.

Atherosclerosis

Endothelial dysfunction and arterial stiffness have been well documented in Behçet's syndrome,[25] but clinical cardiovascular disease or its associated mortality seem not to be increased. The prevalence of angina and history of ischaemic heart disease was found to be similar between patients and non-diseased controls.[26] Evidence for subclinical atherosclerosis is also weak.[27]

Neurological involvement

The frequency of neurological involvement is around 5%. There are mainly two types, parenchymal disease (75–80%) and dural sinus thrombosis (10–20%).[28–30] The two types are rarely observed simultaneously in the same patient. Parenchymal disease is usually a late manifestation, developing after 5–10 years of disease onset. Male patients have more severe disease. It usually affects the brainstem, but hemispheric, meningeal, and spinal cord lesions are also seen.[31] The lesions are best demonstrated by MRI. In contrast to the other vasculitides, peripheral nerve disease is quite unusual.[28] Pyramidal signs, hemiparesis, behavioural–cognitive changes, and sphincter disturbances and impotence are the main clinical manifestations. Character disorders, impairment of memory and dementia, and other psychiatric symptoms may also occur.

Cerebrospinal fluid (CSF) findings are usually non-specific. An inflammatory CSF indicates a severe prognosis.

The lesions may progress to produce bulbar paralysis and this may often lead to disability and death.[28,29]

Dural sinus thrombosis is usually associated with other types of venous disease[32] and has a significantly better outcome.[28,29] It occurs earlier in the disease course. Severe headache, papilloedema, and motor ocular nerve palsies may be seen. Bilateral swollen optic disc is the most frequent sign. Persistent intracranial pressure may cause optic atrophy and blindness despite treatment.[33]

Headache is the most common neurological symptom in Behçet's syndrome.[34] It can be due to various causes such as parenchymal

central nervous system (CNS) disease, dural sinus thrombosis, ocular inflammation, acute attacks of Behçet's syndrome itself, and coexisting primary headaches like migraine.

Gastrointestinal involvement

Gastrointestinal involvement is seen in about one-third of patients from Japan, but it is rare among patients in Turkey.[35,36] The basic pathology is that of mucosal ulceration. This is most commonly seen in the ileum, followed by the caecum and other parts of the colon. Enteroclysis findings are usually mild when compared with those seen in Crohn's disease.[37] Histologically, the ulcers are indistinguishable from those found in ulcerative colitis. The usual symptoms are abdominal pain and melena. A mass is often palpable in the abdomen. Ileocaecal ulcers have the worst prognosis, with a distinct tendency to perforate.

It must be emphasized that the differential diagnosis from Crohn's disease can be very difficult.[36]

Other clinical features

Renal involvement is seen much less frequently than one would expect in a systemic vasculitis. Glomerulonephritis is occasionally reported. Epididymitis and voiding dysfunction are well-recognized symptoms.

Amyloidosis of the AA type is seen sporadically, usually presents with nephrotic syndrome, and carries a grave prognosis.

Diagnosis

The full-blown Behçet's syndrome is easy to identify; the so-called incomplete forms sometimes cause problems. The main conditions that should be considered in the differential diagnosis are shown in Table 135.2.[38]

Using the presence of recurrent oral ulceration as mandatory, and with proper exclusions, the International Study Group criteria[39] require involvement of two other organ systems specified in the criteria for a diagnosis, or more correctly classification, of Behçet's syndrome (Table 135.3). In this scheme a positive pathergy test can replace involvement of an organ system.

Laboratory investigations

There are no laboratory findings specific for Behçet's syndrome. A moderate anaemia of chronic disease and leucocytosis are seen in 15% of patients. The erythrocyte sedimentation rate (ESR) is only mildly elevated, as is the C-reactive protein (CRP). Neither correlates well with disease activity.

The synovial fluid is usually inflammatory. The cell count is between 5000 and 50 000/mm^3 with neutrophils predominating. Despite this high cell count the mucin clot is usually good.

Serum immunoglobulins are sometimes elevated, while autoantibodies are absent. Complement levels may be high. Despite the pauci-immune nature of the basic disease process, anti-neutrophilic antibodies are not a feature of Behçet's syndrome.

Genetics and pathogenesis

Behçet's syndrome is an inflammatory vasculitis. The precise mechanisms that initiate and sustain the increased inflammatory state that characterizes the syndrome remain unknown.

Most cases are sporadic and do not show a mendelian inheritance pattern. On the other hand, familial cases exist and a sibling recurrence risk ratio (λ_s) of 11.4–52.5 has been reported.[40] In a recent study among a limited number of monozygotic twins the concordance for Behçet's syndrome was found to be 2/6 (95% CI −0.21–0.88).[41]

HLA B51 has been associated with Behçet's syndrome especially in areas where the syndrome shows the highest prevalence, but the strength of this association decreases in patients from the United Kingdom and the United States. A recent meta-analysis indicated that the risk of *HLA B51* carriers developing Behçet's syndrome is increased by a factor of 5.90.[42] Genes in linkage disequilibrium with *HLA B51* such as MHC class I chain related gene A (*MICA*) have also been linked to the syndrome but recent analyses in different ethnic groups have shown that *HLA B51* itself still confers the highest susceptibility. This was recently confirmed in two genome-wide studies.[43,44] Moreover, these studies also showed associations with non-HLA, *IL10*, and *IL23R-IL12RB2* loci. Interleukin (IL)-10 is an anti-inflammatory cytokine and a deficiency of this cytokine due to a mutation is certainly in line with the increased inflammation paramount in Behçet's syndrome. Non-HLA loci such as IL-10 variant and a variant between IL-23 and IL-12 receptors may also be operative. The exact direct role of HLA B51 in the pathogenesis is not known. Cross-reaction with self-peptides[45] and HLA B51 has been implicated as a potential mechanism.[46]

An infectious aetiology has been implicated in the pathogenesis since the original description. Herpes simplex virus type I[47] and streptococci (*S. oralis*) have been held responsible but a direct link has not been shown. The cellular and humoral immune response to mycobacterial heat shock proteins (HSP65) and to their human homologues—coupled with the production of uveitis in Lewis rats with some of these proteins—have also been proposed as a unifying mechanism that bridges the role of different microorganisms.[48]

Behçet's syndrome does not have the features of a classical autoimmune disorder such as female predominance, hypergammaglobulinaemia, a coexistent Sjögren's syndrome, autoantibodies, and a heightened T-cell response. Neutrophil hyperreactivity in the form of increased superoxide production, endothelial adhesion, chemotaxis, and phagocytosis have been reported and an animal model has linked increased superoxide production to the presence of HLA B51.[49]

Both the adaptive and innate immune systems are activated. While a Th1 predominant cytokine profile, a Th1 type tissue infiltration in cutaneous[11] and intestinal tissues, and elevated IL-17 levels are examples in favour of the adaptive system, the primed state of neutrophils, circulating polyclonal γδ T cells in the serum, and the decreased mannose binding leptin levels are in favour of the action of the innate immune system.[46,50]

A non-specific hyperreactivity as exemplified by the pathergy phenomenon constitutes an important feature of Behçet's syndrome. The spontaneous or induced overproduction of proinflammatory cytokines from mononuclear cells in Behçet's syndrome may also constitute an aspect of this non-specific hyperreactivity.[51]

No consistent coagulation abnormality has been found.[52] Increased factor V Leiden and prothrombin gene *G20210A* mutations have been observed mainly in patients with venous thrombosis but their exact roles in the pathogenesis have been inconclusive. Anti-endothelial cell antibodies, anti-phospholipid antibodies, and various endothelial cell activation markers have also been reported.

Table 135.2 Highlights of the clinical manifestations of Behçet's syndrome and differential diagnosis[38]

Manifestation	Comment	Differential diagnosis
Mouth ulcers	Similar in appearance to common aphthous ulcers, more frequent and frequently multiple	Reactive arthritis—painless ulceration
Genital ulcers	Most commonly scrotal or vulval, painful, recurrent, and usually with scarring. Urethral discharge and penile lesions very rare	Reactive arthritis
Skin	Acneiform lesions as common acne in appearance and histology but also at uncommon sites such as the extremities. Erythema nodosum-like lesions leaving pigmentation. Not psoriasis	Seronegative arthropathies; inflammatory bowel disease; sarcoidosis
Eyes	Panuveitis and retinal vasculitis, usually bilateral occurring within about 2 years of the onset of the disease. Conjunctivitis and sicca syndrome most unusual	Seronegative arthropathies
Joints	Monoarthritis in 50%, otherwise oligoarticular or polyarticular, involving relatively few joints; may be symmetrical; knees most frequently; intermittent resolving in 2–4 weeks or chronic and continuous; not involving sacroiliac joints or spine; deformity and erosions rare. Inflammatory synovial fluid with a good mucin clot	Inflammatory arthropathies
Peripheral arterial and venous disease	Subclinical peripheral large vein disease uncommon, usually involves large segments with skip areas without embolization; arteritis with occlusion and/or pseudoaneurysms; microaneurysms of the polyarteritic type very uncommon	Other vasculitides
Neurological involvement	Peripheral neuropathy with isolated cerebellar involvement very unusual, headaches with dural sinus thrombosis; vascular CNS lesions including transverse myelitis-type manifestation. Multiple sclerosis with aphthous ulcers a problem but no plaques on MRI	Multiple sclerosis
Pulmonary involvement	Haemoptysis associated with pulmonary artery aneurysm; pulmonary artery occlusion; pleural involvement uncommon; interstitial involvement very rare	Pulmonary embolism; any cause of haemoptysis
Gastrointestinal involvement	Severe abdominal pain; ulcerative lesions at any level but mainly in the ileocaecal region; mild gastrointestinal symptoms should not be associated with Behçet's syndrome	Inflammatory bowel disease
Cardiac disease	Pericarditis, valve lesions, and coronary artery involvement uncommon; rarely intracardiac thrombi	Valve lesions in seronegative arthropathies

From Barnes and Yazici.[38]

There is some debate whether Behçet's syndrome belongs to the group of autoinflammatory diseases; a group characterized by the episodic inflammatory attacks, specific mutations (e.g. pyrin, CARD, NOD), and the absence of specific autoantibodies. Most of these entities begin in infancy whereas paediatric Behçet's syndrome is not frequent. Paroxysmal attacks that last from a couple of hours to a couple of weeks with frequent serosal involvement and fever characterize autoinflammatory diseases, while they are not at all common in Behçet's syndrome. On the other hand the extensive vasculitis, the hypercoagulability, and the more severe disease among males are features of Behçet's syndrome that are not characteristic of the autoinflammatory conditions.

Finally, the presence of disease clusters, especially with the acne–arthritis clustering in families,[19] the differences in organ response to the same agent (see below), and differences in disease expression between different geographies suggest that what we call Behçet's syndrome today might be due to more than one pathophysiological pathway, or more simply, more than one disease.

Management

There are several important features of Behçet's syndrome that have to be taken into consideration when planning management:

◆ The usual course of the syndrome in any organ system is that of exacerbations and remissions with the overall activity generally

Table 135.3 International Study Group criteria for the diagnosis of Behçet's syndrome

Criterion	Definition
Recurrent oral ulceration	Aphthous or herpetiform lesions; recurring at least 3 times a year
Recurrent genital ulceration	Aphthous ulceration or scarring
Eye lesions	Anterior or posterior uveitis or cells in the vitreus body on slit-lamp examination or retinal vasculitis
Skin lesions	Erythema nodosum, pseudofolliculitis, papulopustular lesions or acneiform nodules, not related to glucocorticoids treatment or adolescence
Positive pathergy test	Papule or pustule formation at 48 h

Source: International Study Group for Behçet's Disease.[39]

abating with the passage of time; thus, the principal aim is to prevent irreversible structural damage, which is the outcome of the early stormy course.

◆ Being young and male are separate and additive negative prognostic factors.

◆ Eye disease usually has its onset, if at all, either initially or within the first few years.

◆ The syndrome can be fatal, especially in a young male patient.

◆ There are many patients with Behçet's syndrome who do not need any treatment other than reassurance.

Immunosuppressive drugs are the main line of treatment for eye involvement. Although corticosteroids have been used for a long time, there is no formal evidence that they are effective. Their short-term use over a few months, however, may shorten the duration of an attack.

Azathioprine at 2.5 mg/kg per day is useful in maintaining visual acuity and, perhaps more importantly, in preventing the emergence of new eye disease. Its early use in the disease course leads to a better long-term outcome. It is important that treatment is begun well before structural changes appear in the eye. The drug has also beneficial effects on oral and genital ulcerations, arthritis, and possibly thrombophlebitis. Because of its slow onset of action, it requires more than 3 months for efficacy at the recommended dosage. Ciclosporin is an effective and rapidly acting drug in sight-threatening and progressive uveitis, especially with retinal vasculitis of Behçet's syndrome. Problems with ciclosporin are its potential nephrotoxicity, especially at doses greater than 5 mg/kg per day, and the very frequent relapses after cessation of therapy. The high cost is another problem. Eye disease in remission for 2 years or more usually needs no further treatment. Young males, in general, need to be treated more vigorously. Once initiated, the usual course for cytotoxic or cyclosporin therapy is a minimum of 2 years, after which attempts at discontinuation are made. There is the concern that this medication not only tends to accelerate the development of CNS symptoms but also can cause CNS symptoms that can be confused with those in Behçet's syndrome itself.[53] Thus, its use is not recommended in patients with neurological involvement. In some patients, after a course for 6–8 months of combined azathioprine and ciclosporin, treatment is continued with azathioprine only. In more resistant cases azathioprine is used in combination with ciclosporin (both at conventional doses) for extended periods of time. Our uncontrolled experience with this mode of therapy in severe eye disease is quite favourable.

Data on biological agents such as interferon-α2a (IFN-α) and anti-tumour necrosis factor (TNFα) antagonists have been promising. IFN-α, subcutaneously, 3–6 MU/day, three times a week decreases the mucocutaneous lesions and is beneficial in posterior uveitis refractory to conventional medications.[54] Long-lasting remissions have been reported after stopping the drug.[55] Side effects include flu-like symptoms, liver enzyme elevations, cytopenias, and severe mood changes. Its drawbacks are high cost and frequent side effects. TNFα agents such as infliximab, etanercept, and adalimumab have been effective for various lesions of the disease, including eye, mucocutaneous, gastrointestinal, and neurological disease, and even pulmonary artery aneurysms. Among them infliximab has been the most commonly used anti-TNFα agent.[56,57] Infliximab is recommended as a first agent at a dosage of 5 mg/kg for sight-threatening uveitis as an add-on immunosuppressive therapy for patients who are refractory or intolerant to traditional immunosuppressives.[57] The initial response is generally seen within 24 hours, but relapses are frequent after withdrawal; therefore, continuous treatment are needed. The only placebo-controlled study with etanercept showed the drug significantly decreased the mucocutanous lesions in patients with mainly mucocutaneous lesions. Interestingly, however, it did not suppress the pathergy or the urate crystal skin response.[58] Its high cost, and side effects such

as an increased risk of tuberculosis and other infections, are still concerns.

The European League against Rheumatism (EULAR) has published recommendations for the therapy of Behçet's syndrome.[59,60] In ocular disease they suggest:

> If the patient has severe eye disease defined as >2 lines drop of visual acuity on a 10/10 scale, and/or retinal disease (retinal vasculitis or macular involvement), it is recommended that either ciclosporin or infliximab be used in combination with azathioprine and corticosteroids; alternatively, INF-α with or without corticosteroids could be used instead.

Concomitant use of other immunosuppressive agents together with the TNFα blocker has been suggested to prevent the development of antibody formation. IFN should not be used alongside an immunosuppressant because of the possibility of bone marrow suppression.

Structural eye damage can be managed surgically (i.e. vitrectomy) at specialized centres. However, results are not uniformly satisfactory. There is always the problem of new attacks of inflammation in surgically handled tissue in Behçet's syndrome. Also, already established disease in the retina cannot be helped by surgery. Local mydriatics should be used in the acute stage to prevent synechiae.

The oral and genital ulcers are usually well controlled by immunosuppressives and steroids. However, these should be reserved for more severe cases. Often, a local steroid preparation that adheres to fresh ulceration (such as triamcinolone acetonide oral paste) is all that is required.

A 2 year controlled trial has shown that colchicine is more effective than placebo in the treatment of mucocutaneous and joint symptoms and that this effect is especially prominent among females. Most notably, colchicine did not have any effect on the genital ulcerations in male patients.

Thalidomide at a dose of 100 mg/day can induce dramatic relief from oral and genital ulcers. Relapses are a rule after stopping treatment. Teratogenesis and polyneuropathy are the drawbacks of chronic thalidomide use.

Cyclophosphamide, either 2–2.5 mg/kg per day orally or 500–1500 mg weekly or monthly intravenous boluses, is required to treat those patients with severe cutaneous, arterial, or pulmonary vasculitis, or those with arterial aneurysms or vena caval involvement. There is no formal experience with any therapy for CNS disease; however, steroids, immunosuppressives, and biological agents are again used.

Gastrointestinal involvement is initially managed by sulfasalazine at a dosage of 2–6 g/day. Sometimes surgery is required, with resection of large segments of bowel. Usually, a good portion of uninvolved area should also be removed to prevent recurrences. Surgery is usually successful in aneurysms of peripheral vessels.

There is debate whether to use heparin or oral anticoagulants for the thrombophlebitis of Behçet's syndrome. Pulmonary embolism is seldom observed, as explained above. Further evidence that pulmonary emboli are rare comes from our recent observation that those lesions reported as pulmonary emboli in perfusion lung scans continue to persist after several months in Behçet's syndrome while, as a rule, they disappear in ordinary pulmonary emboli.[21] The role of anti-coagulation in deep vein thrombosis has not been evaluated in a controlled study. However, studies showed that anti-coagulant treatment is ineffective in preventing venous thrombosis.[61,62] In

this setting, anti-platelet drugs (i.e. aspirin) are probably sufficient. We also use azathioprine in thrombophlebitis of Behçet's syndrome to suppress the disease activity in general.

Combination of these drugs with steroids or the combination of azathioprine and ciclosporin can be tried in cases resistant to a single agent.

In the absence of any hard data it is customary to stop treatment in a patient in remission after 2–4 years.

Prognosis

The disease intensity usually abates with the passage of time. On the other hand, it may cause several serious morbidities and a fatal outcome. A follow-up study of 20 years found an overall mortality rate of 10% among an inception cohort of 423 patients.[14] Standardized mortality ratios were specifically increased among young males while older males and females had a normal lifespan. Furthermore, the mortality rate was highest during the first 7 years of disease onset and had a tendency to decrease with time. Major causes of death were large-vessel (especially pulmonary artery) aneurysms and parenchymal CNS involvement. A more recent study reported a mortality rate of 5% among 817 patients followed for a median of 8 years.[63] Similarly, the mortality rate was increased among young patients and males.

Paediatric vasculitis

Despina Eleftheriou and Paul A. Brogan

Introduction

Apart from relatively common vasculitides such as Henoch–Schönlein purpura (HSP) and Kawasaki's disease (KD), most of the primary vasculitic syndromes are rare in childhood, but when present are associated with significant morbidity and mortality.[1,2] Until recently clasifications in childhood vasculitis have been based on modifications of those used in adult populations. In 2005 the vasculitis working group of the Paediatric Rheumatology European Society (PRES) proposed preliminary classification criteria for some of the most common childhood vasculitides namely HSP, childhood polyarteritis nodosa (PAN), Wegener's granulomatosis (WG, now referred to as granulomatosis with polyangiitis (GPA) in adult classification systems), and Takayasu's arteritis (TA).[3] Subsequently, with support from the European League Against Rheumatism (EULAR), the Paediatric Rheumatology International Trials Organization (PRINTO) and PRES established a formal statistical validation process with a large-scale data collection that culminated in the final 2008 Ankara Consensus Conference.[4] Only paediatric diseases were considered, so giant cell arteritis was omitted.[3,4] Also a group of other vasculitides, including vasculitic disorders that did not fit into any category or fitted more than one, was defined. KD was not included since the clinical phenotype was already well described; nor are definitions for microscopic polyangiitis (too few cases included in dataset).[4] The general scheme for the classification of paediatric vasculitides is summarized in Box 136.1. This chapter summarizes the epidemiology, aetiopathogenesis, presenting clinical features, and current management strategies for paediatric vasculitides.

Predominantly small-vessel vasculitis

Henoch–Schönlein purpura

Epidemiology

HSP is the most common childhood primary systemic vasculitis.[1] Gardner-Medwin et al. reported a large population-based survey of 1.1 million children (aged <17 years old) from a multiethnic region of the United Kingdom.[1] The annual incidence was estimated to be 20.4 per 100 000 children in the United Kingdom, with greater incidence in children from the Indian subcontinent (24 per 100 000) compared

---

Box 136.1 Classification of childhood vasculitides[3–4]

Predominantly small-vessel vasculitis

Granulomatous

- Granulomatosis with polyangiitis (GPA, Wegener's)
- Churg–Strauss syndrome (CSS)

Non-granulomatous

- Microscopic polyangiitis
- Henoch–Schönlein purpura (HSP)
- Isolated cutaneous leukocytoclastic vasculitis
- Hypocomplementemic urticarial vasculitis

Predominantly medium-sized vessel vasculitis

- Childhood polyarteritis nodosa (PAN)
- Cutaneous polyarteritis
- Kawasaki disease (KD)

Predominantly large-vessel vasculitis

- Takayasu's arteritis (TA)

Other vasculitides

- Behçet's disease
- Vasculitis secondary to infection (including hepatitis B associated PAN), malignancies, and drugs, including hypersensitivity vasculitis
- Vasculitis associated with other connective tissue diseases
- Isolated vasculitis of the central nervous system (childhood primary angiitis of the CNS, cPACNS)
- Cogan's syndrome
- Unclassified

From Ozen et al.[3,4]

with white Europeans (17.8 per 100,000) and black (predominantly Afro-Caribbean) children (6.2 per 100 000).[1] Yang et al. reported an annual incidence of 12.9 per 100 000 children in Taiwan.[5]

Classification criteria

According to the new EULAR/PRINTO/PRES definition a patient is classified as having HSP in the presence of purpura or petechiae with lower limb predominance (mandatory criterion; Figure 136.1), plus one of the following four criteria[4]:

- abdominal pain
- histopathology showing typical leucocytoclastic vasculitis with predominant IgA deposit; or proliferative glomerulonephritis with predominant IgA deposit
- arthritis or arthralgia
- renal involvement (proteinuria or haematuria or presence of red blood cell casts).

In cases with purpura with atypical distribution a demonstration of IgA is required as a mandatory criterion, although in routine clinical practice skin biopsy with immunofluorescence is rarely performed. Another caveat regarding this point is that if the skin biopsy is taken in the centre of the necrotic lesion, IgA deposition may be falsely negative due to the presence of proteolytic enzymes. Despite some of the controversies surrounding inclusion of skin biopsy in the HSP classification criteria, the new definition provides sensitivity and specificity for classification of HSP (using other forms of vasculitis as controls) of 100% and 87% respectively.[4] It should be noted, however, that vasculitis classification criteria are not the same as diagnostic criteria, since they are designed to differentiate

Fig. 136.1 Typical (severe) palpable purpura of Henoch–Schönlein purpura in a 13 year old female without renal involvement.

one form of vasculitis from another, rather than diagnose vasculitis in the first instance.

Aetiopathogenesis

As many as 50% of occurrences in paediatric patients are preceded by an upper respiratory tract infection.[6,7] HSP occurrence following occurring vaccination has also been described,[8] although this remains a contentious issue. Several infectious agents have been implicated, including group A streptococci, varicella, hepatitis B, Epstein–Barr virus, parvovirus B19, mycoplasma, campylobacter, and yersinia.[6]

It is suggested that IgA has a pivotal role in the pathogenesis of the disease, a hypothesis supported by the almost universal deposition of IgA in lesional vascular tissue.[9] Skin or renal biopsies demonstrate the deposition of IgA (mainly IgA1) in the wall of dermal capillaries and postcapillary venules and mesangium.[9] In addition, serum IgA levels have been reported to be increased during the acute phase of the disease, and a proportion of patients have circulating IgA-containing immune complexes and cryoglobulins.[10] Some studies have found IgA anti-neutrophil cytoplasmic antibodies (IgA-ANCA) in a proportion of patients with HSP, while others have shown an increase in IgA-rheumatoid factor, or IgA-anti-cardiolipin antibodies.[9] Recently, galactose deficiency of O-linked glycans in the hinge region of IgA1 has been reported in adults with IgA nephropathy and children with HSP.[11] Additionally, Hiasano et al. showed complement activation in the glomerulus through both the alternative and lectin pathways in patients with HSP nephritis.[12] IgA immune complexes and activation of complement lead to the formation of chemotactic factors (such as C5a), which in turn recruit polymorphonuclear leucocytes to the site of deposition,[13,14] resulting in further inflammation and necrosis of vessel walls, with concomitant thrombosis[9] and extravasation of erythrocytes from haemorrhage. The histological endpoint is that of a typical leukocytoclastic vasculitis.[9] The term 'leukocytoclasis' refers to the breakdown of neutrophils in lesional tissue, resulting in the characteristic nuclear debris or 'nuclear dust' observed, and is not specific for HSP.

Several genetic polymorphisms have been linked to HSP in various population cohorts.[15,16] On the whole, however, studies of this nature have been hampered by relatively small patient numbers and lack of power to be definitive or necessarily applicable to all racial groups.[16]

Clinical features

Skin involvement is typically with purpura which is generally symmetrical, affecting the lower limbs and buttocks in the majority of cases, the upper extremities being involved less frequently.[17,18] The abdomen, chest, and face are generally unaffected by purpura, although the face can be affected by angioedema. New crops of purpura may develop for several months after the disease onset, though generally fade with time.[17,18] Lesions can be induced by mild trauma. Angioedema and urticaria can also occur.[17,18] Around two-thirds of children have joint manifestations at presentation, with the knees and ankles most frequently involved.[17,18] Symptoms, which take the form of pain, swelling, and decreased range of movement, tend to be fleeting and resolve without the development of permanent articular damage.[7,17,18] Three-quarters of children develop abdominal symptoms ranging from mild colic to severe pain with ileus and vomiting.[7,17,18] Haematemesis and melaena are sometimes observed, due to mesenteric vasculitis.[17] Other serious

complications include intestinal perforation and intussusception.[17] The latter may be difficult to distinguish from abdominal colic, and the incidence of intussusception is significant enough to warrant exclusion by ultrasound where suspected.[17] Acute pancreatitis is also described, although is a rare complication.[17]

Other organs less frequently involved include the central nervous system (cerebral vasculitis), gonads (orchitis may be confused with torsion of the testis), and lungs (pulmonary haemorrhage).[17] Ureteric obstruction has been reported.[17] Many cases follow an upper respiratory tract infection and the onset of the disorder may be accompanied by systemic symptoms including malaise and mild pyrexia.[17] Multiple organ involvement may be present from the outset of the disease, or alternatively an evolving pattern may develop, with different organs becoming involved at different time points over the course of several days to several weeks.[17] Recurrence of symptoms occurs in around one-third of cases, generally within 4 months of resolution of the original symptoms. Recurrences are more frequent in those with renal involvement.[17]

Reports of HSP nephritis indicate that between 20–61% of cases are affected with this complication. Renal involvement is normally manifest between a few days and a few weeks after first clinical presentation, but can occur up to 2 months or (rarely) more from presentation. There appears to be an increased risk of renal disease in those with bloody stools.[19] Renal involvement can present with varying degrees of severity. This includes isolated microscopic haematuria, proteinuria with microscopic or macroscopic haematuria, acute nephritic syndrome (haematuria with at least two of hypertension, raised plasma creatinine and oliguria), nephrotic syndrome (usually with microscopic haematuria), or a mixed nephritic–nephrotic picture.[17]

Most children do not require a tissue (renal and/or skin) biopsy diagnosis, with the exception of children with atypical skin findings, or suspected severe renal involvement. The skin lesion of HSP is that of a leucocytoclastic vasculitis with perivascular accumulation of neutrophils and mononuclear cells.[17] Immunofluorescence studies reveal vascular deposition of IgA and C3 in affected skin, though similar changes may be observed in skin unaffected by the rash.[17]

The renal lesion of HSP nephritis is characteristically a focal and segmental proliferative glomerulonephritis with IgA deposition (Figure 136.2). Severe cases with rapidly progressive glomerulonephritis can demonstrate crescentic glomerular changes on renal biopsy (Figure 136.2). Indications for diagnostic renal biopsy in children with HSP are[17,20]:

- nephritic/nephrotic presentation (urgent)
- raised creatinine, hypertension or oliguria (urgent)
- heavy proteinuria (Ua:Ucr persistently >100 mg/mmol) on an early morning urine sample at 4 weeks; serum albumin not necessarily in the nephrotic range
- persistent proteinuria (not declining) after 4 weeks
- impaired renal function (GFR <80 mL/min/1.73m^2).

Management

The large majority of cases of HSP require symptomatic treatment only. Arthropathy is managed with rest and analgesia. Controversies concerning the use of corticosteroids in the treatment of HSP exist with regard to whether or not they can[1] reduce severity or duration
Fig. 136.2 Immunohistochemistry of renal histology from a 16-year-old male with Henoch–Schönlein purpura and heavy proteinuria. Diffuse mesangial matrix expansion and thickening of capillary walls. Strong diffuse granular mesangial and capillary wall IgA deposition. Fibrocellular crescentic change is also present in both the glomeruli (arrowed).

of disease,[2] decrease the risk of glomerulonephritis, and[3] prevent relapses of the disease.[21,22] Zaffanello and Fanos reviewed the treatment of HSP nephritis, concluding that currently prescribed treatments for HSP nephritis are not adequately guided by evidence obtained in robust randomized placebo-controlled trials with outcome markers related to the progression to end stage renal disease.[23] Current evidence is summarized in more detail below.

Treatment to prevent renal disease

Various treatment strategies and strategies aiming to prevent disease complications such as renal disease have been reported with variable effect. The efficacy of corticosteroids to prevent complications such as abdominal pain is still debated.[21,22] Chartapisak et al. recently systematically reviewed all published randomized controlled trials (RCTs) for the prevention or treatment of renal involvement in HSP.[24] Meta-analyses of four RCTs which evaluated prednisone therapy at presentation of HSP showed that there was no significant difference in the risk of development or persistence of renal involvement at 1, 3, 6, and 12 months with prednisone compared with placebo or no specific treatment. Thus it is becoming clearer that prophylactic corticosteroid does not prevent the onset of HSP nephritis. That said, there could still be a role for early use of corticosteroids in patients with severe extrarenal symptoms and in those with renal involvement, as suggested by the findings of a study performed by Ronkainen et al.[21] Prednisone (1 mg/kg per day for 2 weeks, with weaning over the subsequent 2 weeks) was effective in reducing the intensity of abdominal pain and joint pain. Prednisone did not prevent the development of renal symptoms but was effective in treating them if present; renal symptoms resolved in 61% of the prednisone patients after treatment, compared with 34% of the placebo patients.[21]

Treatment of rapidly progressive glomerulonephritis

There are good data indicating that crescents in >50% of glomeruli and nephrotic range proteinuria carry an unfavourable prognosis, thus

highlighting the need for an effective intervention. Unfortunately, to date, there is only one RCT evaluating the benefit of treatment, which shows no difference in outcome using cyclophosphamide vs supportive therapy alone.[25] A major limitation of the study, however, is that it did not examine combined therapy, i.e. cyclophosphamide and corticosteroidsteroid, a regimen used in most other severe small-vessel vasculitides (see below). For patients with rapidly progressive glomerulonephritis (RPGN) with crescentic change on biopsy, uncontrolled data suggest that treatment may comprise aggressive therapy with corticosteroid, cyclophosphamide, and possibly plasma exchange,[26] as for other causes of crescentic nephritis. Other therapies such as ciclosporin, azathioprine, and cyclophosphamide have been reported by some authors to be effective.[17,26] As HSP is the commonest cause of rapidly progressive glomerulonephritis in childhood, more aggressive therapeutic approaches have been employed in some cases. Shenoy et al. reported 14 children with severe HSP nephritis treated successfully with plasma exchange alone.[26] These treatment options, although potentially important in select cases, are not yet supported by RCTs.

Treatment of HSP nephritis which is not rapidly progressive

Such patients may exhibit the following features: less than 50% crescents on renal biopsy, suboptimal glomerular filtration rate (GFR), heavy proteinuria which is not necessarily in the nephrotic range.[20] There are no robust clinical trials to guide therapy of this type of presentation. Many would advocate corticosteroids. Others advocate the addition of cyclophosphamide to corticosteroids in HSP nephritis with biopsy showing diffuse proliferative lesions or sclerosis, but with less than 50% crescentic change in patients who have ongoing heavy proteinuria. A typical regimen would comprise 8 weeks of oral cyclophosphamide (2 mg/kg per day) with daily prednisolone, converting to alternate-day prednisolone and azathioprine for a total of 12 months.[20] Published evidence for the efficacy of this approach is lacking, but this may be a reasonable option bearing in mind the adverse prognosis of children with HSP who have a nephritic–nephrotic phenotype. In patients with greater than 6 months duration of proteinuria an angiotensin converting enzyme (ACE) inhibitor may be indicated to limit secondary glomerular injury, although again the evidence to support this therapy is lacking.[23] Mycophenolate mofetil (MMF) has been reported in small case series as an effective treatment of recurrent skin, articular, and gastrointestinal symptoms as well as nephrotic-range proteinuria in children who failed to respond to systemic steroid therapy.[27,28]

Outcome

The majority of children with HSP make a full and uneventful recovery with no evidence of ongoing significant renal disease. Renal involvement is the most serious long-term complication of HSP. A study of long-term outcome of 78 subjects who had HSP nephritis during childhood (mean of 23.4 years after onset) demonstrated overall that initial findings on renal biopsy correlated well with outcome, but had poor predictive value in individual patients.[29] Forty-four per centof patients who had nephritic, nephrotic, or nephritic–nephrotic syndromes at onset had hypertension or impaired renal function, whereas 82% of those who presented with haematuria (with or without proteinuria) were normal.[29] Seven patients deteriorated clinically years after apparent complete clinical recovery. Sixteen of 44 full-term pregnancies were complicated by proteinuria and/or hypertension, even in the absence of active renal disease.[29]

Furthermore, Narchi systematically reviewed all published literature with regard to long-term renal impairment in children with HSP.[30] Twelve studies with 1133 children were reviewed. Renal involvement occurred in 34% of children; 80% had isolated haematuria and/or proteinuria while 20% had acute nephritis or nephrotic syndrome.[30] Renal complications, if they did occur, developed early—by 4 weeks in 85% and by 6 months in nearly all children.[30] Persistent renal involvement (hypertension, reduced renal function, nephrotic or nephritic syndrome) occurred in 1.8% of children overall but the incidence varied with the severity of the kidney disease at presentation, occurring in 5% of children with isolated haematuria and/or proteinuria but in 20% who had acute nephritis and/or nephrotic syndrome in the acute phase.[30] Children with significant renal impairment at presentation, and/or persistent proteinuria should undergo regular assessment of their GFR, e.g. at 1, 3, and 5 years after the acute episode of HSP.[20] Some instances of hypertension have been reported many years after normalization of renal function and urinalysis.[31] An increased incidence of pre-eclampsia has also been reported.[32]). Interestingly, in children who underwent repeat renal biopsies the majority of children with HSP still had IgA years later,[33] which could explain in part the late renal morbidity sometimes described. Thus it is clear that robust clinical trials for the treatment of moderate and severe HSP nephritis are urgently required. Lastly, it is recognized that HSP can occur in renal allografts.[34]

Acute haemorrhagic oedema of infancy

Acute haemorrhagic oedema of infancy (AHEI; Finkelstein–Seidlmayer syndrome) is often described as a variant of HSP that can affect young infants and toddlers under the age of 2 years.[35] More than 100 cases of this variant have been published in medical literature worldwide. Although initially considered a variant of HSP, it is now considered a separate entity, mainly because it predominantly affects the skin without the organ involvement described for typical HSP described above.[35] AHEI is characterized by the triad of fever; oedema (swelling of the skin); and rosette-, annular-, or targetoid-shaped purpura primarily over the face, ears, and extremities.[35] The cutaneous findings are dramatic both in appearance and in rapidity of onset, and are easily recognized once seen. The prognosis is usually excellent with resolution of the skin lesions within a few weeks without treatment, although attacks may recur.[35] Histopathology is typical of a leucocytoclastic vasculitis with occasional demonstration of perivascular IgA deposition.[35]

ANCA-associated vasculitides

Definitions, epidemiology, and classification

The ANCA-associated vasculitides (AAV) are considered in detail in Chapters 131 and 132. Although rare, AAV do occur in childhood and are associated with significant morbidity and mortality.[17]

The recently modified classification definition for GPA (formerly known as Wegener's granulomatosis) requires the presence of three out of the following criteria[4]:

- renal involvement (proteinuria or haematuria or red blood cell casts)

- positive histopathology (granulomatous inflammation within the wall of an artery or in the perivascular or extravascular area)

- upper airway involvement (nasal discharge or septum perforation, sinus inflammation)

- laryngo-tracheo-bronchial involvement (subglottic, tracheal, or bronchial stenosis)
- pulmonary involvement (chest radiograph or CT)
- ANCA positivity (by immunofluorescence, or by ELISA PR3 ANCA or MPO ANCA).

Sensitivity and specificity of the new EULAR/PRINTO/PRES criteria are 93% and 99% respectively for the classification of GPA from other forms of vasculitis in the young.[4]

Clinical features of granulomatosis with polyangiitis

From a clinical perspective in children it may be useful to think of GPA as having two forms: a predominantly granulomatous form with mainly localized disease with chronic course; and a florid, acute small-vessel vasculitic form characterized by severe pulmonary haemorrhage and/or rapidly progressive vasculitis or other severe vasculitic manifestation. These two broad presentations may coexist or present sequentially in individual patients.

In one case series of 17 children with GPA the frequency of different system involvement was: respiratory 87%, kidneys 53%, sinuses 35%, joints 53%, eyes 53%, nervous system 12%, skin 53%.[36] Another paediatric series of GPA reported even higher frequency of renal involvement with 22/25 cases having glomerulonephritis at first presentation, and only 1/11 patients who had renal impairment in that series recovered renal function with therapy.[37] In the most recent paediatric series of 65 children classified as having GPA, renal involvement was reported up to 75.4% of cases.[38] Dialysis was necessary in 7 patients (10.8%), and endstage renal disease was present in a single patient of that series.[38] Of note, renal involvement in GPA is recruited with increasing age which could account in part for the variation in reported renal involvement in paediatric GPA.

In a recent review of 33 cases of childhood Churg–Strauss syndrome (CSS), all patients had significant eosinophilia and asthma.[39] Furthermore histological evidence of eosinophilia and/or vasculitis was present in virtually all patients.[39] ANCA were found in only 25% of children with CSS.[39] There is considerable clinical overlap between CSS and primary hypereosinophilic syndromes in the young, and the differentiation of these two entities is challenging and beyond the scope of this chapter; the reader is referred to Kahn et al.[40]

Treatment of AAV

Treatment for paediatric AAV is broadly similar to the approach in adults, with corticosteroids, cyclophosphamide (usually 6–10 intravenous doses at 500–1000 mg/m^2 (maxiumm 1.2 g) per dose given 3–4 weekly; alternatively given orally at 2 mg/kg per day for 2–3 months), and in select patients plasma exchange (particularly for pulmonary capillaritis and/or rapidly progressive glomerulonephritis—'pulmonary–renal syndrome') routinely employed to induce remission.[2,41] Anti-platelet doses of aspirin (1–5 mg/kg per day, typically 37.5–75 mg/day) are empirically employed on the basis of the increased risk of thrombosis associated with the disease process.[42] Methotrexate may have a role for induction of remission in patients with limited GPA,[43] but is less commonly used as an induction agent in children with AAV. Recommendations regarding duration of maintenance therapy are based on adult trial data, with no clinical trials in children performed.

Biological therapy is also increasingly used to treat children with small-vessel vasculitis, including AAV and ANCA-negative vasculitides.[44] Agents used include rituximab, and anti-TNFα (etanercept, infliximab, and adalimumab).[44] These therapies are mainly reserved for children who have failed standard treatment, or in those patients where cumulative cyclophosphamide and/or corticosteroid toxicity is of particular concern.[44]

Outcome of AAV

The mortality for paediatric GPA from one recent paediatric series was 12% over a 17 year period of study inclusion.[36] Another paediatric series of GPA reported 40% of cases with chronic renal impairment at 33 months follow-up,[37] despite therapy.

For microscopic polyangiitis (MPA) in children, mortality during paediatric follow-up is reportedly 0–14%.[32,45] For CSS in children, the most recent series quotes a related mortality of 18%, all attributed to disease rather than therapy.[39]

Predominantly medium-vessel vasculitis

Polyarteritis nodosa

Definitions, epidemiology, and classification criteria

Polyarteritis nodosa (PAN) is a necrotizing vasculitis associated with aneurysmal nodules along the walls of medium-sized muscular arteries and is the condition classically described by Kussmaul and Maier in 1866.[46] Although comparatively rare in childhood it is the most common form of systemic vasculitis after HSP and KD.[46]

The new EULAR/PRINTO/PRES classification criteria for PAN[4] are:

- histopathological evidence of necrotizing vasculitis in medium-sized or small arteries or angiographic abnormality (aneurysm, stenosis, or occlusion) as a mandatory criterion, *plus* one of the following five:
  - skin involvement
  - myalgia or muscle tenderness
  - hypertension
  - peripheral neuropathy
  - renal involvement.

Sensitivity and specificity for these criteria were 73% and 100% respectively.[4]

Aetiopathogenesis

The immunopathogenesis leading to vascular injury in PAN is probably heterogeneous.[46] The mechanism of vascular inflammation most often implicated is mediated by immune complex deposition.[46] Infections including hepatitis B, parvovirus B19, cytomegalovirus, and HIV[46] have been implicated. PAN-like illnesses have additionally been reported in association with cancers and haematological malignancies.[32,46] However, these associations are rare in childhood. Streptococcal infection may be an important trigger, and indirect evidence suggests that bacterial superantigens may play a role in some cases.[47]

Genetic predisposing factors may make individuals vulnerable to develop PAN. Yalcinkaya et al. have recently reported on the prevalence of familial Mediterranean fever (FMF) mutations in 29 children with PAN showing that 38% of the patients were carriers of *MEFV* mutations.[48]

Clinical features

The main clinical features of systemic PAN are malaise, fever, weight loss, skin rash, myalgia, abdominal pain, and arthropathy.[49] In addition, there may be ischaemic heart and testicular pain, renal manifestations such as haematuria, proteinuria, and hypertension,[50,51] and neurological features such as focal defects, hemiplegia, visual loss, mononeuritis multiplex, and organic psychosis.[52,53] Skin lesions are variable and may masquerade as those of HSP or multiform erythema but can also be necrotic and associated with peripheral gangrene.[46] Livido reticularis is also a characteristic feature and occasionally subcutaneous nodules overlying affected arteries are present.[46] Systemic involvement is variable but the skin, the musculoskeletal system, the kidneys, and the gastrointestinal tract are most prominently affected, with cardiac, neurological, and respiratory manifestations occurring less frequently.[50,54] In some patients rupture of arterial aneurysms can cause retroperitoneal and peritoneal bleeding, with perirenal haematomata being a recognized manifestation of this phenomenon. This feature has been noted a number of times in Turkey where it has occurred in patients with the well-recognized association of PAN and FMF.[55]

The characteristic histopathological changes of PAN are fibrinoid necrosis of the walls of medium or small arteries with a marked inflammatory response within or surrounding the vessel wall.[46] Indirect evidence of the presence of medium-sizes artery vasculitis affecting the renal arteries may be obtained by demonstrating patchy areas of decreased isotope uptake within the renal parenchyma on technetium-99 m dimercaptosuccinic acid (DMSA) scanning of the kidneys.[46,56] However, the most valuable investigative procedure is selective visceral catheter digital subtraction arteriography (DSA).[56] Occasionally there is a requirement to undertake cerebral arteriography at the same examination (if there is suspicion of cerebral vasculitis), and in that setting the dose of contrast agent administered requires careful consideration, particularly in small children. Findings on catheter arteriography include aneurysms, segmental narrowing, and variations in the calibre of arteries together with pruning of the peripheral vascular tree.[56]

Magnetic resonance angiography (MRA) usually fails to detect small or microaneurysms although can demonstrate large intra- and extrarenal aneurysms and stenoses/occlusions of the renal arteries or their branches, and areas of ischemia and infarction.[57] Of note, MRA may overestimate vascular stenotic lesions,[46] and this is a particular caveat of this test in small children. CT angiography (CTA) may also be able to reveal larger aneurysms and occlusive lesions and demonstrate areas of renal cortical ischemia and infarction, but concerns regarding the significant radiation exposure and its lack of sensitivity for the detection of vasculitic changes affecting smaller arteries in comparison to catheter arteriography limit its use.[46]

Cutaneous polyarteritis nodosa is a form of vasculitis affecting small and medium-sized vessels limited (essentially) to the skin.[58] It is characterized by the presence of fever, subcutaneous nodular, painful, non-purpuric lesions with or without livedo reticularis occurring predominantly in the lower extremities, with no systemic involvement (except for myalgia, arthralgia and non-erosive arthritis).[46] The disease is well recognized in childhood and there are a number of reports in the literature.[46] In a recent international survey of childhood vasculitis approximately one-third of children identified as having PAN were categorized as cutaneous PAN without systemic involvement.[32] The clinical course is characterized by periodic exacerbations and remissions that may persist for many years throughout childhood. The condition usually remains localized to the skin although a proportion of cases appear to evolve into full-blown systemic PAN in time, and clinicians need to be mindful of this possibility.[46]

Management

As in other forms of systemic necrotizing vasculitis, induction and remission phases of treatment are required.[46] Early diagnosis and treatment are key to successful outcomes.[46] The treatment of PAN involves the administration of high-dose corticosteroid with an additional cytotoxic agent such as cyclophosphamide to induce remission, typically for the first 3–6 months.[46,59] Empirically, aspirin has also been given as an anti-platelet agent by some clinicians.[46] Once remission is achieved maintenance therapy with daily or alternate-day prednisolone and oral azathioprine is frequently utilized for an additional 18 months. Adjunctive plasma exchange can be used during the induction phase of treatment in life- or organ-threatening situations.[46] Use of biological agents including anti-TNFα and rituximab is also described for children with systemic PAN, particularly those not responding to standard therapy or because of concern regarding cumulative cyclophosphamide toxicity.[44]

Treatment of cutaneous PAN is typically much less aggressive. Agents commonly utilized include low-dose prednisolone, anti-platelet agents (aspirin or dipyridamole), colchicine, hydroxychloroquine, or azathioprine.[46] However, in a few cases cutaneous PAN may progress over time to the systemic form of the disease and therefore require more aggressive therapy.[60] Cutaneous PAN may respond to non-steroidal anti-inflammatory drugs,[61] but can require oral corticosteroids in moderate dose to achieve remission.[46] When streptococcal infection is implicated penicillin may be effective.[62] Some clinicians recommend continuing prophylactic penicillin throughout childhood since relapses are common and occur in up to 25% of cases in association with further streptococcal infections.[62] In circumstances where there has been lack of response to standard treatment or concerns about possible steroid toxicity, intravenous immunoglobulin (IVIG) has been successfully utilized.[63] Some success has also been reported with the use of methotrexate, colchicine, dapsone, cyclophosphamide, pentoxyfylline, and chloroquine,[46] or (more commonly in the authors' opinion) hydroxychloroquine.

Outcome

PAN, unlike some other vasculitides such as GPA, appears to be a condition where permanent remission can be achieved. However, if treatment is delayed or inadequate, life-threatening complications can occur due to the vasculitic process. After treatment has commenced severe complications, especially infective, can arise as a sequel to the immunosuppressive drugs used. In comparison to the almost 100% mortality seen in the presteroid era, mortality rates are presently remarkably low—1.1% in a recent retrospective multi-centre analysis.[32] However, this may not be truly reflective of mortality in circumstances of severe disease since in that series 30% of patients were considered to have cutaneous PAN.[32] A mortality rate of 10% was recently recorded from a major tertiary referral centre seeing predominantly children with aggressive advanced disease.[64] The impact of newer biological therapies on these outcomes is not yet clear-cut.

Kawasaki's disease

Definitions, epidemiology, classification

KD is an acute self-limiting systemic vasculitis predominantly affecting young children. It is of worldwide distribution with a male preponderance, an ethnic bias towards East Asian children, some seasonality, and occasional epidemics.[65,66] It is the second commonest vasculitic illness of childhood (the commonest being HSP) and the commonest cause of acquired heart disease in children in the United Kingdom and the United States.[67] The incidence in Japan is 138/100 000 in children younger than 5 years,[68] whereas in the United States[69] it is 17.1 and in the United Kingdom[70] 8.1 per 100 000 children less than 5 years old.

Aetiopathogenesis

The aetiology of KD remains unknown, but currently it is felt that some ubiquitous infectious agent produces an abnormal immunological response in a genetically susceptible subject that results in the characteristic clinical picture.[46,71] Pronounced seasonality and clustering of KD cases have led to the hunt for infectious agents as a cause. However, so far no single agent has been identified, a fact most recently highlighted by the negative results that emerged from studies examining the potential link between coronavirus infection and KD in Taiwan.[47,71] One debate regarding the cause of KD has centred around the mechanism of immune activation: conventional antigen vs superantigen (SAg).[72] A superantigen is also responsible for induction of coronary artery disease in a murine model of KD. Experimental mice develop coronary arteritis in response to intraperitoneal injections of *Lactobacillus casei* wall extract (LCWE), providing a murine model of KD.[73] The peripheral immune activation within hours of LCWE injection is followed by local infiltration into cardiac tissue at day 3 with the inflammatory infiltrate consisting mainly of T cells.[73] This inflammatory response peaks at day 28 post injection and is accompanied by elastin breakdown with disruption of the intima and media, as well as aneurysm formation at day 42.[74] Rowley et al. reported three fatal cases of KD and observed IgA plasma cell infiltration into the vascular wall during the acute phase of the illness.[75] They observed that the IgA response was oligoclonal, more suggestive of a conventional antigenic process than a superantigenic-driven one.[75]

Although the clinical syndrome and occurrence of epidemics suggest an infectious cause for KD, a genetic contribution to risk is suggested by the much higher prevalence of the disease in Japan and Korea than elsewhere, and by increased prevalence within families with an increased relative risk to siblings compared to the general population.[6,16] Recently, a number of polymorphisms have been identified that appear to be linked to disease susceptibility in KD or the risk of coronary artery aneurysms.[16]

Clinical manifestations

The principal clinical features are fever persisting for 5 days or more, peripheral extremity changes (reddening of the palms and soles, indurative oedema and subsequent desquamation), a polymorphous exanthema (Figure 136.3), bilateral conjunctival injection/congestion, lips and oral cavity changes (reddening/cracking of lips as shown in Figure 136.3, strawberry tongue, oral and pharyngeal injection) and cervical lymphadenopathy (acute non-purulent).[46] For the diagnosis to be established according to the Diagnostic Guidelines of the Japan Kawasaki Disease Research Committee, five of six criteria should be present.[76] The North American recommendations for

Fig. 136.3 Characteristic polymorphous exanthema and reddening of the lips in a 4 year old child with Kawasaki disease.
Courtesy of Prof N Klein "Training in Paediatrics" Edited by Mark Gardiner, Sarah Eisen, and Catherine Murphy, Oxford University Press.

the diagnosis are similar except that fever is a mandatory criterion and four of the remaining five criteria are required to establish the diagnosis.[66] If coronary artery aneurysms are present, fewer features are required for diagnostic purposes.[46,66] The cardiovascular features are the most important manifestations of the condition with widespread vasculitis affecting predominantly medium-sized muscular arteries, especially the coronary arteries. Coronary artery involvement occurs in 15–25% of untreated cases with additional cardiac features in a significant proportion of these including pericardial effusion, electrocardiographic abnormalities, pericarditis, myocarditis, valvular incompetence, cardiac failure, and myocardial infarction.[66] If looked for, damage to other medium-sized arteries including the major limb arteries, renal and other visceral arteries, and, at times, the aorta can be demonstrated.[46]

Other systemic involvement can occur including the gastrointestinal tract; the hepatobiliary tract, with hydrops of the gallbladder being well recognized; the respiratory tract (pneumonitis); and the central nervous system with aseptic meningitis and seizures, deafness, and arthropathy.[46] Renal manifestations include pyuria, proteinuria, tubulointerstitial nephritis, and renal failure.[46] The mechanism of the renal impairment is unclear although IVIG used in treatment may play a role.[46]

Another clinical sign that maybe relatively specific to KD is the development of erythema and induration at sites of BCG inoculations.[46] The mechanism of this sign is thought to be cross-reactivity of T cells in KD patients between specific epitopes of mycobacterial and human heat shock proteins.[77]

Routinely, two-dimensional echocardiography is the means of identifying coronary artery involvement acutely, and monitoring changes in the longer term.[65] Coronary catheter arteriography may have a role, particularly for monitoring the course of giant coronary artery aneurysms (>8 mm internal diameter), since in the longer term these can be associated with stenotic lesions at the inlet and/or outlet of

the giant aneurysm, or in other circumstances where stenotic arterial lesions are suspected. This investigation provides little information about the microvasculature, however.[66] In addition, caution is advised regarding the timing of the timing of the timing of catheter coronary arteriography, since since this may be associated with significant risk of myocardial infarction if performed when the coronary vasculitis is still active. Dobutamine stress echocardiography has a role in follow-up evaluation of those with coronary artery aneurysms.[46] Spiral CTA and MRA have been advocated but the former is associated with significant radiation and the latter has limited resolution.[46]

Management

The management of KD is summarized in Figure 136.4. Early recognition and treatment of KD with aspirin and IVIG has been shown unequivocally by meta-analysis to reduce the occurrence of coronary artery aneurysms (CAA).[66,78] The prevalence of CAA is inversely related to the total dose of IVIG, 2 g/kg of IVIG being the optimal dose usually given as a single infusion over 12 hours.[66,78] Meta-analysis of RCTs comparing divided lower doses of IVIG (400 mg/kg per day for 4 consecutive days) vs a single infusion of high-dose IVIG (2 g/kg over 10 hours) has clearly shown that even though the 4 day regimen has some benefit, a single dose of 2 g/kg has a greater therapeutic effect in the prevention of CAA.[79]

IVIG resistance occurs in up to 20% of cases.[66] In those cases most advocate a second dose of IVIG based on the rationale that if there was an initial but temporary response, a second dose may adequately switch off the partially treated vasculitic process. Increasingly, however, many will consider the use of corticosteroids prior/or in addition to a second dose of IVIG.[80,81]

Regarding corticosteroid use in IVIG resistant to KD, there are apparently conflicting data from clinical trials. Inoue et al. reported on an RCT of 178 KD patients who were assigned to receive IVIG (2 g/kg) given over 2 consecutive days, or IVIG plus prednisolone sodium succinate (2 mg/kg per day) 3 times daily given by intravenous (IV) injection until the fever resolved, and then orally until the C-reactive protein (CRP) level normalized.[80] Patients in both groups received aspirin (30 mg/kg) and dipyridamole (2 mg/kg per day).[80] The addition of corticosteroid was associated with reduced CAA compared with IVIG alone: in those receiving IVIG and anti-platelet therapy, 11.4% had CAA at 1 month, compared with 2.2% in those receiving IVIG plus corticosteroids.[80] The duration of fever was shorter, and the CRP decreased more rapidly in the group of patients receiving corticosteroids.[80] In contrast Newburger et al. in a randomized, double-blind, placebo-controlled trial examined the effect of the addition of a single dose of intravenous methylprednisolone to standard therapy.[81] They found that this corticosteroid regimen did not improve the CAA outcome in these children.[81] Interestingly, a meta-analysis by Zhu et al. looked at all studies investigating the efficacy of corticosteroid therapy in KD by comparing it with standard IVIG and aspirin therapy. This analysis revealed a significant reduction in the rates of initial treatment failure among patients who received corticosteroid therapy in combination with IVIG compared to IVIG alone.[82] Furthermore, the use of corticosteroids reduced the duration of fever and the time required for CRP to return to normal.[82] Importantly, there was no increase in the frequency of coronary artery lesions in the patients receiving corticosteroids.[82] This meta-analysis therefore suggests that corticosteroids do have an important therapeutic role for the prevention of CAA, particularly in those resistant to a single IVIG dose, but that the dose and duration of corticosteroids is critical when considering this as adjunctive therapy in KD.

Infliximab, a chimeric monoclonal antibody against TNFα, has been reported to be effective for the treatment of IVIG-resistant KD.[83] In 13 of 16 patients with failed response to a single dose of IVIG who received infliximab, there was cessation of fever followed by reduction in CRP.[83] More recently, Burns et al reported on a multicentre, randomized, prospective trial of second IVIG infusion (2 g/kg) vs infliximab (5 mg/kg) in 24 children with acute KD and fever after initial failed treatment with IVIG.[84] There was resolution of fever within 24 hours in 11 of 12 subjects treated with infliximab, and in 8 of 12 subjects retreated with IVIG.[84] No significant differences were observed between treatment groups in the change from baseline for laboratory variables, fever, or echocardiographic assessment of coronary arteries.[84] These reports are encouraging, but further RCTs to establish the optimal management of KD, and in particular IVIG-resistant KD, are needed. Lastly, plasma exchange has been employed in refractory cases.[46]

In the convalescent phase of the condition, if aneurysms persist, anti-platelet therapy in the form of low-dose aspirin should be continued long term until the aneurysms resolve.[66] In the presence of giant aneurysms (>8 mm) warfarin is recommended in addition to aspirin.[85] Some patients may require coronary angioplasty or other revascularization procedure should ischaemic symptoms arise.[66]

Outcome

The outlook for KD patients is generally good. The standardized acute mortality ratio in Japan is 1.14.[86] Angiographic resolution 1–2 years after onset of disease has been observed in 50–70% of vessels with coronary aneurysms.[87] About 20% of patients who develop CAA during the acute disease will develop coronary artery stenoses and the risk is greater with giant (>8 mm) aneurysms.[87] However, there are data suggesting that in spite of seeming recovery, there could be long-term cardiovascular sequelae that persist into adult life.[46] In a study exploring the long-term outcomes of a cohort of 6576 patients with KD enrolled between 1982 and 2004 the mortality rate for patients without cardiac sequelae in the acute phase of the disease and for female patients with sequelae did not differ from the normal population.[86] The mortality rate of males with cardiac sequelae was, however, 2.4 times higher than the normal population.[86] Epidemiological studies from Japan have also demonstrated that late sequelae, especially in patients with large aneurysms, include myocardial ischaemia with a frequency of 3% within 4 years after the onset of the disease.[78] The study of late vasculopathy years after KD is therefore an important ongoing area of research to try to identify those patients who may in the future require interventions for the primary prevention of late cardiovascular complications.

Predominantly large-vessel vasculitis

Takayasu's arteritis

Definitions, epidemiology and classification

The onset of TA is most common during the third decade of life but has been well reported in young children.[88] The EULAR/PRES/PRINTO classification criteria for childhood TA are:

- angiographic abnormalities of the aorta or its main branches (also pulmonary arteries) showing aneurysm/dilatation (mandatory criterion), *plus* one of the five following criteria[4]:

  - pulse deficit or claudication

  - four-limb blood pressure discrepancy

Establish diagnosis of Kawasaki Disease*

- IVIG 2g/kg as a single infusion over 12 hours (consider splitting the dose over 2–4 days in infants with cardiac failure)
- Aspirin 30–50 mg/kg /day in four divided doses
- Perform echocardiography, and ECG
- Aspirin 2–5 mg/kg/day when fever settled (disease defervescence) continuing for a minimum of 6 weeks.

Disease defervescence

- ♠Repeat echocardiography at 2 weeks and 6 weeks

No Disease defervescence within 48 hours, or disease recrudescence within 2 weeks

Seek expert advice to consider:
- Second dose of IVIG at 2g/kg over 12 hours
- Consider pulsed methyl prednisolone at 15–30 mg/kg daily for 3 days to be followed by oral prednisolone 2 mg/kg/day OD weaning over 6 weeks-seek expert advice
- Infliximab (6mg/kg) for refractory cases-seek expert advice

No Coronary artery abnormalities (CAA)
- Stop aspirin at 6 weeks
- Consider lifelong follow up at least every 2 years

CAA < 8mm, no stenoses
- Continue aspirin until aneurysms resolve
- Repeat echocardiography & ECG at 6 monthly intervals
- Discontinue aspirin if aneurysms resolve
- Consider exercise stress test if multiple aneurysms
- Specific advice RE minimising atheroma risk factors, and consider lifelong follow up

¶CAA > 8mm, and/or stenoses
- Lifelong aspirin 2–5 mg/kg/day
- Warfarin
- Consider coronary angiography (after at least 6 months from disease onset) and exercise stress testing
- Repeat echocardiography & ECG at 6 monthly intervals
- Specific advice RE minimising atheroma risk factors
- Lifelong follow up

Notes:
*Treatment can be commenced before full 5 days of fever if sepsis excluded; treatment should also be given if the presentation is >10 days from fever onset
♠Refer to paediatric cardiologist
¶Other specific interventions such as PET scanning, addition of calcium channel blocker therapy, and coronary angioplasty at discretion of paediatric cardiologist.

Fig. 136.4 Management of Kawasaki disease.

Reproduced from Oxford Specialist Handbook of Paediatric Rheumatology, ed Helen Foster and Paul Brogan. © Oxford University Press, 2012.

- bruits
- hypertension
- acute-phase response.

Familial occurrence of the disease has been extensively reported, leading to a hypothesis for a hereditary basis, and should be considered when the disease presents in young children.[89]

Clinical features

Clinical diagnosis of TA is commonly challenging for the clinician, especially when it presents in young children. An initial florid inflammatory vasculitic phase is followed by a later fibrotic phase of the illness.[88] It is estimated that one-third of children present within this late fibrotic/stenotic phase of the disease. It is a misconception that this is in some way an 'inactive', or 'burnt-out' stage of the disease, since progressive stenotic disease may be the consequence of persistent but low-level large-vessel vasculitic disease activity, but without evidence of conventional laboratory markers of systemic inflammation such as elevated CRP or increased erythrocyte sedimentation rate (ESR).[88] The time from onset of symptoms to diagnosis are variable, but can be several years.[4]

Although hypertension and/or its sequelae is the most common form of presentation in both children and adults,[90] the overall clinical spectrum at presentation of children with TA may differ from that in adults. Cakar et al. reported in a series of 19 children with TA that the most common complaints at presentation were headache (84%), abdominal pain (37%), claudication of extremities (32%), fever (26%), and weight loss (10%).[90] One child presented with visual loss. Examination on admission revealed hypertension (89%), absent pulses (58%), and arterial bruits (42%) in the same cohort.[90] Aortic and mitral valve involvement with the vasculitic process are recognized,[88] as is myocardial involvement including the formation of ventricular aneurysms, sometimes with calcification.[88]

Treatment and outcome

Treatment is broadly similar to that for adults with TA. Ozen et al. described six children with TA, and treatment with steroid and cyclophosphamide induction followed by methotrexate (MTX) was suggested as effective and safe for childhood TA with widespread disease.[88] Anti-TNF therapy may be beneficial.[91] The 5 year mortality rate in children has been reported to be as high as 35%,[88] with prognosis dependent upon the extent of arterial involvement and on the severity of hypertension.[88,90]

Miscellaneous vasculitides

Richard A. Watts and Eleana Ntatsaki

Introduction

This chapter covers a wide range of individual conditions, which come under the umbrella of the term vasculitis. Where appropriate we have followed the Chapel Hill Classification and Nomenclature system.[1]

Immune complex small-vessel vasculitis

Hypocomplementaemic urticarial vasculitis

Hypocomplementaemic urticarial vasculitis (HUV) is defined as a vasculitis accompanied by urticaria and hypocomplementaemia affecting small vessels (i.e. capillaries, venules, or arterioles), and associated with anti-C1q antibodies. Common clinical features include glomerulonephritis, arthritis, and ocular inflammation (uveitis, scleritis, and episcleritis). The urticarial wheals may be accompanied by central purpura, are more painful, and tend to persist for longer (24–72 hours) compared to those of chronic urticaria (<24 hours). Laboratory findings include low complement levels of classical pathway, namely C1q, C2, C3, and C4, together with an acute-phase response. Antibodies against C1Q are invariably present in HUV, and this 100% sensitivity suggests a pathogenic role.[2] Systemic glucocorticoids can control the attack and prevent relapses. The urticarial lesions respond poorly to antihistamines. Patients may have significant morbidity and mortality, most commonly caused by chronic obstructive pulmonary disease and acute laryngeal oedema.

IgA vasculitis (Henoch–Schönlein purpura)

This is a vasculitis with IgA1–dominant immune deposits affecting small vessels. It typically involves the skin, gut, and glomeruli and is associated with arthralgia and arthritis.[3] It is predominately a childhood disease (see Chapter 136) but occurs rarely in adults, in whom it may be a more severe disease. The typical rash is erythematous papules followed by non-thrombocytopaenic purpura and is characteristically the presenting feature (Figure 137.1). A small proportion of patients (8%) with renal involvement and a mixed nephrotic/nephritic picture develop chronic renal failure. Most cases are self-limiting, but patients with severe skin or renal disease may need immunosuppressive therapy.

Cryoglobulinaemic vasculitis

Cryoglobulinaemic vasculitis is a rare small-vessel vasculitis that is often associated with hepatitis C virus (HCV) infection.

Cryoglobulinaemia is the presence in the serum of immunoglobulins that precipitate in vitro at temperatures below 37 °C. Cryoglobulins are classified according to the clonality and type of the immunoglobulins[4]:

- type I consists of monoclonal immunoglobulin, either IgM or IgG
- type II are a mixture of monoclonal IgM and polyclonal IgG
- type III are a mixture of polyclonal IgM and IgG.

Types II and III are also known as mixed cryoglobulins as they have both IgG and IgM components.

A strong association is recognized between HCV infection and predominately type II cryoglobulinaemia. Hepatitis B (HBV) infection can also be associated with mixed cryoglobulinaemia. Cryoglobulinaemic vasculitis is more common in areas endemic for HCV and has a predilection for women (3:1).[5]

The clinical features of cryoglobulinaemic vasculitis were first described by Meltzer and colleagues in 1966.[6] The triad of purpura, arthralgia, and weakness, accompanied by organ dysfunction constitute the typical presentation in less than 40% of patients with cryoglobulinaemia.[7] The most frequently affected internal organs are peripheral nerves (polyneuropathy, mononeuritis multiplex of acute onset, or peripheral neuropathy of subacute gradual onset), kidneys (nephritic syndrome or nephritic urinary sediment due to mesangial proliferative glomerulonephritis in 40%) and joints

Fig. 137.1 Typical purpuric rash on a patient with IgA vasculitis.

(arthralgia or non-erosive arthritis in 10%). Systemic symptoms such as fever, weight loss, and myalgia are common. Purpura is the most typical cutaneous manifestation; however, urticaria, livedo, exanthema, acral necrosis, and leg ulcers may also occur. Raynaud's phenomenon is seen in 20% of cases.[8]

There are no standardized or validated diagnostic or classification criteria for cryoglobulinaemic vasculitis. Diagnosis is based on clinical presentation and the presence of circulating cryoglobulins. Viral serology together with appropriate tissue biopsy differentiates the diagnosis from the other systemic vasculitides.

High titres of rheumatoid factor (RF) are present in 70% of patients. Anti-neutrophil cytoplasmic antibodies (ANCA), anti-nuclear antibodies (ANA) and anti-cardiolipin antibodies are usually absent and complement levels are low in 90% of cases. Sample collection and handling is crucial when testing for cryoglobulins. The blood should be collected in pre-warmed syringes, transported, clotted, and centrifuged at 37–40 °C. The serum is thereafter stored at 4 °C for 7 days. Type I cryoglobulins precipitate within hours whereas mixed cryoglobulins can take days to precipitate.[9]

More than 90% of cases of cryoglobulinaemia have a recognized underlying cause. Therapy is focused on treating the cause of the disorder rather than simple symptomatic management. A combination of pegylated interferon-α and ribavarin is the therapeutic cornerstone for HCV-related cryoglobulinaemic vasculitis. Current consensus suggests that severe or life-threatening disease should be treated with steroids and cyclophosphamide together possibly with plasma exchange.[10] B-cell depleting therapies, although promising, should currently be reserved for severe refractory cases while the results of randomized trials are awaited.[4]

Anti-glomerular basement membrane disease

Anti-glomerular basement membrane (GBM) disease (Goodpasture's syndrome) is a vasculitis affecting glomerular capillaries, pulmonary capillaries, or both, with basement membrane deposition of anti-basement membrane autoantibodies. Lung involvement causes pulmonary haemorrhage, and renal involvement causes glomerulonephritis with necrosis and crescents.

Anti-GBM disease is an autoimmune disorder that mostly presents as rapidly progressive glomerulonephritis and pulmonary haemorrhage together with raised titres of antibodies against the GBM. The target autoantigens are the non-collagenous (NC1) regions of the α3 and to a lesser extent the α5 chains of type IV collagen. Treatment is generally immunosuppression combined with plasma exchange.[11]

Single-organ vasculitis

Single-organ vasculitis is a condition where the inflammatory process affecting the vessel walls appears to be localized to a single organ and there is no evidence to suggest local expression of a systemic process. Vasculitis may be unifocal or diffuse within the affected organ. Typical examples of diffuse forms of single-organ vasculitis include primary angiitis of the central nervous system (CNS), and cutaneous leucocytoclastic vasculitis.

Cutaneous vasculitis

Cutaneous vasculitis is one of the most frequent expressions of vasculitis; the appearances can be quite varied and a number of different types have been described.

Leucocytoclastic vasculitis

Leucocytoclastic vasculitis is one of the most common types of skin vasculitis in adults and it usually affects the lower legs. Lesions range from palpable purpura to urticarial plaques and haemorrhagic bullae. Leucocytoclasis is the destruction of cell nuclei with accumulation of nuclear dust. Chronic disease may result in ulceration. Precipitants include drugs (e.g. sulphonamides and penicillins), infection, or foreign protein (serum sickness) and therefore the condition is sometimes referred to as a hypersensitivity vasculitis. The prognosis is generally good with spontaneous resolution of lesions following withdrawal of the trigger. Development of systemic features such as arthralgia, abdominal pain, or haematuria should prompt assessment for systemic vasculitis and is indicative of a worse prognosis.

Cutaneous polyarteritis nodosa

Cutaneous polyarteritis nodosa is a chronic relapsing arteritis of subcutaneous and deep dermal small and medium-sized vessels. By definition, visceral organs are spared. Progression to systemic disease is rare. The cutaneous lesions are painful nodules which may ulcerate and occur most frequently on the lower legs (Figure 137.2). There may be marked livedo reticularis. There are no diagnostic markers and the diagnosis is made on the typical lesions and histology. Treatment usually requires glucocorticoids in moderate doses. Other agents that have been used include sulphapyridine, dapsone, and stanazolol. The role of other immunosuppressants is uncertain.[12]

Erythema elevatum diutinum and granuloma faciale

These represent rare but distinctive forms of localized chronic cutaneous leucocytoclastic vasculitis with no systemic involvement
Fig. 137.2 Typical cutaneous lesions and livedo reticularis on a patient with cutaneous polyarteritis nodosa.

and unknown aetiology. Erythema elevatum diutinum presents with oedematous purplish-brown plaques over the back of hands, elbows, or knees which slowly enlarge and heal over months or years with fibrosis. Granuloma faciale is a persistent well-defined smooth papule and plaque on the face consisting of one or more pink-brown lesions.[13,14]

Isolated central nervous system angiitis (primary angiitis of the CNS)

CNS vasculitis is one of the rarest forms of vasculitis, with a large differential diagnosis. Due to a lack of validated diagnostic criteria it often poses a difficult challenge for the clinician. Primary angiitis of the central nervous system (pACNS) refers to disease confined to the brain, spinal cord, and overlying leptomeninges. Secondary CNS vasculitis occurs in the context of vascular inflammation caused either by systemic vasculitis, lymphoproliferative disease, infection (herpes zoster, syphilis, brucellosis, HIV), sarcoid, or amyloidosis.[15]

Typical presentation of pACNS is with headaches and behavioural/mental changes lasting a few weeks. Intermittent confusion and focal neurological changes such as aphasia, hemiparesis, seizures, transient ischaemic attacks, and strokes may also occur. Vision is commonly affected with visual defects in 1 in 5 patients and decreased acuity in 1 in 10 patients.

The diagnosis of CNS angiitis is usually based on a combination of MRI, cerebrospinal fluid (CSF), and biopsy findings.[16] Routine laboratory investigations are important in excluding secondary CNS vasculitis. However, inflammatory markers are not a reliable guide for monitoring disease activity or response to treatment. CSF abnormalities are found in 88% of patients and consist of elevated white cells and protein. Cerebral imaging is abnormal in 97% of patients and may reveal cerebral infarction in 50% of the patients. Intracranial haemorrhage is not as common (~10%). MRI has been shown to have a high positive predictive value in children.[17] Gadolinium enhancing of the leptomeninges may be useful in guiding a biopsy.

Biopsy of the leptomeninges, although only 75–80% sensitive, is necessary for a definitive diagnosis. Histological features of granulomatous vasculitis with or without acute necrosis or lymphocytic pattern support a diagnosis of primary CNS vasculitis. A biopsy can also prove useful in excluding other forms of vascular inflammation, malignancy and infection.

Treatment remains empirical. Induction therapy is with high-dose corticosteroids (1 mg/kg, maximum 60 mg and then tapered to 10 mg at 6 months; or intravenous methylprednisolone in severe cases) combined with intravenous cyclophosphamide in patients with poor prognosis. Maintenance therapy with oral corticosteroid is rarely required beyond 18 months. Refractory disease may respond to immunosuppression with mycophenolate mofetil or biologic therapy, although there is little evidence to support this. Relapse is not uncommon occurring in up to one-quarter of patients followed for 13 months in adults, whereas in children relapse rates are lower.[18]

Other organs

Several case series and individual reports have described patients with isolated vasculitis of the abdominal, gastrointestinal,[19] or genitourinary system,[20] breast, ascending aorta,[21] and skeletal muscle.[22]

Depending on the organ affected, clinical, serological, and histopathological features are helpful in diagnosing the severity of the inflammatory process. There are no features in the history, examination, laboratory testing, radiological, or angiographic investigations that are specific for the diagnosis of single-organ vasculitis. Histology is crucial for definitive diagnosis but may be indistinguishable from systemic syndromes.

In contrast to the systemic vasculitides the prognosis of single focal-organ vasculitis is very good as excision of the affected organ can be curative.[20,21] However, the prognosis is worse where ischaemic or haemorrhagic complications of the visceral organs or dissection/rupture of the aortic arch develop. Even forms of single-organ vasculitis may require treatment with systemic immunosuppressants if diffuse and severe disease is present depending on the organ involved.

It is very important to exclude systemic illness at the time of diagnosis and throughout the period of treatment and follow-up, as well as infection, malignancy, and other systemic autoimmune diseases. Progression to systemic disease is unusual even without immunosuppression. However, as many of the systemic vasculitides present initially as a localized process, it is important to remain vigilant and look out for features that are associated with progression to systemic disease.[23]

Infection and vasculitis

The notion of infection acting as a trigger for autoimmunity is not new. Infection may induce de-novo expression and relapse of vasculitis.[24] This may occur via direct microbial toxicity affecting the endothelium, either by invasion or the effect of microbial toxins. Humoral or cellular immune responses can lead to vasculitis via immune complex pathways (such as in HCV and cryoglobulinaemia) and also through mechanisms of molecular mimicry and superantigens.[25,26]

An increasing number of organisms are implicated in triggering vasculitis (Table 137.1). Identifying an infectious origin of vasculitis is of paramount importance as treatment strategies will need to include effective antimicrobial drugs.[27] Infection can also be a consequence of intensive immunosuppressive treatment for vasculitis.

Bacterial infections

Direct invasion of blood vessels by pyogenic organisms (e.g. staphylococcus and streptococcus) is a well-described cause of vasculitis, as is septic haematogenous embolization. Vessels previously damaged due to atheroma and surgery are more susceptible and conditions such as diabetes mellitus are predisposing. Bacterial infections with meningococcus or gonococcus can affect small vessels, causing necrotizing vasculitis or thrombosis. This can lead to maculopapular or purpuric lesions which when aspirated can isolate the organisms. In 50% of cases the microorganism can be isolated from blood cultures and prompt targeted antimicrobial therapy to eliminate the infective cause of the secondary vasculitis.[27]

A wide variety of bacteria including streptococcus, staphylococcus, klebsiella, pseudomonas, and more unusual microorganisms such as haemophilus and brucella have been reported to cause large-vessel arteritis. Although rare, it usually presents with the formation of mycotic aneurysms. Salmonella aortitis usually affects the abdominal aorta presenting with fever and abdominal and back pain. Predisposing conditions such as diabetes, intravenous drug

Table 137.1 Infection and vasculitis

	Infection	Vessel involved	Typical clinical associations
Bacterial	*Staphylococcus*	LA, MA, SVMA,SVLC	Mycotic aneurysm
	Salmonella	LA, MA, SVMA,SVLC	Abdominal aortitis
	Mycobacteria	LA, MA, SVMA,SVLC	Erythema nodosum
	Streptococcus	LA, MA, SVMA,SVLC	Mycotic aneurysms
	Klebsiella	LA	Mycotic aneurysms (rare)
	Pseudomonas	LA	Mycotic aneurysms (rare)
	Hemophilus, Brucella	LA	Mycotic aneurysms (very rare)
	Yersinia	SVLC	Digital vasculitis
	Neisseriae	SVLC	Necrotizing vasculitis and thrombosis
	Pseudomonas	SVMA	Ecthyma gangrenosum
	Nocardia	SVMA	Ecthyma like lesions
	Rickettsiae	SVLC	Macular papular rash
	Borrelia burgdorferi	SVMA	CNS vasculitis
Viral	HBV	MA, SVMA, SVLC	PAN
	HCV	MA, SVMA, SVLC	Cryoglobulinaemic vasculitis, PAN
	HIV	MA, SVMA, SVLC	PAN large/medium/small-vessel vasculitis cerebral vasculitis
	parvovirus B19	MA, SVLC	PAN, purpuric rash
	CMV	SVMA, SVLC	Retinitis, Colitis, PAN
	Herpes/Varicella zoster	SVLC	Retinitis meningo-encephalomyelitis
	HTLV-1	SVMA	Necrotizing retinitis, cerebral vasculitis
Spirochaetal	*Treponema pallidum*	LA	Syphilitic aortitis
Fungal	*Coccidiomycosis*	LA	Basilar granulomatous meningitis

CMV cytomegalovirus; CNS central nervous system; HBV hepatitis B virus; HCV hepatitis C virus; HIV human immunodeficiency virus; HTLV-1 human T-cell lymphotropic virus type 1; LA, large arteries; MA, medium arteries; PAN, polyarteritis nodosa; SVLC, small-vessel leucocytoclastic vasculitis; SVMA, small vessels and medium arteries.

abuse, hypertension, malignancy, and immunodeficiency also play a role. Treatment is with intravenous antibiotics and surgery but mortality remains high.

Infections can also affect the course of primary vasculitides. *Staphylococcus aureus* nasal carriage has been linked with higher risk of relapse in patients with GPA and the relative risk is modulated by the type of staphylococcus and is greater in the presence of toxic-shock-syndrome toxin-1.[28]

Mycobacterial infections

Mycobacterial infections can affect all vessels types but in *Mycobacterium tuberculosis* infection veins are more vulnerable than arteries.[25] Tuberculous vasculitis presents clinically with erythema nodosum and histopathology confirms granulomatous panarteritis or thrombophlebitis. Acid-fast bacilli can also be isolated in or adjacent to the vessel wall.

M. leprae infection causes focal vascular lesions of arteries and veins with equal frequency. Erythema nodosum leprosum (painful cutaneous nodules evolving towards ulceration) of the small vessels and vasa vasorum vasculitis of large vessels are the most common presenting features.[27]

Viral infections

The link between hepatitis B infection (HBV) and polyarteritis nodosa (PAN) has been known for 40 years.[29,30] In France, falling HBV infection rates and the development of vaccines against HBV have been correlated with a decrease in HBV-associated PAN.[29,31] Despite that, 400 million people are infected worldwide and 20% of those may develop extrahepatic manifestations.[32] A recent systematic retrospective study of 348 PAN patients registered over 42 years compared patient characteristics and outcome according to HBV status. Patients with HBV-related PAN had more frequent peripheral neuropathy, abdominal pain, cardiomyopathy, orchitis, and hypertension compared with patients with non-HBV-related PAN. HBV-related PAN had significantly better relapse rates and mortality.[33] Treatment is with anti-viral therapy in addition to conventional immunosuppression in combination with plasma exchange.[29,34]

In HCV-associated autoimmune diseases, type 2 cryoglobulinaemia is present in 52% of cases.[34] HCV infection has also been associated with a PAN-type vasculitis with involvement of medium-sized arteries and a necrotizing vasculitis.[35] Anti-viral treatment (pegylated interferon-α and ribavarin) should be considered for

all HCV-positive patients with underlying vasculitis.[4,34] Sustained elimination of HCV RNA is required for long-term suppression of vasculitis, and maintenance of anti-viral therapy is therefore required. Severe or life-threatening disease should be treated with steroids, cyclophosphamide, and possibly plasma exchange.[36] B-cell depletion is a future promising approach.[4]

HIV infection may cause vasculitis either directly or as a consequence of secondary opportunistic infection, particularly with cytomegalovirus or tuberculosis.[37,38] A number of patterns of vasculitis have been described including polyarteritis nodosa-like, hypersensitivity vasculitis, large-vessel disease, and cerebral vasculitis.[27] Vasculitis usually occurs in late HIV infection and treatment is difficult, combining anti-viral therapy, plasmapheresis, and short courses of corticosteroids.

Parvovirus B19, cytomegalovirus (CMV), and herpes zoster are the other major viruses that have been implicated in the pathogenesis of vasculitis.[25] Parvovirus has been associated with PAN and IgA vasculitis. Herpes zoster is associated with meningoencephalitis and retinitis while CMV is associated with colitis, PAN, and retinitis.[27]

Vasculitis and malignancy

Acute vasculitis may be the presenting feature of an undiagnosed malignancy. Vasculitis has been associated with a variety of malignancies, mainly haematological and more rarely solid malignancies (Table 137.2). Possible pathogenic mechanisms include immune complex formation, tumour antigens acting as a sensitizing antigen, malignant cell products stimulating vascular inflammation, and direct invasion. Malignancy may also occur as a result of toxic immunosuppressive treatments.

Malignancy developing in patients with a diagnosis of vasculitis

Hejil et al.[39] reviewed the incidence of malignancy in patients treated for ANCA-associated vasculitis (AAV) using follow-up data from European Vasculitis Study Group clinical trials. This analysis concerned 535 patients with newly diagnosed AAV from 15 European countries. During the 2650 person-years observation period, 50 cancers were diagnosed in 46 patients. The standardized incidence ratios (SIR) and their 95% confidence intervals were 1.58 (1.17–2.08) for cancers at all sites, 1.30 (0.90–1.80) for cancers at all sites excluding non-melanoma skin cancer (NMSC), 2.41 (0.66–6.17) for bladder cancer, 3.23 (0.39–11.65) for leukaemia, 1.11 (0.03–6.19) for lymphoma and 2.78 (1.56–4.59) for NMSC. Cancer rates for AAV patients treated with conventional immunosuppressive therapy were found to be higher than those expected for the general population. This difference was attributed to the increased incidence of NMSC.

A population-based cohort study from the Mayo clinic that compared 204 giant cell arteritis (GCA) patients with 407 age- and sex-matched subjects suggested that such patients are not at increased risk of cancer following disease diagnosis. The hazard ratio for developing cancer was 1.26 (95% CI 0.87–1.83) and there was no difference in overall mortality between the two groups.[40]

Malignancy associated with subsequent development of vasculitis

A review of 2800 patients with vasculitis and 69 000 patients with cancer identified 69 patients with both diagnoses. In 12 of those vasculitis occurred within 12 months of the malignancy.[41] Half of those patients had solid tumours and the rest had haematological malignancies including lymphoma, myeloma, and leukaemia. The most common type of vasculitis seen was cutaneous leucocytoclastic vasculitis.

Malignancy related to toxicity from vasculitis therapy

Knights et al. looked at the risk of developing bladder cancer in relation to cyclophosphamide treatment in patients with GPA and reported that the risk doubled for every 10 g increment of cyclophosphamide used.[42] Treatment duration of more than 1 year was associated with an eightfold increased risk of bladder cancer and the absolute risk reached 10% 16 years after diagnosis of GPA. A more recent review concluded that daily oral cyclophosphamide is associated with an increased risk of both haemorrhagic cystitis and bladder cancer, in a dose-dependent and/or duration-dependent

Table 137.2 Malignancy and vasculitis

Malignancy developing in patients with a diagnosis of primary systemic vasculitis	Malignancy associated with subsequent development of vasculitis	Malignancy related to toxicity from vasculitis therapy	Vasculitis associated with malignancy	Vasculitis mimicking malignancy
Bladder cancer	Myelodysplasia	Bladder cancer	GPA	GPA and Lymphoma
Lymphoma	Lymphoma	Lymphoma	PAN	Primary CNS vasculitis and brain neoplasms
Leukaemia	Hairy cell leukaemia	Leukaemia	IgAV	PAN and testicular cancer
Non-melanoma skin cancer	Myeloma	Squamous cell skin cancer	Cutaneous Leucocytoclastic Vasculitis	Paraneoplastic syndormes
Renal cell carcinoma	Solid tumours	Renal cell carcinoma	MPA	
Colon adenocarcinoma		Colonic cancer		
		Cholangiocarcinoma Breast cancer		

CNS, central nervous system; GPA, granulomatosis with polyangiitis; IgAV IgA vasculitis; MPA, microscopic polyangiitis; PAN, polyarteritis nodosa.

manner with an increased risk of bladder cancer years later.[43] Intravenous cyclophosphamide therapy, as prescribed for rheumatic diseases, was reported to carry a low risk of cystitis and probably also of bladder cancer.

In the Wegener's Granulomatosis Etanercept Trial (WGET study) there was an increased frequency of solid tumours in the etanercept group, including colonic cancer, cholangiocarcinoma, breast cancer, and renal cell carcinoma. The long-term follow-up data of the WGET cohort (43 months) showed that the incidence of solid malignancy remained increased, although it is uncertain if this represents the association between GPA and malignancy or whether it was a result of the treatment. Nevertheless, anti-TNF therapy with etanercept appeared to further increase the risk of malignancy observed in patients with GPA treated with cytotoxic agents and should be avoided in these patients.[44]

Other immunosuppressive drugs such as azathioprine have also been associated with malignancies such as lymphoma, squamous cell skin cancer, and leukaemia.

Vasculitis mimicking malignancy

Finally, vasculitis may also mimic malignancy. A large mass of inflammatory tissue associated with constitutional symptoms can easily be misdiagnosed as a malignancy. Differentiating between lymphoma and GPA of the upper airways can be very challenging. There are several case reports of localized vasculitis mimicking neoplasms. Examples include testicular PAN mimicking testicular neoplasms,[45] or primary angiitis of the CNS mimicking tumour-like brain lesions.[46,47] Paraneoplastic syndromes often present as cutaneous vasculitis and skin manifestations may represent the very first diagnostic sign of a neoplastic disease in about 1% of patients.[48]

Drugs and vasculitis

The commonest clinical feature of drug-induced vasculitis is leucocytoclastic vasculitis (see 'Leucocytoclastic vasculitis'). It usually presents with a purpuric rash affecting symmetrically the lower extremities. The rash disappears within several weeks of drug withdrawal but may scar or leave haemosiderosis. Laboratory findings may include leucocytosis, hypocomplementaemia, and raised acute-phase response, although these are non-specific. An eosinophilia can be suggestive of drug aetiology but is also a typical feature of eosinophilic granulomatosis with polyangiitis (EGPA, Churg–Strauss syndrome). MPO-ANCA may be present and sometimes reflects systemic involvement. The most frequent precipitants are hydralazine and propylthiouracil. Although the condition is usually self-limiting on withdrawal of the trigger drug, it may relapse. Treatment options depend on the underlying cause and mainly consist of removal of the precipitating factor. Non-steroidal anti-inflammatory drugs (NSAIDs) have been used with encouraging response in cases with coexisting arthralgia. Immunosuppressive therapy is recommended only in patients with vital organ involvement without requiring maintenance therapy.[49]

The development of EGPA has been associated with use of leukotriene inhibitors and the anti-IgE monoclonal antibody omalizumab, which may due to unmasking previous undiagnosed disease with reduction in glucocorticoid use.[50,51]

A number of recreational drugs such as heroin, cocaine, and methamphetamine have also been reported as vasculitis triggers and are mainly associated with cerebral vasculitis. Cocaine-induced midline destructive lesions may mimic the midfacial destructive change of GPA. Cocaine-levamisole induced vasculopathy is associated with cutaneous vasculitis, leucopenia, and ANCA positivity.[52,53]

Inflammatory rheumatic disease

Systemic rheumatoid vasculitis

Rheumatoid vasculitis is a destructive inflammatory process affecting the blood vessels of patients with long-standing severe rheumatoid arthritis (RA). It is an uncommon but potentially serious systemic disease manifestation that can affect all vessel sizes from aorta to capillaries in patients with seropositive disease.

During the 1990s and 2000s there have been significant changes in the treatment of RA with a focus on aggressive control of inflammation. These might have contributed to the significant incidence decrease reported by recent studies, both in the United Kingdom and the United States, estimating the current incidence of systemic rheumatoid vasculitis (SRV) at less than 4 per million.[54,55] The effects of genetic factors such as *HLA DRB1* shared epitope genotypes,[56] and environmental factors such as change in smoking status are also considered important.[57]

Rheumatoid vasculitis presents in a wide spectrum of organs and systems. Cutaneous changes, nailfold infarcts, peripheral nerve involvement, and systemic symptoms are the most common manifestations. Pulmonary, renal, and cardiovascular involvement (pericarditis) and more rarely ophthalmic involvement (corneal melt, scleritis) are also seen. The typical patient is male with nodular erosive seropositive disease with a severe disease course and extra-articular manifestations such as nodules and pulmonary fibrosis.

There are no validated diagnostic criteria for the definition of SRV. The classification criteria proposed by Scott and Bacon (Box 137.1)[58] are most commonly used.

Leg ulcers are multifactorial but common in RA patients. True vasculitic ulcers are painful, deep, punched-out lesions of acute onset in sites not typically associated with venous stasis ulceration.

The three main patterns of rheumatoid vasculitis are (1) isolated nailfold vasculitis (Figure 137.3) due to digital endarteritis with intimal proliferation, (2) venulitis and small-vessel arteritis characterized by rash, skin eruptions or purpura, and (3) necrotizing

---

Box 137.1 Proposed classification criteria (Scott and Bacon 1984) for systemic rheumatoid vasculitis

- Presence of one or more of the following criteria in a patient with RA:
  - Mononeuritis multiplex or acute peripheral neuropathy
  - Peripheral gangrene
  - Biopsy evidence of acute necrotizing arteritis plus systemic illness (e.g. fever or weight loss)
  - Deep cutaneous ulcers or active extra-articular disease (e.g. pleurisy, pericarditis, scleritis) if associated with typical digital infarcts or biopsy evidence of vasculitis
- Other causes of such lesions, such as diabetes and atherosclerosis should be excluded and nailfold or digital infarcts alone do not suffice for a diagnosis of SRV to be made

Fig. 137.3 Typical nailfold lesions on a patient with systemic rheumatoid vasculitis.

arteritis of small and medium-sized arteries with involvement of internal organs and peripheral nerves. Patients presenting with isolated nailfold vasculitis have a low risk of progressing from localized to systemic disease.[59] Peripheral nerve involvement occurs due to necrotizing vasculitis of the vasa nervosum. Acute mononeuritis multiplex is very specific to systemic vasculitis. A distal symmetric sensory or sensorimotor pattern of peripheral neuropathy is more commonly described.

There are no current evidence-based therapeutic guidelines for SRV. Treatment with cyclophosphamide and corticosteroids follows similar protocols to those used for AAV and is recommended for SRV with visceral involvement or active disease. Mild cases can be treated with disease-modifying anti-rheumatic drugs (DMARDs) such as methotrexate or azathioprine in combination with oral prednisolone. Isolated nailfold vasculitis may be treated symptomatically. Use of anti-TNF treatment is controversial. There is some supportive evidence for its use,[55] but also some case series reports propose a causal association between biologics and SRV.[60] Rituximab has also been successfully used.[61–63] Aggressive treatment of traditional risk factors for atherosclerotic disease and smoking cessation should also be pursued alongside mainstream treatment.

SRV has significant mortality and morbidity and should be recognized and treated promptly and aggressively. Its increasing rarity may prevent larger controlled trials from providing strong evidence-based management guidelines; therefore empirical treatment with cyclophosphamide and steroids is likely to remain the dominant therapeutic paradigm.

Seronegative spondyloarthopathies

The commonest form of vascular involvement in ankylosing spondylitis is an aortitis affecting predominately the aortic root and ascending aorta. Distal aortitis is less frequent. Aortic incompetence may present as a result of aortic root inflammation. Aortic incompetence occurs in up to 5% of cases of ankylosing spondylitis, 2.5% of cases of reactive arthritis, and probably less frequently in the other seronegative spondyloarthropathies.[64] The duration of disease is associated with an increased risk of developing aortitis and is estimated at 10% for a patient diagnosed with ankylosing spondylitis for 30 years.

Echocardiography shows thickened aortic leaflets and histology reveals lymphocytic infiltration possibly with fibrosis in the aortic wall and aortic root. Obliterative endarteritis and fibrosis can be caused by vasculitis affecting the small arteries of the cardiac and aortic tissues.[65] Other types of large-vessel vasculitis such as Takayasu's arteritis have been described in patients with seronegative spondyloarthropathies.[66]

There is no evidence-based treatment for aortitis secondary to spondyloarthropathies, but anecdotal reports suggest the use of immunosuppressive drugs in cases of active inflammation. Surgery is particularly risky in the context of uncontrolled inflammation.

Systemic lupus erythematosus

The most common organ affected by vasculitis in systemic lupus erythematosus (SLE) is the skin.[65] Punch biopsy of cutaneous SLE lesions most commonly show findings of fibrinoid changes in the vessel walls composed of immunoglobulin and complement compatible with leucocytoclastic vasculitis.[67] Vasculitic skin lesions are usually found at the fingertips or toes, or on the extensor surface of the forearm. Vasculitis causing neurological, renal, or cardiac involvement is rare but may present as mononeuritis multiplex, progressive glomerulonephritis, and pericarditis respectively. Treatment of SLE-associated vasculitis is similar to that of ANCA-associated vasculitides. In most cases where vasculitis occurs in the course of SLE, it is unlikely to be AAV.

Sjögren's syndrome

Cutaneous vasculitis has been reported in 9–23% of patients with Sjögren's syndrome,[68] and is associated particularly with patients seropositive for Ro and La antibodies. Renal involvement presents with segmental necrotizing glomerulonephritis and treatment is the same as for AAV.

Anti-phospholipid antibody syndrome

In anti-phosphlipid syndrome (APS) the primary vascular pathology is thrombosis without evidence of vessel wall abnormality. It may present with recurrent arterial and venous thrombosis, peripheral gangrene, and organ infarction.[69] All these manifestations may mimic vasculitis. The presence of anti-cardiolipin antibodies combined with a typical clinical context establishes the diagnosis. Anticoagulation is the main treatment for APS.

Scleroderma

Despite the systemic vasculopathy associated with scleroderma, true vasculitis is considered rare.[65] Vasculitis occurs in the limited cutaneous form of scleroderma (SSc). Histologically it is typically leucocytoclastic and cutaneous. Treatment with immunosuppressives and corticosteroids is dependent on the severity of disease. AAV occurring with SSc has been reported in 37 patients with clinical features including include rapidly progressive glomerulonephritis, alveolar haemorrhage, limb ischaemia, and vasculitic skin rash. ANCA-associated glomerulonephritis in SSc patients occurs later, after several years of illness. Almost all cases of AAV in SSc were positive for MPO-ANCA. Differential diagnosis from scleroderma renal crisis is crucial as the treatment approach is significantly different. High doses of

corticosteroids and immune suppression are recommended for severe AAV. In refractory cases, rituximab treatment may be considered.[70]

Variable vessel vasculitis

Relapsing polychondritis

Relapsing polychondritis (RP) is a rare immune-mediated condition characterized by inflammation and destruction of cartilage throughout the body. Males and females are equally affected with a peak age of onset at 50 years. There is an association with *HLA DR4*. Around 30% of cases are associated with other diseases, especially systemic vasculitis.

RP may present with non-specific symptoms like fever, weight loss, and fatigue. Clinical features include cartilage inflammation, with auricular inflammation being present in approximately 85% of patients. Characteristically, the cartilaginous part of the pinna is involved, sparing the non-cartilaginous lobe (Figure 137.4). Nasal chondritis occurs in about 50% of cases and may lead to saddle-nose deformity. Pulmonary involvement is the most serious complication of RP and affects half of the patients. Dyspnoea with stridor suggests tracheal involvement. Arthralgia is common,

involving large and small joints and the axial skeleton. Ophthalmic manifestations include scleritis or episcleritis. Purpura is the most common skin involvement.

Laboratory features include raised inflammatory markers and immunology is typically negative. The diagnosis is made based on typical clinical features (Box 137.2).[71] Conditions such as GPA, lethal midline granuloma leading to nasal destruction, and infective perichondritis should be excluded.

Treatment is with NSAIDs for mild cases. Laryngotracheal involvement requires corticosteroids at high doses. Although there are no randomized controlled trials, immunosuppression with methotrexate, azathioprine, leflunomide, and ciclosporin has been reported to be effective. Anti-TNF and rituximab have also been used successfully in isolated case reports.[72,73]

MAGIC syndrome: mouth and genital ulcers with inflamed cartilage

First described in 1985 by Firestein,[74] the term 'MAGIC' as an acronym for 'mouth and genital ulcers with inflamed cartilage' was proposed to describe an overlap syndrome of RP and Behçet's disease. An immunological abnormality involving elastin as the possible target antigen was suspected to be common in both conditions. Clinical features include chondritis and oral aphthous ulcers, as well as ocular inflammation (mainly anterior uveitis or scleritis/episcleritis). Most patients also presented with genital ulcers and arthritis. Aneurysms seem to be a common complication of MAGIC syndrome (21.1%), even under immunosuppressants, and can require emergency surgery.[75] Anti-TNF may be used in order to control vascular inflammation and endovascular stent-grafting may be an alternative to surgery. Mainstay treatment is with azathioptine, methotrexate, or cyclophosphamide.

Cogan's syndrome

Cogan's syndrome (CS) is a rare inflammatory disease of unknown aetiology characterized by involvement of the eye and inner ear. It occurs mainly in young adults with a peak incidence in the 20s.

Fig. 137.4 Auricular cartilage inflammation on a patient with relapsing polychondritis.

Box 137.2 Proposed diagnostic criteria (McAdams 1976) for relapsing polychondritis

1. Recurrent chondritis of both auricles

2. Non-erosive seronegative inflammatory polyarthritis

3. Nasal chondritis

4. Inflammation of the ocular structures (conjunctivitis, keratitis, scleritis, episcleritis, uveitis)

5. Chondritis of the respiratory tract involving laryngeal and or tracheal cartilage

6. Cochlear and/or vestibular damage causing sensorineural hearing, tinnitus and/or vertigo

To establish diagnosis, a patient must fulfil one of the following:

◆ at least three of the above six criteria, *or*

◆ one or more of the criteria in conjunction with cartilage biopsy confirmation, *or*

◆ chondritis or two or more separate anatomical locations with response to steroids and/or dapsone

Although the true aetiology is unknown it is believed to result from an environmental trigger interacting with a genetically predisposed host. Infection may act as a precipitator: 25–33% of patients with CS have an antecedent flu-like illness.[76] However, antibiotic treatment is not effective.[77]

There are no validated diagnostic criteria for CS and therefore the diagnosis is based on demonstration of characteristic involvement of both the eye and the inner ear in a young adult. The predominant ocular feature is interstitial keratitis typically presenting with painful red eye, photophobia, and blurred vision. Diplopia, tearing, visual filed defect, and sensation of foreign body in the eye also occur frequently. Vestibular and auditory features include sudden onset vertigo, nausea, vomiting, tinnitus and hearing loss are also seen; symptoms that mimic attacks caused by Menière's disease. Systemic symptoms are often seen such as fever, weight loss, and fatigue, particularly at the initial stages. CS-related vasculitis may affect vessels of any size, but most commonly causes large-vessel vasculitis resembling TA. Neurological involvement is uncommon but may present with meningitis, encephalitis, psychosis, and seizures.

Laboratory tests may show an acute-phase response but immunological tests are usually negative. Corneal biopsies may show a plasma cell infiltrate and lymphocytes in the deeper layers of the cornea with scarring and neovascularization. The histology of vessels resembles GCA findings.

Treatment is with corticosteroids for acute flares and recurrences of ocular or auditory inflammation. Topical glucocorticoids are used for keratitis and anterior uveitis, whereas oral steroids are necessary for posterior scleritis and retinitis. Audiovestibular disease requires high-dose steroids (1–2 mg/kg per day). Additional immunosuppressive therapy with methotrexate, azathioprine; ciclosporin; tacrolimus, and cyclophosphamide maybe required for resistant disease. There are no controlled trials of therapy in CS and therefore the role of biologic agents remains undetermined.

Prognosis depends on disease activity. Although ocular outcomes are good, deafness remains the most common long-term sequel. If CS is complicated by large-vessel vasculitis this is generally associated with a poor prognosis.

Osteoarthritis

This page intentionally left blank

Pathogenesis of osteoarthritis

Tonia L. Vincent and Linda Troeberg

Structure and function of articular cartilage

Healthy articular cartilage provides a low-friction surface that facilitates smooth articulation of opposing bones (Figure 138.1). Chondrocytes are the only cell type present in cartilage, and they synthesize and are surrounded by a large volume of extracellular matrix (ECM), which gives the tissue its mechanical properties and hence enable its articulating function. The two most abundant components of the cartilage ECM are the protein collagen and the proteoglycan aggrecan.

Collagen provides cartilage with mechanical strength. The main type of collagen found in articular cartilage is type II collagen, a triple-helical collagen that forms strong, rope-like molecules which are cross-linked to form fibrils.[1] These are arranged tangentially near the articulating surface, and radially deeper within the tissue, to dissipate mechanical forces acting on the tissue.

Aggrecan is a proteoglycan, composed of a protein to which are attached many glycosaminoglycan (GAG) side chains (Figure 138.2). The protein 'core' is folded into three globular domains (called G1, G2, and G3) separated by interglobular regions. The GAGs (chondroitin sulfate and keratan sulfate) are attached in the extended region between G2 and G3. These aggrecan monomers aggregate into large extended complexes through interaction with link protein and hyaluronan. The GAGs are highly negatively charged, which draw water into the matrix and causes hydrostatic swelling of the matrix, providing resistance to compression.

The ECM is organized into different structural and functional regions. These can broadly be divided into the pericellular matrix (PCM), which surrounds individual chondrocytes, and the further removed matrix (comprised of the territorial and interterritorial matrices). Type II collagen and aggrecan are distributed in the further removed matrix and are largely absent from the PCM. The PCM is enriched for growth and regulatory factors that modulate the behaviour of the chondrocyte. For example, the PCM contains fibroblast growth factor 2 (FGF-2) that is released in response to mechanical loading and acts on chondrocytes through cell-surface FGF receptors.[2] Thus the extracellular matrix has two principal functions: (1) to withstand mechanical load and (2) to sense and respond to changes in the mechanical environment in order to maintain tissue homeostasis.

Changes to cartilage in osteoarthritis

OA is characterized by a number of changes within the cartilage. Most importantly, the cartilage ECM is progressively degraded, leading to loss of tissue and impairment of mechanical function. This degradation is not a passive wear-and-tear process, but is an active response of the tissue to an altered mechanical or biochemical environment. Chondrocytes alter their gene expression profile to take on a catabolic phenotype, synthesizing increased levels of proteolytic enzymes that degrade the cartilage ECM. In particular, chondrocytes synthesize collagenases that degrade collagen, and aggrecanases that degrade aggrecan. Degradation of these components leads to weakening of the cartilage ECM, causing surface roughening of the tissue and subsequent deep fibrillation of the matrix.

Some OA chondrocytes appear to have increased synthetic activity, suggesting that they attempt to repair the damage to the tissue. Safranin O staining of histological sections of OA cartilage shows increased proteoglycan around some chondrocytes (red staining in Figure 138.1).

Chondrocytes both proliferate, by a process of clonal expansion, and die in OA. Chondrocyte death occurs via various mechanisms, including apoptosis and necrosis and is often seen as empty lacunae on histological sections. Causes of chondrocyte death are postulated to involve mechanical injury and reactive oxygen species derived from dysfunctional mitochondria.[3]

Changes to other joint tissues in osteoarthritis

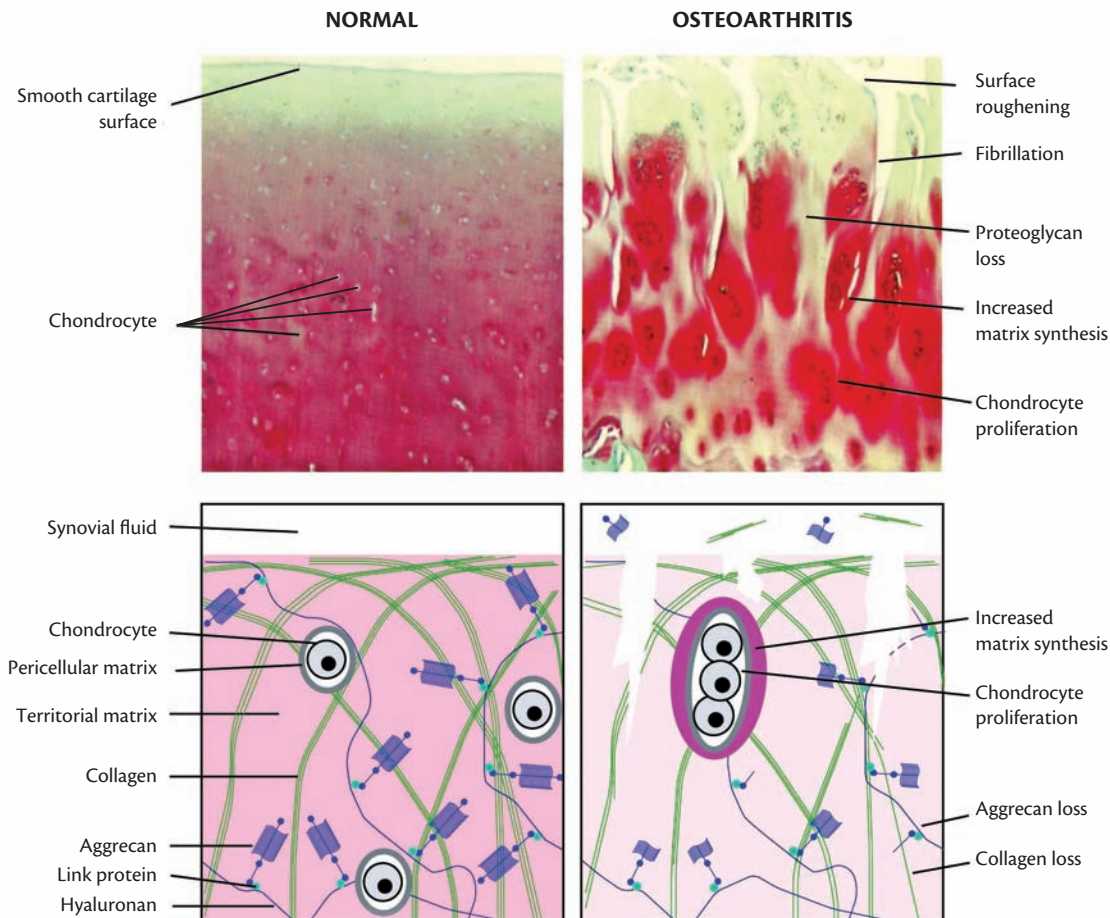
Early tissue responses in OA have mainly been studied at the level of the articular cartilage, indicating the early nature of these changes, and the largely chondrocentric view of those in the field. Other tissues of the joint are strongly altered in OA, especially the bone, capsule, and synovium. Bone changes in OA are early and pathognomonic and include thickening or sclerosis of the subchondral bone followed by reactive remodelling changes that lead to the formation of osteophytes, bone cysts, and epiphyseal expansion. These changes are diagnostic on plain radiographs and may represent mechano-adaptation to the altered mechanical environment.


Fig. 138.1 Structure of normal and osteoarthritic cartilage. Histological sections (top panels) and diagrammatic representations (lower panels) of normal and osteoarthritic cartilage stained with the proteoglycan-reactive dye Safranin O. Aggrecan and other minor proteoglycans are uniformly distributed in normal cartilage, giving a uniform staining pattern. In osteoarthritis increased Safranin O staining is seen around some chondrocytes, indicative of anabolic attempts by the chondrocytes to repair the damage.

To what extent these changes are due to disease in the articular cartilage is unknown; whether subchondral bone changes predispose to cartilage loss (by altering the compliance of the tissue at the base of the cartilage) or whether bone remodels as a results of loss of integrity of the cartilage that protects it, is an argument that has raged for several decades. Some also regard these changes as an overzealous tissue repair response. It is of some interest that osteophytes form principally from the region of the joint where the synovium, periosteum, growth plate, and articular cartilage meet. Osteophytes form by a process of endochondral ossification (as is seen in long bone development) and typically have new cartilaginous caps that are indistinguishable from articular cartilage (Figure 138.2).[4]

Changes occurring in other tissues of the joint are less well studied. It is well accepted that the synovium is often thickened and may be moderately inflamed, especially at late stages of disease. Fibrotic change, laying down of a disorganized type I collagenous matrix, within the joint is common and affects tissues such as the capsule and menisci.

Early views of osteoarthritis pathogenesis

The concept that mechanical factors contribute to the development of OA cannot be overstated. Epidemiological data are compelling; OA is both a disease of joint overuse—seen in specific occupational settings such as cotton pickers (hand disease) and coal miners (back disease)—and is increased by joint injury. Both direct joint injury, e.g. through intra-articular fracture, and indirect injury, where the stabilizing structures of the joint (e.g. menisci and cruciate ligaments) are damaged, are associated with a substantially increased risk of developing OA.[5] Perhaps as many as 50% of individuals with meniscal injury will go on to develop OA within 5–10 years.[6] Moreover, a high percentage of individuals with age-related disease appear to have meniscal failure (in the absence of a history of injury), suggesting that this is an important consequence during ageing.[7] Individuals with deformities that change the loading patterns within a given joint are also at increased risk of disease, and these can be modified by osteotomy or joint distraction (where mechanical forces are absorbed by a temporary metal cage attached on either side of the joint).[8]

In a healthy joint there are a number of levels at which mechanical protection is enabled: within the joint itself, the ligaments, menisci and capsule provide stability, preventing excessive antero-posterior movement as well as rotational stress. The articular cartilage as well as the meniscus is uniquely adapted to withstand mechanical load. The orientation of collagen fibres and distribution of negatively charged proteoglycans protect the chondrocytes from compressive and shear forces generated by joint movement and fluid flow through the matrix. Outside the joint, engagement of muscles to
Fig. 138.2 Histological appearance of osteoarthritis in a metatarsal joint. Note uneven loss of articular cartilage (stained blue in this image) and dorsal osteophyte with cartilaginous cap. Other features include synovial and capsular thickening.

splint the joint during activity, as well as reflex actions that lead to deceleration of movement upon heel strike during the normal gait cycle are also likely to provide significant protection. Some of these responses are blunted with age.[5]

For many years these mechanical associations with disease were largely explained by passive attrition of joint tissues, so-called 'wear and tear'. It was thought that loss of lubrication of the joint surface may contribute to premature disease; the rationale for studies on intra-articular hyaluronan and lubricin, molecules that reduce frictional forces at the articular surface.[9] It was later in the 1950s when Maroudas[10] described a likely breakdown of the collagen fibres in the tissue and subsequently the discovery of proteases that specifically degraded components of the extracellular matrix, so-called matrix metalloproteinases (MMPs), that an active, enzymatically driven process of matrix destruction was proposed. One pivotal discovery in the early 1990s was finding fragments of aggrecan in the synovial fluid of patients with OA which had been cleaved at specific regions of the molecule. As none of the known MMPs at the time were predicted to cleave at this site it was proposed that this indicated a new disease-related enzyme activity that was termed 'aggrecanase'[11,12] (discussed further below).

Until this time, OA research was significantly limited by a number of factors. First, pathogenic mechanisms of disease tend to come from observations made in early human disease, and early OA was often subclinical or difficult to diagnose because the tools for making the diagnosis (plain radiographs) were too crude. Moreover, even when early disease could be identified, it was not possible, except in rare circumstances, to acquire joint tissues. Studies performed on late-stage cartilage (taken from joint replacement) have documented pathways activated in late disease, but do not provide insights into early molecular events. Analyses were also limited by the tissues themselves; cartilage is a paucicellular tissue and its highly negatively charged matrix posed many problems in the early days of molecular biology.

Using small-animal models to study osteoarthritis pathogenesis

Significant breakthroughs in pathogenic mechanism subsequently arose from rapid advances in accessible molecular tools, and in the widespread use of mechanically induced models of OA in mice,

which could be combined with genetic modification to interrogate the role of specific molecules in the disease process.[13] Joint instability-induced models of OA have been favoured in many studies as they recapitulate many of the features of human disease: insidious cartilage degradation, subchondral bone sclerosis, osteophyte formation, and pain that arises relatively late in the disease process (when significant cartilage has been lost).[14] There is little in the way of synovitis except in the immediate postoperative period and this differentiates them from some historical models such as those induced by intra-articular collagenase or monosodium iodoacetate injection. Surgical models are regarded as being good models of injury-induced OA, for which there is a good clinical corollary. Pathways that are identified in these models may or may not be relevant to age-related disease.[15]

The mouse has proved a tractable system in which it is possible, not only to investigate specific molecules in the course of OA, but to study all the tissues of the joint. Although the cartilage has been the focus of most studies thus far (the OA Research Society International (OARSI) guidelines for scoring these models are validated only for cartilage measurements),[16] an increasing number of studies are beginning to look at changes in bone, menisci, and synovium. Genetic modification is also becoming increasingly sophisticated with the creation of conditional and inducible knockout and overexpressing mice in which the gene of interest can be deleted/overexpressed in a tissue-specific manner and at specified times.

Molecular basis for osteoarthritis

Aggrecan degradation by aggrecanases

Degradation of aggrecan is a key early event in the pathogenesis of OA. Some studies suggest that aggrecan protects collagen from proteolytic degradation and that collagen degradation only occurs when aggrecan is lost from the tissue. Additionally, aggrecan degradation is thought to be reversible, while collagen loss is irreversible.[17] There has thus been considerable interest in identifying the enzyme(s) responsible for aggrecan degradation in OA, with numerous candidate enzymes proposed since the 1960s.[18]

In a landmark study, Sandy and colleagues analysed the synovial fluid of patients with early and late OA and patients who had experienced a recent knee injury.[11] They found that in all cases the synovial fluid contained aggrecan fragments with the N-terminal

Fig. 138.3 Structure of aggrecan in normal and osteoarthritic cartilage. Aggrecan consists of a core protein (blue) attached to chondroitin sulfate and keratan sulfate glycosaminoglycan chains (orange) that retain water in the cartilage matrix and hence enable resistance of the tissue to compression. In normal cartilage, aggrecan is immobilized in the cartilage matrix through interaction with link protein and hyaluronan. In osteoarthritic cartilage, ADAMTSs cleave aggrecan at the NITEGE[373]~[374]ARGSV bond in the interglobular domain between the G1 and G2 domains, releasing the majority of the molecule from the tissue. ADAMTSs and other enzymes can also cleave aggrecan at other sites, releasing smaller fragments from the tissue.
sequence [374]ARGSV. Cleavage at this site releases the water-bearing GAG-rich region of the molecule from the cartilage ECM, abrogating the function of the molecule (Figure 138.2). The MMPs, a family of zinc-dependent proteolytic enzymes, had been suggested to degrade aggrecan in OA cartilage, but these enzymes cleave aggrecan at the nearby DIPEN[341]~[342]FFGV site and are not active against the aggrecanase NITEGE[373]~[374]ARGSV site. This indicated that an unknown enzyme was responsible for pathological aggrecan cleavage in OA (see Figure 138.3).

Cleavage at the NITEGE[373]~[374]ARGSV bond was observed in vitro when cartilage explants were stimulated with inflammatory cytokines, enabling researchers to purify the aggrecanase enzyme from conditioned medium of bovine cartilage stimulated with interleukin-1 (IL-1).[19] Sequencing analysis revealed that the aggrecanase was a metalloproteinase, and that its active site is homologous to those of MMPs. The aggrecanases also contain additional domains not found in MMPs, such as disintegrin and thrombospondin domains, which determine substrate specificity and localization within the ECM. This family of proteinases are thus named as a disintegrin and metalloproteinase with thrombospondin domains (ADAMTS). Following discovery of aggrecanase 1 (designated ADAMTS-4), aggrecanase 2 (now designated ADAMTS-5, initially called ADAMTS-11) was later characterized.[20]

The importance of this family of proteases in vivo was then demonstrated by showing that mice lacking the gene for *Adamts5* had reduced disease following surgical joint destabilization compared to wild-type mice.[21] This experiment was a turning point in how OA was perceived, not only because it had identified the first realizable target for OA, but also it proved that disease was not a passive process of attrition, as the cartilage was preserved despite the joint being destabilized. Mice lacking genes for *Adamts4* were not protected, indicating that ADAMTS-5 was the primary aggrecanase in mice. Since then several other pathways have been shown to influence Adamts5 expression and activity in vivo.[15,22]

The relative importance of ADAMTS-4 and ADAMTS-5 in human OA is still under debate.[23] A limited number of studies have examined the effect of silencing specific proteases in human OA tissue (by molecular interference) and these suggest that, in humans, both ADAMTS-4 and ADAMTS-5 are important in driving aggrecan degradation. Several research groups are developing ADAMTS inhibitors as possible disease-modifying osteoarthritis drugs (DMOADs).[24] These are still in the early stages of development, but are reported to show some efficacy in animal OA models.

Collagen degradation by collagenases

In addition to aggrecan degradation, breakdown of collagen is a hallmark of osteoarthritic cartilage damage. Increased levels of collagen breakdown products are detectable in the cartilage ECM by immunohistochemistry,[25] and collagen fragments are found in the synovial fluid after joint injury and in patients with OA.[26]

Collagen is a very stable cross-linked protein and is resistant to cleavage by most proteinases, with only 6 of more than 500 proteinases in the human genome being capable of digesting triple-helical collagen. Five of these collagenases are members of the MMP family: MMP-1 (collagenase 1), MMP-8 (collagenase 2), MMP-13 (collagenase 3), MMP-2 (gelatinase A), and MT1-MMP (membrane-type MMP 1). The collagenases cleave collagen at a specific site, causing the triple helix to unravel and rendering it susceptible to further cleavage by non-collagenolytic proteinases (Figure 138.4).

MMP-13 is thought to be the primary cartilage collagenase in vivo. Expression of MMP-13 expression is increased in human OA cartilage, and mice overexpressing MMP-13 develop OA-like lesions.[22] Mice lacking the MMP-13 gene develop less severe cartilage damage in a surgical model of OA.[27] Several MMP-13 inhibitors are in the early stages of development, and some have been shown to reduce collagen breakdown and cartilage loss in animal models of OA.[24]

Global changes in chondrocyte gene expression

Global analyses of OA tissues have been performed at the mRNA and protein levels. Most of the studies published thus far have focused

NORMAL TYPE II COLLAGEN

OSTEOARTHRITIC TYPE II COLLAGEN

MMP-13

Further degradation by proteases
Fig. 138.4 Collagen degradation by collagenases. The main collagen found in cartilage is type II collagen, which is a triple helix composed of three α_1 (II) chains. These collagen molecules aggregate to form cross-linked fibrils. In osteoarthritic cartilage, collagenases such as MMP-13 initiate collagen degradation by unwinding the triple helix and cleaving the α_1 (II) chains at a specific site three-quarters of the length between the N-terminus (designated N) and the C-terminus (designated C) of the molecule. This destabilizes the helix, allowing collagenases or other non-collagenolytic proteases to cleave further, generating smaller fragments.

on the articular cartilage and have included proteomic (for proteins) and microarray (for mRNA) methodologies. Validation studies have tended to use quantitative RT-PCR (for RNA) and immunohistochemistry (for protein). In-situ hybridization (demonstration of the mRNAs within sections of mature joint tissue) remains challenging. Studies have been performed both in human tissue, acquired from individuals with established late disease, and preclinical models where early disease processes have generally been examined. For human studies, acquiring age-matched control samples is an ongoing difficulty.

The overall conclusion from these studies is that the chondrocytes in OA are highly active and express and secrete large numbers of proteins that promote catabolic processes within the joint as well as driving apparent repair/remodelling responses. Some of the genes identified by microarray are reminiscent of those activated during embryonic bone and cartilage development, such as type X collagen, Runx2, and the Wnt pathways, leading to the suggestion that OA to some extent recapitulates developmental processes.[28,29] They also reveal altered expression of many genes whose function in the joint is not yet known. Some consistent changes are seen, for instance chondrocytes from patients with late-stage OA express increased levels of collagen type II and VI at mRNA and protein levels,[30,31] but protease regulation in human studies has been inconsistent.[32–34] Interpretation of human studies is limited by large interpatient variability.

Gene expression profiling has been performed in rodent models of OA and is surprisingly consistent even when comparing rat with mouse, and across different models. For example, increased expression of *Mmp13 and Adamts5* is seen in rats and mice following surgical injury to either the cruciate ligament or the meniscus.[35,36]

Growth factors in osteoarthritis

Chondrocyte proliferation and matrix synthesis in OA may be mediated by local production of growth factors. Many of these stimulate synthetic responses in chondrocytes in vitro and are upregulated in disease.[34] Some growth factors such as FGF-2 and osteogenic protein-1 (OP-1, also known as BMP-7) are thought to reside within the matrix and are released in a rapid and controlled fashion, albeit through mechanisms that are currently unclear.[2,37] Insulin-like growth factor (IGF)-1 also promotes matrix synthesis in vitro,[38] and may be tethered within the matrix attached to its binding protein.[39]

The transforming growth factors (TGFs) α and β are pleotropic molecules that have mixed functions in the joint, both promoting disease and likely protecting from it. In vitro, TGFβ promotes matrix synthesis and is regarded as an important anabolic factor in cartilage. It also has anti-catabolic actions including the ability to suppress cytokine-induced protease gene expression.[40] Loss of TGFβ signalling leads to development of OA in transgenic mice. Conversely, TGFβ has also been used to promote the development of OA in experimental models and probably plays roles in osteophyte formation and synovial hyperplasia.[40,41]

The role of growth factors in OA is complex and is not only dependent upon expression and bioavailability of the factor. Some growth factors, such as FGF-2 and TGF, may have unpredictable effects in vivo, which are dependent upon differential receptor expression and variable intracellular signalling responses.[42]

Inflammation in osteoarthritis

OA is not considered to be a classical inflammatory disease as the synovial fluid rarely contains high levels of neutrophils, and

there is an absence of systemic inflammation. On the other hand, chemokines, cytokines, cytokine receptors, and other inflammatory mediators are expressed by connective tissue cells of the joint and could have a role in driving disease processes. Some of these have been investigated in knockout mice and have failed to demonstrate a pathogenic role. For instance, the IL-1α/β double knockout and TNFα knockout mice are not protected from development of OA following surgical joint destabilization.[43] The presence of synovitis in disease, and its relevance to OA progression is also controversial.[44] Synovitis is commonly found transiently in individuals following acute knee injury and also present in most patients (by MRI assessment) with late-stage painful disease,[45] but whether this contributes to cartilage degradation is unclear.

The presence of calcium pyrophosphate and other crystals within the joint may also contribute to inflammatory episodes in OA. Crystals are powerful activators of 'inflammasones' which drive caspase 1 activation and allow processing and secretion of cytokines including IL-1 and IL-18.[46] Uric acid levels correlate with disease and synovial levels of IL-1 and IL-18 in patients with OA.[47]

Perhaps the most compelling argument that OA is inflammatory is that it depends on the expression and activation of 'inflammatory response genes' such as *Adamts5* and *Mmp13*. These genes are normally induced by inflammatory cytokines through a network of intracellular inflammatory signalling pathways. These pathways and the induction of inflammatory response genes can also be induced by crude cartilage injury (cutting with a scalpel),[48] suggesting either that mechanical injury can induce inflammatory cytokines, or that the innate response to tissue injury can drive inflammatory response genes in the absence of cytokine release. The importance of this in vivo has been demonstrated by showing that early induction of proteases in the articular cartilage of mice after joint destabilization is prevented if the joint is paralysed.[36] Taken together these data present an attractive link between mechanical factors as strong aetiological agents in OA and the key role of proteases in disease. In essence it is necessary to define what is meant by inflammation and to distinguish between inflammation mediated by cells of the immune system (classical inflammation) and inflammation that is defined by the activation of inflammatory signalling pathways and by the induction of inflammatory response genes in cells that are not of immune origin—chondrocytes, fibroblasts etc. The fact that mechanical injury alone is able to activate these inflammatory pathways in non-immune cells has led to the use of the term 'mechanical cytokine'.

Epidemiological factors that influence the molecular pathogenesis of osteoarthritis

Ageing

Ageing is arguably the most important risk factor for the development of disease. In recent years a number of biological sequelae that are consequent upon ageing have been described in other systems/diseases, with the emerging paradigm that ageing is not simply a process of tissue wear over time, but is at least in part dependent upon the failure of various cellular pathways/mechanisms involved in growth, nutrition, and injury responses. The mitochondrion is increasingly seen as a principal offending organelle; it is responsible for the production of reactive oxygen species and for the manufacture of anti-oxidant genes such as superoxide dismutase.[49] Such genes are strongly regulated by inflammatory

cytokine stimulation in articular cartilage. Failing mitochondria are removed by autophagy, a process that becomes defective in aged cartilage.[50] The molecular response to acute joint destabilization in the mouse (viewed as a form of acute mechanical derangement) is altered in aged vs young mice, suggesting that pathways that detect and respond to injurious pathways change with age also.[51] This may in part be due to the changes that occur in tissues over time such as glycosylation of matrix proteins and accumulation of turnover products within tissues.[52,53]

Gender

The relationship between gender and OA is complex, with symptomatic and radiographic disease generally increased in females. Most of these cases are in postmenopausal women, and increased disease in females is lost when one isolates those that are premenopausal. Indeed epidemiological studies point to a protective effect of oestrogen status, with the oral contraceptive pill, a late menopause, and hormone replacement therapy being associated with a degree of protection.[54] Premenopausal female mice display significantly reduced disease compared to male mice, an effect that is changed when the sex hormones are manipulated.[55] Oestrogens are important determinants of healing responses in other systems such as the skin and following brain injury,[56,57] so it is tempting to speculate that in OA, oestrogen alters the ability of the joint tissues to repair following injury.

Obesity

Obesity is a strong risk factor for OA. While this is in part due to increased mechanical loading of joints, adipokines synthesized in adipose tissue are also thought to contribute to OA pathogenesis by increasing joint inflammation.[58]

Genetics

Heritability of OA is in the region of 60% across all joints. Given this large heritability it is perhaps surprising that linkage studies have only identified a relatively small number of gene polymorphisms associated with disease (see Chapter 44), and these have frequently been of small effect size and not replicated in other cohorts. A recent genome-wide association study (GWAS) for OA has recently been published.[58a] Consistent with the linkage studies, only a handful of new genes were identified as being linked with the risk of OA (patients were identified on the basis of their needing a joint replacement) and the effect sizes were once again very small. Some further potential gene candidates were identified if patients were stratified according to joint site. Genes that we know are important in OA pathogenesis, e.g. *Adamts5* and *Mmp13*, have not come up in linkage or GWAS investigations. This is most likely explained either by the fact that these genes do not have polymorphic variants, or more likely that the principal level of regulation is post-translational (these proteases require extracellular processing to their active form), and transcriptional control of gene expression correlates poorly with tissue enzyme activity.

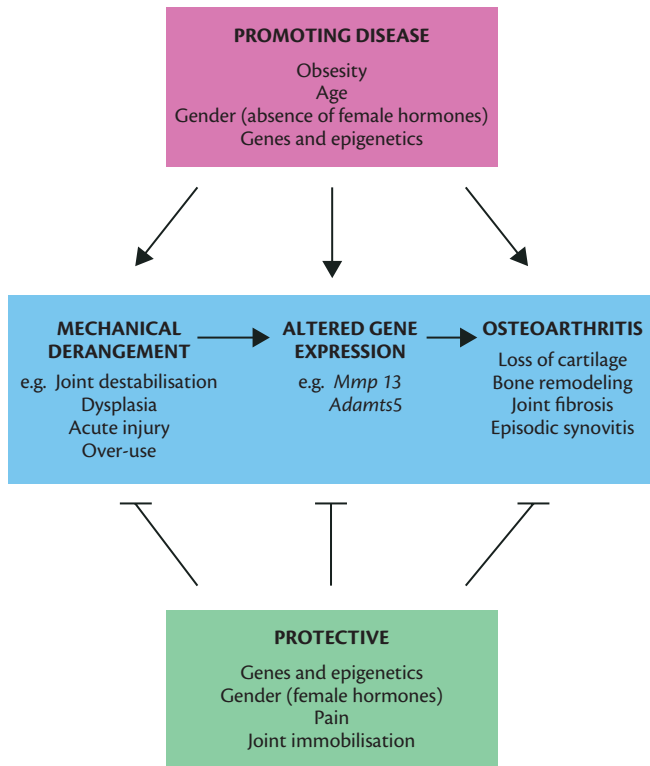
Another level at which genes are controlled (beyond their coding sequences) is epigenetically. Selective modification to either the DNA itself or to histone proteins, for instance by acetylation, is increasingly recognized as an important controller of how, where, and why certain genes are transcribed.[59] There are now many new epigenetic modifiers being identified, and the use of highly selective inhibitors of these is likely to reveal important levels of gene


Fig. 138.5 A summary of processes driving the pathogenesis of osteoarthritis.

expression in coming years. A summary of how these factors contribute to disease pathogenesis is shown in Figure 138.5.

Pathogenesis of pain in osteoarthritis

Most of the studies described thus far have focused on the structural features of the disease with pathogenic studies mainly geared towards finding structure-modifying targets. The correlation between structural damage and patient symptoms is not strong, and determining the processes that drive symptomatic disease is important. This is surprisingly difficult to do in human disease and in the main is reliant on careful correlative studies of pain with radiographic features (mainly MRI-based). Such studies have suggested likely candidates for pain in late OA. These include the presence of synovitis, which is invariably present (by gadolinium-enhanced MRI) in patients with late-stage painful OA.[60] Pain also likely arises from the bone where there is some correlation with the presence of subchondral bone oedema and osteophytes.[61] Cells lining vascular channels at the osteochondral junction are seen to express pain-sensitizing molecules such as nerve growth factor (NGF).[62] Clinical trials of anti-NGF in late-stage OA have demonstrated that this approach is efficacious in treating pain, although unfortunately a subgroup of patients developed accelerated disease in the index as well as non-index joints and this forced the United States Food and Drug Administration (FDA) to halt trials temporarily, although they have now been reinstated.[63,64] NGF was also demonstrated as an effective analgesic target in mice with OA.[65]

One very important feature of long-standing pain in OA is the development of central sensitization. This can be visualized in patients through functional and structural MRI studies of the brain.[66] Changes in the central nervous system (CNS) may identify

those individuals for whom centrally acting drugs would improve their pain. They may also be able to predict which patients will do well with standard analgesia and following joint replacement.[67]

Future perspectives and limitations for osteoarthritis therapies

Most patients and practitioners would prioritize identifying new targets for pain and improving joint function over preservation of joint structure. However, the results from anti-NGF trials highlight the potential pitfalls of effective pain targeting and support the concept (which is not novel), that pain is a protective response in the joint, and mechanically offloading the joint because of pain is a way of limiting matrix breakdown. These results suggest that effective analgesia needs to be combined with disease-modifying drugs for optimal long-term patient benefit.

Another issue that is still unclear is which tissues should be targeted. Is OA a disease of cartilage, synovium, or bone? Targeting bone in OA is not a new concept, but has recently made headline news with the finding that strontium ranelate can act as a disease-modifying drug.[68] Although there is little mechanistic insight for its success, the trial nonetheless demonstrates a significant reduction in joint space narrowing over 3 years and a late reduction in pain compared to placebo. Whether these treatments are likely to become integrated into existing treatment guidelines will depend upon their reproducibility and cost-effectiveness, most probably linked to a demonstrable reduction in numbers of individuals needing joint replacement surgery.

Targeting cartilage is attractive if one believes that cartilage damage precedes bone change, but many patients present after significant damage has already taken place. Although a number of aggrecanase and collagenase inhibitors have been developed by industry, we still know little about how important these enzymes are once disease is established and whether inhibiting these pathways once significant cartilage is lost will be able to halt disease.

One new and exciting realization is that spontaneous intrinsic repair of articular cartilage may occur in certain individuals given the correct joint environment. For instance focal cartilage lesions, identified on arthroscopy, appear to heal well in approximately 30% of individuals. They are more likely to progress to OA if there is coexistent joint inflammation.[69] The mechanical environment is also critical and there are now a number of case studies and small series of individuals with established OA who appear to recover their joint space after a period (usually 3 months) of joint distraction.[8]

The most significant limitation that we face in trying to put novel targets into clinical trial is the lack of sensitive biomarkers of disease, either circulating or radiographic. These are essential for detecting early disease, predicting which patients will go on to develop severe disabling disease (and should therefore be treatment priorities), and assessing an individual's response to treatment. This is compounded by the insidious nature of the disease, the often late presentation (when significant joint damage has already occurred), and the broad pathogenic heterogeneity that is seen in late (and presumably also early) disease. Successful translation is most likely to come from selecting individuals with high risk of disease, e.g. following acute joint injury or strong family history, in which disease biomarkers can be studied and utilized in a more controlled setting. These are also likely to be the individuals for whom treatment is

likely to be deemed most 'cost-effective' given that these individuals will develop OA at a young age, which will impact on their working lives. Tackling disability due to OA in the very old is likely to remain a huge challenge.

Clinical features of osteoarthritis

Abhishek Abhishek and Michael Doherty

Introduction

Osteoarthritis (OA), the commonest of all arthropathies, is a leading cause of pain, disability, healthcare utilization, and economic loss. For example, in the United Kingdom symptomatic knee OA occurs in 15% of people over 55 years of age,[1] and approximately 2 million adults visit their GP each year with symptoms of OA. It is therefore important for healthcare professionals to diagnose and manage OA appropriately. In this chapter, we describe the symptoms and signs of OA, in general and for each of its clinical subsets.

Osteoarthritis in a clinical context— structural changes vs symptoms

There are several operational definitions of OA. These may be based on structural changes (e.g. Kellgren and Lawrence grade ≥2), irrespective of symptoms; symptoms (e.g. pain on most days of a month, regardless of structural changes); or require the presence of both. This is potentially confusing, as not all patients with radiographic structural changes have symptoms consistent with OA, and vice versa. Indeed, most patients with knee pain for more than 3 months who do not have radiographic knee OA, go on to develop radiographic changes over a 12 year period, suggesting that knee pain may be the first clinical manifestation of OA.[2] Thus, OA can be separated into two interrelated states:

◆ 'disease' OA—structural changes of OA at the joint level

◆ 'illness' OA—patient-reported symptoms and consequences of OA.[3]

Using this framework, it is clear that researchers studying structure modification target the 'disease' OA, and therefore define OA according to structural changes. However, until such interventions enter routine clinical practice, clinicians target the 'illness' OA. Therefore, in routine clinical practice, symptoms are more relevant when considering a diagnosis of OA than isolated structural changes alone.

Clinical presentations of osteoarthritis

Patients with OA may have

◆ symptoms and structural changes

◆ symptoms without apparent structural changes, or

◆ structural changes alone (incidentally identified on imaging or clinical examination).

The reason why a proportion of patients with structural changes of OA are asymptomatic is not well understood. Some of these may develop joint symptoms attributable to OA later in life. Symptomatic patients with OA have pain, stiffness, and locomotor restriction. These result in varying degrees of functional impairment, physical disability, and psychological distress. Though they are interrelated, there is often a marked discordance between symptoms, functional impairment, physical disability, and psychosocial impact.

Symptoms

Pain

Pain worsening with joint use and relieved by rest ('usage' or 'mechanical' pain') is often the chief complaint. It is insidious in onset, deep, aching, and frequently poorly localized, especially when chronic. For instance, diffuse knee pain may be present in just under one-quarter of symptomatic knee OA patients.[4] Pain in OA often progresses through three clinical stages[5]:

◆ **Stage 1 (early OA):** predictable sharp pain usually brought on by a mechanical insult that is intermittent but eventually limits some activities with relatively little effect on overall function.

◆ **Stage 2 (mild OA):** pain is more constant, begins to affect daily activities, and there may be unpredictable episodes of stiffness.

◆ **Stage 3 (advanced OA):** constant dull/aching pain, punctuated by short episodes of often unpredictable exhausting exacerbations.

Not all patients go through these three stages. Diurnal and seasonal variations in OA pain have been described. Pain due to OA may be worst on first rising, and subsequently improve over the next 2 hours.[6] It may then worsen during the late afternoon/early evening before lessening again later in the evening.[6] Night pain may also occur, and is regarded as a particularly poor prognostic factor indicating severe damage. Anecdotally, OA pain may be worse during damp, low-pressure weather.

The mechanism of pain in OA is incompletely understood. Hyaline cartilage is avascular and aneural,, therefore metabolic or structural alterations in this tissue are unlikely to be directly perceived as painful. Several mechanisms of OA related pain have been suggested (Figure 139.1).[5,7–11] These include:

- **Articular**:
  - Synovial and capsular pain fibres and mechanoreceptors are stimulated by raised intra-articular pressure.
  - Inflammatory mediators stimulate nociceptors in synovium and capsule.

- **Bony**:
  - Denuded subchondral plate and subchondral microfractures stimulate nociceptors.
  - Bone marrow lesions (areas of bone marrow necrosis, fibrosis, oedema, and trabecular abnormalities near subchondral plate on MRI) cause pain by intraosseous hypertension or by stimulating periosteal nerve fibres.

- **Periarticular**:Painful periarticular structures such as ligaments, entheses, periosteum (growing osteophytes may cause pain by this mechanism) and bursae possibly result from abnormal biomechanics and/or muscle weakness.

- **Neural**:
  - Peripheral nociceptive system can become sensitized, resulting in hyperalgesia or allodynia.
  - Adaptive changes in the spinal cord (central sensitization—persistent activation of the primary afferent neuron or 'wind-up') and brain can lead to intensified, and persistent pain perception.

It has been suggested that these different mechanisms may produce different pain characteristics.[5,7,9,12] It is suggested that pain:

- **on usage**—is principally due to mechanical or entheseal problems
- **after rest**—is inflammatory in origin
- **at night or at rest**—is due to intraosseous hypertension
- **burning (neuropathic) pain**, with associated hypersensitivity and paresthesia—is due to central sensitization.

Correlation between pain and radiographic change varies according to site. It is best at the hip and then the knee, with the poorest correlation occurring in the hands and intervertebral facet joints. Some people even with severe structural changes on radiographs may be asymptomatic. Joints with more severe radiographic changes are more likely to be symptomatic than those with mild change (Figure 139.2) but other factors are also important.[13] These include:

- **demographic factors** such as age, gender, socio-economic status, social support, racial and cultural background
- **constitutional factors** such as increasing body mass index (BMI), and pain at other sites[4,14]
- **psychological factors** including affect, cognitive state (e.g. pain beliefs, expectations, and memories), self-efficacy (individual's confidence in their abilities to accomplish a desired task e.g. control arthritis pain), and pain catastrophizing (the tendency to focus upon and feel helpless in the face of pain)
- **genetic factors** such as Val158Met single nucleotide polymorphism (SNP) in *COMT* (association with pain in hip OA),[15] and Ile585Ile SNP in *TRPV1* genes (negative association with pain in knee OA).[16]

Stiffness

Stiffness is the other chief complaint. It is of shorter duration than in inflammatory arthritis. Stiffness is difficulty or discomfort in movement due to a perceived inflexibility localized to the joint. This is sometimes described as 'gelling', i.e. short-lived joint stiffness after inactivity. Prolonged morning or inactivity stiffness, often taken as a reflection of inflammation, is uncommon but may occur in OA.

Aesthetic problems

Aesthetic problems such as swelling and deformity in hand OA and crepitus in knee OA may be prominent symptoms in some patients. Knee crepitus may be especially prominent when coming downstairs. At the knee, associated meniscal damage or loose body may result in other mechanical symptoms such as 'locking'. There may

be a feeling of instability or 'giving way'—especially at the knees or ankles.

Functional impairment

Disability is principally associated with pain. However, psychological factors and muscle weakness are also important and in most cases more important than radiographic change.[17–19] For an individual patient reduced range of movement (e.g. at the hip) may be associated with specific functional limitations, for instance during sexual intercourse or getting out of a car. Postural instability at the knee may impair mobility, and therefore restrict participation.[20]

Signs

Several features reflecting altered joint structure and function may be present.

◆ On inspection (**look**):

- bony enlargement—due to remodelling and osteophytosis, seen at both large (e.g. knee), and small joints (e.g. interphalangeal joints)

- deformity—occurs in late disease e.g. knee malalignment, and fixed flexion at the hip

- muscle wasting around an affected joint—globally affecting all muscles acting over the joint.

◆ On palpation (**feel**):

- palpable bony swelling and osteophyte

- varying degrees of 'cool' joint effusion may be present, especially at the knee

- joint line or periarticular tenderness

◆ During movement (**move**):

- crepitus—a coarse crunching sensation or sound caused by friction between two articular surfaces, often more prominent during active movement and occurring throughout most of the range

- restricted movement—equal for both active and passive movement

- instability—may occur late in knee and thumb-base OA, but uncommon at other sites.

Signs of associated meniscal damage and 'loose body' can occur and periarticular sources of pain, demonstrated by point tenderness away from the joint line and by stress testing, are commonly seen.

Osteoarthritis 'subsets'

OA can affect any synovial joint. However, it preferentially targets the knees, hips, certain hand joints, the first metatarsophalangeal ('bunion') joint and apophyseal (facet) joints of the lower cervical and lower lumbar spine.[21] Since OA is a process that can potentially be triggered by diverse constitutional and environmental factors, a wide spectrum of clinical expression and outcome is expected. It is possible to look at OA as a single entity, or to try to classify

subgroups of patients with OA. Both strategies are fraught with difficulties.

OA was initially classified as primary (no cause identified) or secondary (an obvious cause identified, such as trauma or dysplasia). Indeed, such a distinction is still retained in the American College of Rheumatology (ACR) criteria.[22] However, such artificial separation has often proved unsatisfactory, for several reasons:

◆ frequent lack of an identifiable cause, resulting in a large heterogeneous primary group

◆ overlap between subsets, as shown, for example, by the influence of predisposition to 'primary' generalized OA in determining development of postmeniscectomy 'secondary' OA[23]

◆ lack of evidence to suggest that the underlying pathological features and processes differ.

Other, more objective, features have therefore often been used to define subsets:

◆ joint site involved (e.g. hip, knee, hand)

◆ site within a joint (e.g. medial tibiofemoral, lateral tibiofemoral, patellofemoral at the knee)

◆ number of joints involved (e.g. one, few, many)

◆ presence of associated calcium crystals

◆ presence of marked clinical inflammation

◆ radiographic bone response (e.g. atrophic, hypertrophic)

◆ age of onset (e.g. premature osteoarthritis under age 45)

◆ syndromal features (e.g. Stickler's syndrome or hereditary arthro-ophthalmopathy).

Although a number of 'subsets' have emerged it is important to note that sharp distinctions between subsets do not exist and many of the above characteristics represent different aspects of the OA process (e.g. the balance between damage and repair, the number of joints involved), and different characteristics may dominate the clinical picture at just one phase in the evolution of the condition. One 'subset' may thus evolve into another and different 'subsets' may exist at different sites within the same individual. The partitioning of OA may be revolutionized by the genetics of OA if specific genotypic subsetting becomes possible.

Generalized osteoarthritis

The concept of generalized OA, with hand involvement as the marker for a generalized predisposition, was first described by Haygarth in 1805 and is supported by several studies. A polyarticular subset of OA particularly involving the distal interphalangeal joints (DIPJs), thumb bases, first metatarsophalangeal joints (MTPJs), lower cervical and lumbar facet joints, knees, and hips was described by Kellgren, who coined the term 'generalized OA' for this subset.[24] The clinical marker for generalized OA is the presence of multiple Heberden's nodes (posterolateral hard swellings of DIPJs). Heberden's nodes are often accompanied by Bouchard's nodes—less well defined posterolateral swellings of the proximal interphalangeal joints (PIPJs) (Figure 139.3). Later on patients with identical targeting of joints as in generalized OA were identified, who did not have Heberden's nodes.[25,26] This led to the classification of generalized OA into two groups (although such a distinction is not supported by others):

Fig. 139.3 Heberden's nodes: posterolateral hard swellings of distal interphalangeal joints.

- nodal generalized OA:
  - nodes
  - DIPJs involved more than PIPJs
  - marked female preponderance
  - familial aggregation
- non-nodal generalized OA:
  - PIPJs involved more than DIPJs
  - more equal sex distribution.

There is no single agreed definition for the number or location of joints that must be affected before a patient is regarded as having generalized OA. Expert panels constituted by ACR and the European League Against Rheumatism (EULAR) suggest that generalized OA is present if there is OA at the spine, or hand respectively, and in at least two other joint regions.[27,28]

Nodal generalized osteoarthritis

This is the best recognized subset and is characterized by:

- polyarticular finger IPJ involvement
- Heberden's and Bouchard's nodes
- female preponderance
- peak onset around the menopause
- predisposition to OA of the knee, hip, spine, and thumb base
- marked familial predisposition.

The typical patient is a woman aged 40–60 years who develops intermittent discomfort followed eventually by swelling of a single finger IPJ. A few months later another IPJ becomes painful, then another, producing a 'stuttering' onset polyarthritis of DIPJs and PIPJs. Affected IPJs may feel stiff and tender and show tight posterolateral swelling. Aspiration of early evolving swellings may reveal viscous, clear, hyaluronate-rich 'jelly'. These cysts are thought to represent mucoid transformation of periarticular fibro-adipose tissue and may communicate with the joint. Each IPJ tends to go through a symptomatic phase while the swelling and deformity becomes established, resulting in perhaps 1–3 years of episodic

discomfort and stiffness. Nodes most frequently appear at the index and middle finger[29] and thumb IPJs. The discrete radial and ulnar Heberden's nodes on one IPJ may eventually coalesce to form a single dorsal bar.

In almost all cases symptoms then subside, leaving the patient with:

- Heberden's and Bouchard's nodes
- characteristic ulnar/radial deviation of IPJs without instability
- underlying radiographic evidence of OA (Figure 139.4).

The functional prognosis for such hand OA seems to be good. A common classification problem is that one or just a few Heberden's nodes and limited IPJ OA are common often asymptomatic findings in elderly people and it is not always clear, therefore, when the title 'nodal generalized OA' should be applied. Although strict criteria for this have not been defined, some studies suggest that involvement of even a single IPJ may be relevant as a risk factor for OA elsewhere.[30]

Hand osteoarthritis

OA targets characteristic sites in hands, i.e. DIPJs (~50%), thumb bases (~35%), PIPJs (~20%), and metacarpophalangeal joints (MCPJs) (~10%), in descending order of frequency.[28,31] Symptoms in hand OA are usually bilateral and joint involvement is usually approximately symmetrical.[28,29] The clinical features of nodal OA have already been described. Thumb-base OA, the other common target site for OA in hands, involves the first carpometacarpal and/ or trapezioscaphoid joints and presents with mechanical joint pain maximal over the thumb base but often with distal or proximal radiation. There may be radial subluxation and adduction, giving the thumb a swollen 'squared' appearance.[28,29] Thumb-base OA commonly associates with persistent symptoms and functional impairment so the prognosis is more guarded than in IPJ OA.
Fig. 139.4 Radiograph of distal interphalangeal joint showing many of the typical radiographic features of osteoarthritis (joint-space narrowing, sclerosis, osteophyte).

At the MCPJs, OA mainly targets the index, middle and thumb MCPJ in a descending order of frequency, often presenting with bony enlargement.[31] Relatively isolated MCPJ OA sometimes occurs, particularly in men with physically demanding occupations ('Missouri arthritis').[32] Widespread MCPJ OA with wrist arthropathy or chondrocalcinosis raises the possibility of haemochromatosis. The differential diagnosis for hand OA includes psoriatic arthritis (which targets DIPJs or commonly affects just one ray), rheumatoid arthritis (which targets wrists, MCPJs, PIPJs), gout (which may superimpose on pre-existing hand OA) and haemochromatosis.[28]

Erosive ('inflammatory') osteoarthritis

Erosive OA, an uncommon subset of OA is characterized by:

- finger IPJ involvement
- often florid inflammation
- lateral IPJ instability
- nodes that are not prominent (but may be present)
- radiographic subchondral erosive change
- tendency to IPJ ankylosis.

The condition clinically resembles nodal generalized OA in beginning as an additive polyarthritis of finger joints. However, multiple IPJs may be affected at the onset, i.e. synchronous polyarticular onset.[28,33] Inflammatory symptoms and signs are often marked although episodic. Pain, tenderness, and inflammation (warmth, soft tissue swelling—sometimes erythema) are more marked and prolonged in erosive OA than in nodal OA.[33,34] Erosive OA usually targets the IPJs, distal more often than proximal, and generally spares the thumb bases and MCPJs.[28,34] However, thumb base and MCPJ erosions have been identified in radiographic studies of hand OA. There is often no association with generalized OA.
IPJ instability, which is rare in nodal generalized OA, is common. The prognosis for hand function is less favourable in erosive OA.[35] Recent studies suggest that there may be individual and familial predispositions to this subset of OA.[36]

The radiographic hallmark feature of this condition is the presence of subchondral erosive change (Figure 139.5) which may lead to a 'gull's wing' appearance as remodelling occurs. Early, florid subchondral erosive change is easily recognized, but lesser degrees of erosion, particularly in established cases, may prove difficult to distinguish from the cysts and subchondral bony change of nodal generalized OA. It is unclear whether erosive OA is a distinct subset or one end of a spectrum of change.[37]

Radiographic subchondral erosion attributed to OA occurs in hands of 2.8% of people over 55 years of age, and in 7–10% of patients with symptomatic radiographic hand OA.[35,36] Whether this is 'erosive OA' in the classic context or not is open to debate. However, the presence of subchondral erosion in even a single joint may be significant as it associates with more disability and hand pain in radiographic hand OA.

Large-joint osteoarthritis

Knee osteoarthritis

Knee involvement is common in OA. It is usually bilateral unless there is predisposing trauma. Although OA may affect the knee as a mono- or pauci-articular problem, it often occurs in association with hand OA, especially in women.[24] Knee OA affects both the tibiofemoral (TFJ) and the patellofemoral joints (PFJ). In symptomatic knee OA, combined TFJ and PFJ involvement, isolated PFJ involvement, and isolated TFJ involvement occurred in 40%, 24% and 4% knees respectively.[38] Medial compartment TFJ OA is more common than lateral compartment TFJ OA (Figure 139.6).[39] Simultaneous involvement of medial TFJ compartment and of PFJ is the commonest distribution of OA in the knees, being present in 50% cases.[39] PFJ OA (lateral more than medial facet involvement), because of its intimate relationship with the quadriceps mechanism, is possibly associated with greater functional impairment.[1]

The location of pain points towards the affected knee compartment(s). Pain may be medial or generalized in medial compartment TFJ OA, and anterior in PFJ OA.[12] Pain from PFJ

Fig. 139.5 Subchondral erosive change in erosive osteoarthritis.

Fig. 139.6 Predominant medial compartment osteoarthritis at the knee (standing anteriopposterior radiograph).

OA is typically exacerbated by prolonged sitting, standing from a low chair, and going up or downhill (coming down is more painful). Generalized knee pain with distal radiation suggests moderate to severe knee OA.[40] Knee OA usually does not cause posterior knee pain unless there is a complicating popliteal ('Baker's') cyst. Apart from pain, there may be a feeling of 'giving way' and instability, both of which may associate with falls.[41] This is particularly common with PFJ OA and associated lateral patellar subluxation. Medial compartment TFJ OA with severe bone and cartilage attrition results in a characteristic varus deformity (Fig. 139.7).

Mild to moderate knee effusion is common in patients attending hospitals, increasing in prevalence with the severity of OA.[42] Many painful periarticular soft tissue pathologies such as medial collateral ligament (inferior insertion) enthesopathy, anserine bursitis, semimembranosus-tibial collateral ligament bursitis, tender medial fat pad, and iliotibial band syndrome may coexist with knee OA.[43,44] Meniscal tears are common in knee OA but are not necessarily a cause of increased symptoms.[45]

Whether differing risk factors are important at different compartmental sites is unclear but some studies do suggest that this may be the case. For example, tibiofemoral disease may be more strongly associated with trauma whereas patellofemoral disease may be associated with coexisting calcium pyrophosphate (CPP) crystal deposition (CPPD), and female gender.

Hip osteoarthritis

Hip OA frequently occurs without OA at other joints, and is commonly unilateral.[46] Although several anatomic risk factors of hip OA have been described, e.g. reduced centre–edge angle (<20º), deep acetabular socket, and pistol grip deformity,[47,48] study of OA at this joint has been hampered by lack of a consistent definition and classification of pattern of involvement. Patients commonly present with pain—typically deep in the groin, aching, stiffness, and symptoms related to restricted movement. Pain in hip OA may be present in the anteromedial or upper lateral thigh, or may radiate to the knee, and occasionally to the shin and ankle. In some cases, hip OA presents with knee pain alone. Unlike knee-originated pain, such hip referred pain is usually more widespread and ill-defined, involves the distal thigh, and may improve on rubbing.

On examination, active and passive hip movements may be painful and/or restricted with internal rotation in flexion being the earliest movement to be affected. Impaired internal rotation in flexion is the most discriminating clinical sign for the presence of radiographic hip OA in those with hip pain.[49] Worsening restriction in hip movements in each plane, and increasing number of planes with restriction in movement, increases the probability of radiographic hip OA in those with hip pain.[49] Movements may be globally restricted in severe hip OA.[50] In advanced hip OA, the affected extremity may be shortened, with external rotation, adduction, and fixed flexion being the typical endstage deformity (Figure 139.8)

Hip OA should be distinguished from other causes of pain in the pelvic girdle. Anterior groin pain may result from avascular necrosis of the femoral head, femoro-acetabular impingement, iliopsoas bursitis, and transient osteoporosis; medial thigh pain may result from osteitis pubis and adductor enthesitis; lateral thigh pain may result from trochanteric bursitis/greater trochanter pain syndrome; while buttock pain may result from lumbar radiculopathy, sacroiliac joint pathology, iliolumbar ligament syndrome, and hip extensor muscle strain.[51]

Hip OA may be subclassified largely according to pattern of migration of the femoral head.[52,53] Differentiation of these patterns appears warranted since there may be implications for prognosis.[54] Two main patterns have been emphasized: superior pole OA and central (medial) OA.

Fig. 139.7 Left knee showing genu varum. This suggests the presence of medial compartment tibiofemoral joint osteoarthritis in this knee.

Fig. 139.8 Posture in advanced right hip osteoarthritis: the affected extremity is shortened, with external rotation, adduction, and fixed flexion.

Superior pole OA

This is the commonest pattern, characterized by focal cartilage loss in the superior part of the joint (Figure 139.9). Further subdivision into supero-lateral, supero-intermediate or supero-medial is sometimes made. Osteophyte formation is most prominent at the lateral acetabular and medial femoral margins, often in combination with thickening (buttressing) of the cortex of the medial femoral neck by periosteal osteophyte (Figure 139.10). Subchondral sclerosis and cyst formation on both sides of the narrowed joint may be marked. Originally it was suggested that this pattern is:
Fig. 139.9 Superior pole pattern of hip osteoarthritis (early) showing localized reduction in interosseous distance with focal sclerosis at the superior part of the joint, minor femoral osteophyte, and acetabular roof cyst.

Fig. 139.10 Superior pole osteoarthritis (late) showing superolateral femoral head migration, bone attrition, and 'buttressing' medial periosteal osteophyte of the femoral neck.

- relatively more common in men
- mainly unilateral at presentation
- likely to progress, with superolateral (Figure 139.10) or supero-medial femoral migration
- commonly secondary to local structural abnormality.

Progression is more likely than with other patterns of hip migration.[54]

Central (medial) OA

This less common pattern shows more central joint-space loss, with less prominent femoral neck buttressing. It is suggested that this pattern is:

- relatively more common in women
- commonly bilateral at presentation
- more strongly associated with nodal generalized OA
- less likely to progress and when it does it is with axial or medial migration (Figure 139.11).

Other patterns are described (e.g. concentric) and many patients have 'indeterminate' radiographic patterns. Most disease is symmetrical unless there is a structural alteration in joint loading.[52]

Facet joint osteoarthritis

Facet joint OA usually coexists with degenerative disc disease (i.e.'spondylosis') and for this reason it can be difficult to attribute symptoms to each condition. Lumbar spine facet joint OA may result in localized pain which may radiate to the buttocks, groin, and thigh.[55] Symptoms are worse in the morning, during inactivity, when standing or sitting for a long time, and during exercise, e.g. lumbar spine extension or rotation, and are eased by lying flat and spinal flexion.[55] Similarly, cervical spine facet joint OA presents with ipsilateral neck pain radiating to the shoulder and worsened by neck rotation or extension.[56]

Osteoarthritis at other joint sites

Selection of OA for certain sites is striking. For example, involvement of the elbow, glenohumeral joint, or ankle is relatively
Fig. 139.11 Medial pole osteoarthritis, showing progression to a acetabular protrusion deformity.

uncommon and principally confined to elderly people. Especially in a younger person, bilateral ankle OA without preceding trauma, and widespread metacarpophalangeal OA, should both suggest haemochromatosis. As with other arthropathies, the predilection of OA for certain sites remains unexplained. One intriguing, unifying hypothesis is that in all species the joints most commonly affected by OA are in general those that have undergone the most rapid and recent evolutionary change. In humans these are the joints associated with bipedal locomotion and oppositional grip.[57] Such joints may not have had sufficient evolutionary time to fully adapt to the tasks demanded of them. They therefore have insufficient mechanical reserve, and thus 'fail' more commonly than joints that have had longer to adapt to their new function.

Crystal deposition in osteoarthritis

A number of particles are commonly identified in synovial fluid and other tissues from OA joints. These include CPP crystals and basic calcium phosphates (BCP)—mainly carbonate-substituted hydroxyapatite. By analogy with monosodium urate crystals in gout, it was initially assumed that such calcium crystals were always pathogenic and cause specific 'crystal deposition disease'. Shedding of CPP crystals into the joint cavity can certainly trigger florid synovitis—'acute CPP crystal arthritis'—but the possible role of CPP and BCP in chronic inflammation is unclear. In addition, being hard particles calcium crystals might also act as wear particles on the joint surface. However, the not uncommon occurrence of these crystals in asymptomatic, otherwise normal joints, and the lack of a clear association with specific clinical phenotypes other than acute CPP crystal arthritis have questioned such a direct pathogenic role. It currently seems that CPP and BCP in the context of common OA are epiphenomena possibly reflecting ageing and the underlying pathophysiological processes of OA respectively. Indeed, apatite is universally present in endstage knee and hip OA.[58,59] Apart from alerting the clinician to an underlying metabolic or genetic predisposition, their value in a clinical setting is unclear. Nevertheless the following OA phenotypes based on crystal deposition have been suggested.

Calcium pyrophosphate crystal deposition (CPPD) and osteoarthritis

CPPD is associated with a form of OA that may have several distinct features compared to common OA.[60] These characteristics include:

◆ predominance in older patients

◆ often florid inflammatory component, possibly with superimposed acute attacks

◆ particular involvement of the knee

◆ frequent involvement of joints and joint compartments uncommonly affected by 'sporadic OA' (e.g. glenohumeral, mid-tarsal, MCP);

◆ frequent 'hypertrophic' radiographic appearance.

Large and medium-sized joints are principally involved, with the knees being the most usual and severely affected site, followed by wrists, shoulders, elbows, hips, and mid-tarsal joints. In the hand, MCPJs (particularly index and middle) are often affected.

Symptoms are usually restricted to just a few joints, though single or multiple joint involvement also occurs.

Acute CPP crystal arthritis may be superimposed upon chronic symptoms. Affected joints show signs of OA (bony swelling, crepitus, restricted movement) and varying degrees of inflammation. Synovitis may be prominent and is usually most evident at the knee, radiocarpal, or glenohumeral joints (chronic CPP crystal inflammatory arthritis). In severe cases fixed flexion with either valgus or varus deformity may occur. Examination often reveals more widespread but asymptomatic joint abnormality.

In hospital-based studies, knees have been shown to have bi- or tricompartmental involvement, with marked, usually predominant patellofemoral disease. However, current evidence does not support the view that CPPD at the knee accelerates the progression of knee OA.[61] The radiographic changes of this arthropathy are basically those of OA, but characteristics which may suggest the presence of CPPD include:

◆ atypical joint and compartment involvement

◆ often prominent, exuberant osteophyte and cyst formation (particularly at the knee).

These features combine to produce a distinctive 'hypertrophic' appearance and distribution which suggests the presence of CPP crystals even in the absence of radiographic chondrocalcinosis (Figure 139.12). Many joints with CPPD + OA however, appear not dissimilar to 'uncomplicated' OA. Since nodal generalized OA often coexists in these patients, it is common to find otherwise typical OA changes in some joints, with more distinctive changes of CPPD + OA at other sites.

Apatite-associated destructive arthropathy (Milwaukee shoulder)

This uncommon condition[62,63] is usually:

◆ confined to elderly patients, particularly women

◆ localized to large joints

◆ associated with rapid progression with resultant joint instability

◆ associated with marked attrition of cartilage and bone

◆ characterized by abundant apatite deposition in synovial fluid and synovium.
Fig. 139.12 Exuberant osteophytosis in patellofemoral compartment in CPPD-positive osteoarthritis.

Typical patients are elderly women with rapidly progressive arthropathy of the hip, shoulder, or knee. Usually only one or a few joints are affected. Onset is often quite sudden and within a few weeks or months the patient has severe rest and night pain, and the joint has a large, cool effusion, with gross instability. Aspirated synovial fluid is often bloodstained, highly viscous but with only a modest increased cellularity. Alazarin red S staining at acidic pH shows multiple calcium-containing aggregates which can be identified as BCP, most commonly carbonate-substituted hydroxyapatite, by more definitive means. The principal radiographic features are marked attrition of cartilage and bone, with a paucity of osteophyte and sclerosis, i.e. a markedly 'atrophic' appearance (Figure 139.13). Such rapidly progressive arthropathy may superimpose upon more typical chronic OA or present apparently de novo. The differential diagnosis includes sepsis, an atrophic neuropathic joint, and late avascular necrosis.

The pathogenesis of this condition, particularly as regards the role of the apatite aggregates, is controversial.[64] McCarty and colleagues emphasize the pathologic role of these crystals in causing structural damage. Others suggest that this is not the case, and that apatite primarily originates from subchondral and marginal bone, or that apatite deposition is just a manifestation of end stage OA. The speed of onset and progression, lack of overt inflammation, marked bone loss, specificity to certain anatomic sites, radiographic similarity to late avascular necrosis, and neuropathic joints support the contention that this arthropathy reflects a widespread nutritional catastrophe for the joint, possibly initiated by age-related compromise of subchondral bone blood flow. The large amount of observed apatite may thus simply reflect the rapidity of bone damage.

Mixed crystal deposition

Comparison of clinical and radiographic features of typical CPPD + OA and apatite-associated arthropathies shows marked contrasts, though each clearly falls within the spectrum of 'OA'. The finding of both CPP and BCP within the same OA joint is very common although there is little evidence that their combined presence is associated with particular clinical or radiographic characteristics.

Fig. 139.13 Radiograph of apatite-associated destructive arthritis of the hip, showing apparent increase in joint space (non-loaded film), marked loss of bone (femoral and acetabular components), and minimal bone response.

Osteoarthritis as part of other diseases

If OA represents the inherent repair process of synovial joints, then it would be expected to occur during certain phases of other defined arthropathies. For example, in rheumatoid arthritis, osteophytosis, sclerosis, and remodelling often occur as a late feature once inflammation has largely been suppressed. In such instances, 'OA' can be viewed as an accompanying process of tissue response/repair rather than an acquired second condition. The same considerations pertain to other inflammatory, metabolic, or structural arthropathies. Ochronosis and spondyloepiphyseal dysplasia, for example, are sometimes included within the umbrella of OA since many of their radiographic features are typical of OA but of course many are not and are very distinctive. Similarly, endemic forms of OA need consideration in their own right. For clinical purposes, however, it may still be useful to consider together conditions that may result in a non-inflammatory arthropathy with radiographic changes predominantly of OA (Table 139.1) when an atypical presentation should lead one to search for a defined, possibly treatable underlying cause. In patients with 'OA' one should consider specific predisposing factors when there is:

◆ premature onset (<45 years) in the absence of preceding joint trauma/insult

◆ an atypical joint distribution for OA, for example, prominent MCPJ, radiocarpal or bilateral ankle involvement in haemochromatosis

◆ an atypical degree of clinical inflammation, or episodes of acute florid self-limiting synovitis at their worst within 24 hours (suspect CPPD or gout)

◆ premature onset of chondrocalcinosis (i.e. age <55 years)

◆ florid polyarticular chondrocalcinosis at any age.

Diagnosis of osteoarthritis

The diagnosis of OA is essentially clinical. It may be diagnosed without recourse to radiographic and/or laboratory investigations in the at-risk age group in the presence of typical symptoms and signs.[28,41,65] For example, NICE guidelines suggest that peripheral joint OA may be diagnosed on clinical grounds alone in the presence of persistent usage-related joint pain in one or few joints; age less than 45 years; and morning stiffness less than 30 minutes.[65] The presence of other clinical features adds to the diagnostic certainty.

The usefulness of radiography relates to exclusion of other diagnostic possibilities rather than confirmation of presence of OA. Appropriate imaging and laboratory assessments, should therefore be carried out in young individuals (i.e. <45 years of age), in the presence of atypical symptoms and signs (e.g. unusual site, clinically evident joint inflammation, marked rest and/or night pain, and rapidly progressive pain), if there is weight loss or constitutional upset, and at the knees if there is true mechanical 'locking'. Synovial fluid examination is not required to diagnose OA. However, joint aspiration and synovial fluid analysis are indicated if there is a suspicion of coexistent crystal deposition. OA encourages urate as well as CPP and BCP crystal deposition and synovial analysis should be undertaken in patients with peripheral joint OA who develop inflammatory features or episodes of acute synovitis.

Table 139.1 Principal conditions with presentations and radiographic changes that may simulate osteoarthritis

Generalized 'osteoarthritis'	Spondyloepiphyseal dysplasia
	Ochronosis
	Haemochromatosis
	Wilson's disease
	Endemic osteoarthritis (e.g. Kashin–Beck disease)
Pauciarticular (large joint) 'osteoarthritis'	Neuropathic joints:
	syringomyelia—shoulders, wrists, elbows
	diabetes—hindfoot, midfoot
	tabes—knees, spine
	Acromegaly
	Avascular necrosis (mainly proximal and distal femur, proximal humerus)

The commonest clinical situation is the patient presenting with joint pain. The priorities in this situation are to determine whether:

- 'OA' is the cause of the symptoms;
- there is an additional periarticular cause for the pain
- there are predisposing or adverse factors for the development or progression of OA
- there is another underlying arthropathy
- there are other factors that are modifying the pain experience.

Resolving these difficulties depends on a careful clinical history and examination; radiography and laboratory investigations play a relatively minor role. The clinical assessment aims to:

- localize the site of the pain—joint line or periarticular
- detect the presence of clinical signs of OA—crepitus, bony swelling, restricted range of motion
- define any adverse features—obesity, malalignment, reduced strength, abnormal usage (occupational or habitual)
- rule out features of other arthropathy—rheumatoid arthritis, gout, seronegative arthropathy
- determine factors which might influence pain experience—multiple regional pain, depression, sleep disturbance
- determine the existence of comorbidities like vestibular imbalance, postural instability, falls; and of polypharmacy, especially the use of sedatives, and opiate analgesics.

Radiographs merely help to confirm the presence of the structural change, but since the radiograph is relatively insensitive, particularly in early disease, a normal radiograph does not rule out a diagnosis of OA. Indeed, knee pain may be the first manifestation of OA, and predate radiographic changes of OA.[2] Conversely, abnormal radiographic changes may not be the cause of the patients' symptoms.

Neurological finding are important, particularly in the lumbar and cervical spine where osteophytosis of the facet or apophyseal joint may lead to foraminal encroachment and subsequent nerve root compression. Peripheral nerve entrapment may also occur as a result of osteophytosis or synovitis of peripheral joints. Possible sites for this are the ulnar nerve at the ulnar groove and the median nerve in the carpal tunnel. In such a situation, particularly in the spine, MRI and/or nerve conduction studies are required to fully elucidate the nature, site, and presence of nerve compression.

As well as direct pressure on a nerve, vascular claudication may also occur, particularly in the lumbar spine. In this situation, exercise results in neurological symptoms and signs in the legs. The diagnosis is essentially based on the history but evidence of canal and/or foraminal stenosis is sought, usually with MRI. In all situations, particularly in the spine, it is essential to ensure that there is a good match between clinical findings and demonstrated structural abnormalities.

Osteoarthritis prognosis

OA is a heterogeneous disease with diverse outcomes. For example, while one in six patients with peripheral joint OA referred to secondary care report a deterioration in their symptoms, 1 in 16 report an improvement during follow-up.[66] Progression of OA is modified not only by the severity of structural changes and symptoms, but also by coexistent risk factors (e.g. high BMI, gender, injury, occupation) and comorbidity (e.g. depression). From the available data one can be relatively optimistic about outcome for most patients, especially those with IPJ OA, and for many people with knee OA.

Knee or hip OA also shortens life expectancy (standardized mortality ratio (SMR) 1.55 (1.41–1.70).[67] This is predominantly due to excess cardiovascular deaths, but exists for other disease specific causes as well. Disability at baseline also associates with excess mortality (SMR 1.48 (1.17–1.86).[67,68] The mechanisms underlying this are unclear but may include:

- side effects of drugs, principally non-steroidal anti-inflammatory drugs
- increased cardiovascular morbidity due to either comorbidities (e.g. obesity, diabetes) or lack of aerobic fitness.

Knee

In a systematic review, risk factors of progression of knee OA included age, BMI, varus (or valgus) knee malalignment, OA at multiple sites, and severe radiographic changes.[69,70] There was not enough evidence to say if female gender, impaired function, and greater pain associated with progression of knee OA by themselves.[69] However, in previous studies female gender, young age of onset, and severity of knee symptoms have been associated with a poor outcome.[70,71] Moderate participation in physical activity is not associated with progression of knee OA.[69] However, intense sporting activity, chronic joint effusions, synovitis, and subchondral bone oedema have all been associated with progressive knee OA.[72] In one study of hospital-referred patients, only the presence of inflammation and CPPD was associated with progression.[73] However, in more recent studies chondrocalcinosis did not associate with radiographic progression of knee OA. In addition to increased morbidity, knee OA is also associated with increased mortality.[61]

Hip

Again the prognosis may be reasonably optimistic. Patients with radiographically severe OA are at a greater risk of structural

progression. Over a 10 year period, Danielsson found deterioration in symptoms in only 17% of people with hip OA, while symptoms improved in 59% and completely resolved in 12%. Radiographic progression similarly occurred in only a minority of cases, principally those with an initial superolateral pattern of joint-space loss.[74] Occasional patients with apparently progressive OA which then improves with spontaneous 'healing' on radiographs (remodelling and partial restoration of joint space) are well described, although uncommon.[75] Possible risk factors for progression of hip OA include superior pole migration, atrophic bone response, chondrocalcinosis at other sites,[76] and possibly hip dysplasias.[54] Higher BMI does not associate with progressive hip OA.[54]

Hand

The prognosis for hand OA depends on the clinical subset. Generally speaking patients with nodal OA have better functional outlook than those with erosive OA or thumb-base OA. Prognosis for hand symptoms is worse in people with hand involvement as part of a generalized OA phenotype. Therefore, patients with generalized nodal OA may have a worse outlook for hand function than those with a few nodes, and underlying IPJ OA. For example, in those with hand OA, and OA at other sites, an increase in pain was reported by 40% whereas 26% reported improvement in pain at 6 years follow-up.[77] Over half of these patients reported worse hand function, while over one-quarter reported improvement in hand function at 6 years follow-up.[77]

Spine

Prognosis for OA of the spine is unclear. This is largely because of the difficulty of correlating symptoms with structural change. In cases with either cord or nerve root compression prognosis is unclear, but deterioration is often slow unless there is additional disc protrusion, vascular insult, or trauma.

Osteoarthritis with coexisting crystal deposition

The natural history of CPPD + OA is poorly documented. Despite often severe symptoms and structural change at presentation, one 5 year, hospital-based, prospective study suggests that most patients run a benign course. Symptomatic deterioration occurred mainly in large lower limb joints (i.e. knees and hips), but even in severely affected knees, two-thirds of patients showed stabilization or improvement of symptoms. The commonest radiographic change is an increase in osteophyte with bone remodelling, rather than progressive cartilage and bone attrition. A recent community-based prospective study of knee OA did not report any association between CC and progressive joint-space narrowing.[61] Nevertheless, severe, progressive 'destructive arthropathy' may occasionally occur, particularly at the knee, shoulder, and hip, especially in elderly women. The prognosis of apatite-associated destructive arthropathy is seemingly poor with the majority requiring joint replacement.

Conclusion

OA targets specific joints including the knees, interphalangeal joints, thumb bases, and hips. It presents with 'mechanical' joint pain, short-lived morning stiffness, and locomotor restriction. Clinical signs include bony enlargement, locomotor restriction, articular or periarticular tenderness, and muscle wasting.

Clinically severe OA is characterized by rest pain, night pain, and joint deformity. CPP or basic calcium phosphate crystals may coexist with OA.

CHAPTER 140

Osteoarthritis—management

Claire Y. J. Wenham and Philip G. Conaghan

Introduction

Osteoarthritis (OA) is the most common cause of disability in the United Kingdom. The resulting pain, stiffness, joint deformity, and loss of joint mobility can affect every aspect of a person's day-to-day activities, as well as their quality of life. The most common reason that people with OA present to their primary care physician is pain; over 50% of people with OA feel that pain is their worst problem.[1] The OA Nation survey of almost 2000 people with OA found that 81% with OA had constant pain or were limited in performing everyday tasks; when their OA pain was 'bad', over half struggled to get out of bed.[1] Management of OA has therefore focused around symptom management, although the concept of structural modification will also be included in this chapter.

Holistic assessment of osteoarthritis

All modern consensus guidelines recommend holistic assessment of people with OA as an essential part of a management strategy. A relationship in which treatment decisions are made jointly by both physician and patient will enhance a self-management approach. Each consultation should take into account a person's existing concerns and expectations and their available support network.

A typical evaluation of a person with OA would assess:

- Severity and extent of joint pain, including the number and pattern of joint involvement, as OA commonly involves multiple joints in the over 50s with differing impairment associations depending on pattern of joint involvement.[2] When are symptoms worse? For example, is knee pain worse at night time and preventing sleep?

- Impact of symptoms on daily living activities such as climbing steps or getting dressed.

- Impact on participation: what key activities have been prevented by the symptoms? OA is not just a disease of elderly people and many people affected by OA are still in employment. It is essential to judge any OA impact on the ability to perform their job, to determine if adjustments in the workplace necessary. This may be as simple as a new chair or forearm rests for a person with hand OA whose work involves a lot of keyboarding.

- Psychological effects of OA. This is very important and should not be underestimated. People with OA report loss of self-esteem, loss of independence and feeling old before their time.[3] Effects on sleep should be noted and if possible, management strategies altered to improve this. Depression is common and should be looked for and treated appropriately.[4]

- Previous treatments that a person may have tried. These include over-the-counter medications that a person is using. Note the types of medication that the person has used previously: which they found helpful and which were stopped because of side effects. The timing of analgesics is also important, for example a long-acting (e.g. modified-release) preparation may be more appropriate so that the analgesic effect is at its best during the most symptomatic period of the day or night.

Management of osteoarthritis symptoms

There are a number of recent excellent expert and evidence-based guidelines for the management of OA,[5,6] with some specific for site of OA—hip,[7–9] knee,[6,8–10] and hand.[11] It is of course important to understand the limitations of the published evidence which is used to underpin these guidelines. The majority of OA studies have focused on knee OA, with much fewer studies on the hip and only a small percentage involving the hand. The majority of studies have utilized pharmacological therapies and most are of short-term (typically 12 week) duration. The nature of clinical trials is such that many people with comorbidities are excluded. Taken together, all these factors influence the generalizability of the published evidence base.

The management options presented below are derived from all the major recommendations and where relevant, differences between treatment guidance will be discussed and specific examples cited; for example, the National Institute for Health and Clinical Excellence (NICE) guidance has a health economics perspective relevant to the United Kingdom. The management options for OA hand is considered separately to that of the knee and hip, and the management of OA of the foot is briefly discussed. Examples of the analgesic effect size (ES) of a treatment or intervention are included, with 95% confidence intervals presented in brackets. For

Table 140.1 Table demonstrating the effect size (ES) for pain relief dependent on the quality of clinical trials

	All trials ES (95% CI)	High-quality trials (Jaded = 5) ES (95% CI)
Acupuncture	0.35 (0.15–0.55)	0.22 (0.01–0.44)
Paracetamol	0.14 (0.05–0.23)	0.10 (0.03 to 0.23)
NSAIDs	0.29 (0.22–0.35)	0.39 (0.24–0.55)
Topical NSAIDs	0.44 (0.27–0.62)	0.42 (0.19–0.65)
Intra-articular HA	0.6 (0.37–0.83)	0.22 (0.11 to 0.54)
Glucosamine	0.58 (0.30–0.87)	0.29 (0.003–0.57)
Lavage/debridement	0.21 (−0.12 to 0.54)	−0.11 (−0.3 to 0.08)
Chondroitin	0.75 (0.5–1.01)	0.005 (−0.11 to 0.12)

HA, hyaluronic acid; NSAIDs, non-steroidal anti-inflammatory drugs.
From Zhang.[9]

clinical practice, an ES of 0.2 is considered small, 0.5 is moderate, and greater than 0.8 is large. A recent systematic review noted that the ES for many commonly used treatments is much smaller than previously thought, when only high-quality trials are included in the analysis. This is demonstrated in Table 140.1.[9]

Recent work has highlighted the importance and magnitude of the placebo effect in OA trials.[12] The non-drug-specific contextual effects of a therapy are highly important. This makes interpretation of trial data even more difficult and it is conceivable that many therapies with small ESs may be placebos.

All management guidelines agree that a combination of pharmacological and non-pharmacological treatment options should be considered for all people with OA and that several key or 'core' principles should be offered to all. These core management suggestions include patient education, exercise, and weight loss.

Patient education and information/encouraging self-management strategies

All treatment guidelines agree that everyone with OA should be offered information (e.g. an information booklet) and should be encouraged to take part in self-management programmes, to increase their understanding of the disease and the management options. Any misconceptions about OA, for example that it invariably progresses or that there are no helpful treatments, should be addressed as early as possible. Education may result in fewer visits to primary care, with one study of knee OA showing that 80% of the costs of delivering effective self-care education were offset within the first year by a reduced number of primary care visits.[13] Reliable websites such as those from arthritis societies can be another source of patient-friendly information. Although these interventions have a small ES in terms of analgesia, they improve other drivers of quality of life such as anxiety and self-efficacy.

Exercise

Exercise can be divided into joint-specific muscle strengthening and range of motion exercises, and general aerobic exercise. Generally, muscle strengthening is important before attempting aerobic exercise. For people with knee OA who cannot straight-leg raise, quadriceps exercises should be advised and forearm strengthening exercises

advised for those with hand OA and weak grip. People should be encouraged to continue these exercises on a regular basis, setting personal achievement targets. It is important to consider analgesia at the time of exercise: this might mean taking medications prior to exercising or even intra-articular corticosteroid (see below). Exercise may be self-led or supervised in individual or group sessions, on land or in water. Exercise in water may be more comfortable for those with knee or hip OA and is effective for both hip and knee OA.[14] The benefits of exercise for knee OA are well known, with improvements in both knee pain and function, with a systematic review demonstrating the benefits of both aerobic walking and home-based quadriceps exercises for pain relief, with an ES of up to 0.52.[15] Although there is less available evidence for hip OA, exercise has also been shown to improve pain in hip OA (ES 0.38).[16] There is surprisingly little published evidence for exercises alone in hand OA so this recommendation is based on expert opinion.[11]

Weight loss (if overweight)

Weight loss, in order to maintain a body mass index (BMI) within normal range, (19–25) is advisable. Obesity is associated with the development and progression of knee OA[17] and weight loss reduces the adverse mechanical forces across a damaged joint. Weight loss can result in a small improvement in function and pain in knee OA[9,18] and although the evidence for the benefits of weight loss in hip OA is very limited, it is still recommended, as it will benefit the person's overall health.[7,9]

Once the core treatment options have been offered to all, a range of other treatments can be considered (Figure 140.1).

Non-pharmacological treatments

In addition to exercise and weight loss (if needed), additional non-drug treatments should be considered for all people with OA. These include simple therapies such as thermotherapy (applying heat or cold to the painful joint), an easy self-management therapy with good safety and very low cost, although there is little evidence for its effectiveness.

Acupuncture

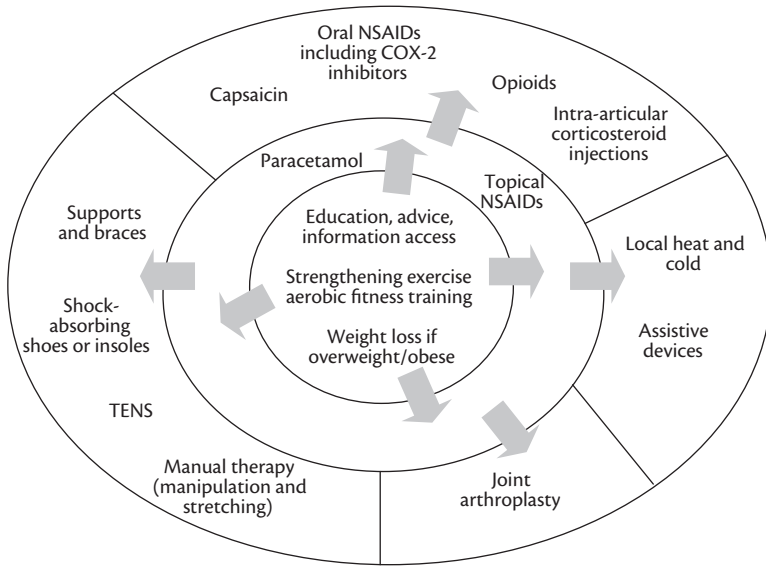
Acupuncture is not a single intervention as it may applied in different ways (e.g. Western or traditional Chinese application) and


Fig. 140.1 Targeting osteoarthritis therapy.
Reproduced from BMJ Conaghan PG, Dickson J, Grant RL. Care and management of osteoarthritis in adults: summary of NICE guidance. 2008;336(7642):502–3 with permission from BMJ publishing group.

often in combination with other therapies. Acupuncture involves positioning fine needles around the site of pain and possibly in other sites, and the needles may be stimulated electrically (electroacupuncture). The neurophysiological mechanism of action of acupuncture is unclear but the release of endogenous opioids has been suggested; the contextual effect of application is important.[19] Courses of acupuncture may involve 6–12 sessions but repeat courses may be required. One difficulty of assessing trials which use acupuncture is that there is no adequate placebo—it is impossible to blind patient or therapist—and even 'sham' acupuncture, when the needles are put in the wrong site or not stimulated, is not thought to be an inactive placebo. Accepting this limitation, several systematic reviews and a recent meta-analysis have concluded that there is evidence for a short-term benefit of acupuncture for people with OA.[9] The ES for pain relief when compared to sham acupuncture is 0.35 (95% confidence interval 0.15–0.55). However, the benefit is usually short-lived, with the ES falling to 0.13 6 months after treatment.[9]

Transcutaneous electrical nerve stimulation

Transcutaneous electrical nerve stimulation (TENS) may stimulate specific nerve fibres via pulsed currents which are delivered through electrodes placed on the skin.[20] Only a few small studies have evaluated the use of TENS and suggest a minimal effect; however, it is a safe treatment that may provide some people with short-term pain relief.

Electromagnetic therapy

This is postulated to work by increasing blood flow to the stimulated area. However, as there is no good evidence for the benefit of electromagnetic therapy in OA,[9] it is not a recommended treatment.

Aids and devices

There is a surprising lack of good trial data in this area of OA treatment. There is no strong evidence to suggest that insoles (wedged or neutral) are of benefit in improving the symptoms of knee OA,[9] although they are recommended in recent management guidelines.[6] However, all people with lower limb OA should be advised

on sensible footwear, usually a flexible, shock-absorbing sole, broad fit, and with arch support.

A walking stick can provide some relief (when held in the contralateral hand to the affected knee or hip) and guidelines support their use if a person finds it helpful.[5,9,10] A knee brace, for those with OA knee with a varus or valgus deformity and instability, can reduce pain and improve function and may also reduce the risk of falls.[9] Specific referral to an orthotics department may be needed to provide a brace. Disability equipment assessment centres can provide expert advice for people struggling with activities of daily living. Likewise, a referral to occupational therapy may be useful for anyone whose joint disease results in significant impact on their day-to-day activities.

Pharmacological treatments for osteoarthritis

The potential side effects of pharmacological therapies must be considered before prescribing, particularly in elderly patients and those with other comorbidities, which are frequent in the OA population. After starting a pharmacological therapy, a person must be reviewed to judge the benefits and any potential side effects, so that treatment can be altered if needed.

Paracetamol

The mechanism of action of paracetamol (acetaminophen) is not completely understood, although it is known to be a weak inhibitor of the cyclo-oxygenase pathway,[21] thereby having anti-inflammatory effects; it also acts on the endogenous cannabinoid receptors.[22] The previous evidence from the few well conducted randomized, controlled trials (RCTs) for the effectiveness of paracetamol for the relief of pain in knee and hip OA[23] demonstrated a small overall ES of 0.21. However, updated management guidelines, which include clinical trials published up to 2009, have noted that the effect size is even smaller than previously thought at 0.14 and if only high-quality trials are assessed, the ES is minimal (0.109). Despite this, all current guidelines recommend that paracetamol should be a first-line treatment if additional analgesia is required after the core management options have been initiated. Regular dosing may be needed to achieve maximum analgesic effect. However there is

some recent evidence of dose-dependent adverse gastrointestinal (GI) events,[12,24] and such data has led to the United States Food and Drug Administration (FDA) recently recommending that maximum adult daily dose of paracetamol should be less than 4 g daily.

Topical non-steroidal anti-inflammatory drugs

Topical non-steroidal anti-inflammatory drugs (NSAIDs) are effective analgesics for knee OA and they have a good safety record.[10] Most studies have evaluated diclofenac or ibuprofen. They are safer than oral NSAIDs as the plasma concentration is less than 15% of the equivalent dose of oral NSAID.[25] The ES (including high-quality trials) is moderate (0.42), although patients may need to be reminded that regular application may be required for the maximal benefit. Side effects from topical NSAIDs are uncommon but may include skin irritation at the site of application. Topical NSAIDs are not recommended for hip OA.

Topical capsaicin

Topical capsaicin cream (0.025% applied 4 times daily) reversibly desensitizes nociceptive C-fibres by acting on vanilloid receptors. This is an additional topical treatment that could be considered before prescribing oral treatments, although it may be relatively expensive. The data for the efficacy of capsaicin in knee OA is limited, hence it was not recommended in the recently published American College of Rheumatology (ACR) guidance.[6] Systemic side effects have not been reported although up to 40% of users will experience local redness or irritation.[9] Patients should be warned of this and advised to wash their hands after use. Patients should be advised that regular application is required for the maximum benefit, which may not be evident for several days.

Oral non-steroidal anti-inflammatory drugs

NSAIDs act by reducing the production of pain-inducing and proinflammatory prostaglandins. They can be broadly divided into selective and non-selective, depending on the differential inhibition of the cyclo-oxygenase (COX) enzymes COX-1 (important in maintaining a healthy GI mucosa) and COX-2 (unregulated at sites of inflammation; blocking this enzyme may alter the balance between pro- and anti-thrombotic mediators). Selective COX-2 inhibitor drugs have a lower incidence of GI side effects but, like all NSAIDs, a definite prothrombotic risk. NSAIDs are covered in detail in Chapter 77.

NSAIDs are effective analgesics in OA. However, there are difficulties with the current trial data in that detailed data is only available for the newer NSAIDs and the doses of drugs used in clinical trials may not represent the doses prescribed or used by patients on a day-to-day basis. Furthermore, the patients recruited to clinical trials of NSAIDs are not usually representative of the typical OA population, who tend to have other comorbidities. Head-to-head comparisons have demonstrated that NSAIDs are superior to paracetamol for pain relief in knee and hip OA, with the most recent review of trials demonstrating a greater ES (0.29) compared with paracetamol (0.149).[26] COX-2 selective drugs and non-selective NSAIDs demonstrate similar pain relief in clinical trials of knee OA.[5]

NSAIDs have potential renal, cardiovascular (CV), and GI side effects; these must be taken into account when prescribing and should be reviewed on a regular basis. NSAIDs should be used at the lowest effective dose for the shortest possible time, in order to minimize potential side effects. GI side effects are common with NSAID use, both gastric upset (discomfort or dyspepsia) and serious GI side effects such as peptic ulcers, perforations, and bleeds. The risk of serious GI side effects appears to be even greater if NSAIDs are combined with paracetamol.[24] Using a COX-2 selective drug reduces the risk of a serious GI event compared with non-selective NSAID,[24] and may be chosen in preference to a non-selective NSAID in a patient with GI risk factors. Using gastroprotective agents with non-selective NSAIDs also reduces the risk of hospitalization from a serious GI event[27] and based on a health economics analysis, the prescribing of proton pump inhibitors (PPIs) with all NSAIDs (including COX-2 inhibitors) is currently recommended in the United Kingdom.[5] All NSAIDs may cause fluid retention and aggravate hypertension and should be used with caution in patients with CV risk factors. Naproxen appears to have a better cardiovascular risk profile[28] than other NSAIDs and maybe considered for any patient with CV risk factors for whom an NSAID is required.

Opioids

Opioids work by acting on endogenous opioid receptors, although the differing opioid drugs may act on different receptor subtypes; they are also reviewed in Chapter 78. Opioids have a role in treating OA pain, and are recommended in evidence-based treatment guidelines, although their use is often limited by side effects, with around one-quarter of people treated with opioids in clinical trials withdrawing due to side effects. The most common reported side effects are nausea (30%), constipation (23%), dizziness (20%), drowsiness (18%), and vomiting (13%).[29] Opioids should be considered if paracetamol and topical NSAIDs have been ineffective in controlling symptoms, and if non-pharmacological treatments have also been instigated, but the side-effect profile must be born in mind when prescribing, particularly for elderly patients who are more prone to side effects.

A large meta-analysis[29] showed a moderate ES for pain relief with opioids in OA (0.78, 95% CI 0.59–0.98) and a small to moderate ES for improvement in function (0.31, 95% CI 0.24–0.39). There was a wide variety in the outcomes of the studies included in the analysis, which did not seem to be related to the type of opioid used. Oxycodone, fentanyl, and morphine sulphate were noted to be more likely to result in side effects which result in stopping the drug than tramadol or codeine. Opioids are available in different preparations. For example, fentanyl and buprenorphine are provided in transdermal patches which may improve patient compliance; and long-acting preparations, for example modified-release tramadol, may be useful for night pain.

Intra-articular corticosteroid

Corticosteroids (CS) have a potent anti-inflammatory action via a reduction in proinflammatory chemicals; they inhibit the production of interleukins (IL)-1 and IL-6 and tumour necrosis factor (TNFα) as well as decreasing the expression of COX-2. Intra-articular (IA) corticosteroid to the OA knee is not recommended for an isolated asymptomatic joint effusion but for the relief of moderate pain that has failed to respond to oral or topical analgesics. The period of pain relief post-injection is the ideal time to reinforce regular quadriceps strengthening exercises. IA CS is effective in the short-term (up to 4 weeks) for the relief of pain in knee OA,[30] although the evidence suggests a smaller effect on function. The ES is particularly high 1 week after injection (0.72,

95% CI 0.41–1.01) but falls to 0.28 after just 4 weeks.[9] One analysis assessing repeated IA corticosteroid injections every 3 months for 2 years noted a persistently high ES (0.67) for the first year of treatment but this had fallen to 0.25 by the second year.[30] There is no clear evidence on whether a particular preparation of CS is more effective than another[5]; an example of a CS used for the knee joint would be 80 mg methylprednisolone or 40 mg triamcinolone.

As yet, there are no current reliable predictors of response to IA steroid to the OA knee. Knees that have effusion may respond better,[31] but this has not been demonstrated in all studies.[32] IA CS is associated with few side effects and the risk of infection is very small.[5] Patients should be warned of potential fat atrophy, which can result in a cosmetic defect, and that symptoms may worsen transiently after injection. Although there have been concerns over potential cartilage toxicity with repeated CS injections, this remains controversial although as a general rule, IA CS should not be offered more than 4 times in a 12 month period.[8]

Although previous studies of IA corticosteroid to the OA hip demonstrated varying benefit,[33,34] a recent RCT demonstrated good pain relief at 8 weeks after IA CS[35]; IA CS could be used for patients with moderate to severe pain who are not responding to analgesics/NSAIDs.[9]

Intra-articular hyaluronan

Hyaluronic acid (also known as hyaluronan, HA) is a glycosaminoglycan (GAG) and a constituent of synovial fluid responsible for its viscous properties. In OA there is reduced HA quantity and quality and the theory of viscosupplementation is to restore good-quality HA in the joint. Several preparations are available with differing molecular weight and manufacturing sources and HA preparations may be administered as single or weekly injections over a period of 3–5 weeks. This heterogeneity of products and their applications makes the trial data complex to interpret. Although some studies suggest HA may give improved longer-term pain relief when compared with IA CS,[36] a recent analysis using only high-quality trials suggests a small ES of just 0.22 (−0.11 to 0.54).[9] There is even less evidence to support the use of HA in hip OA. Although some open-label studies noted an improvement in symptoms,[37] the only placebo-controlled RCT did not show a benefit of HA over CS or IA saline.[38]

IA HA may result in transient pain or swelling at the injection site, which is more likely with the higher molecular weight preparations.[9] There is disagreement among the OA treatment guidelines as to whether HA should be prescribed and it is not yet possible to predict which patients may show a better response.

Glucosamine/chondroitin

Glucosamine is an amino sugar that is a precursor in the production of glycosylated proteins, including GAGs. Chondroitin sulphate is a sulphated GAG. The rationale for these agents is that the limiting factor for the GAG component of cartilage may be the availability of substrates such as glucosamine and chondroitin sulphate. However, the mode of action of both of these agents remains controversial. Neither is licensed by the FDA so they are marketed in the United States as health food supplements. Analysis of previous trials is made difficult by the varying preparations of glucosamine and chondroitin, differing study populations, and differing analgesic use at the time of assessment. Trials of glucosamine sulphate for pain relief in knee OA have shown that the ES for pain is small

when only high-quality trials are considered, although there is very little evidence of harm. The analgesic efficacy of glucosamine hydrochloride is poor, with an ES of just 0.13 (0.02–0.259) Likewise the evidence for pain relief with chondroitin, when just high-quality trials are analysed, is very poor (ES 0.005).[9] The most recent meta-analysis, published in 2010, assessing the effectiveness of glucosamine and chondroitin at both symptom and structure modification for the OA joint concluded that neither has any benefit on pain or structure modification.[39] If patients remain keen to try glucosamine for symptomatic relief of OA, then a three-month trial of 1.5 g of glucosamine sulphate could be suggested as the drug is thought to be very safe, although patients should be advised to stop the treatment if no benefit is noted at 3 months.

Other nutritional supplements

Systematic reviews concluded that there were methodological flaws in the trials of methylsulphonylmethane (MSM), green-lipped muscle extract, and dimethyl sulphoxide (DMSO), so no definite evidence was available. However, the larger, better-designed RCTs of MSM do suggest a small benefit of 3 g MSM twice a day in decreasing pain and improving functional status.[40] The evidence for the efficacy of avocado soybean unsaponifiable (ASU) in trials combining hip and knee OA suggests a small symptomatic benefit in pain reduction (ES 0.39), although the ES reduces to 0.22 (−0.06 to 0.51) when only high-quality trials are assessed.[9] There is no good evidence for the symptomatic or structural benefit of ASU in the treatment of hip OA.[9]

Structure modification

Structure modification of OA with its potential for concomitant or subsequent reduction in symptoms remains an elusive goal of OA therapies. There are as yet no agents with regulatory approval as structure-modifying drugs. Current regulatory requirements mandate radiographic joint space width as the structural outcome of interest (as a surrogate measure of hyaline cartilage) and require an additional symptom-modifying component. The complexities of repositioning a given joint in longitudinal studies have made joint space width a difficult outcome measure to understand,[41] and in future MRI quantification of OA structural pathology may improve understanding in this area.

There is still controversy as to whether glucosamine or chondroitin may have structure-modifying effects in the OA joint. Trials of glucosamine are inconclusive,[9] but a recent meta-analysis suggests neither glucosamine nor chondroitin has structure-modifying effects.[39] Diacerhein is an anthraquinone derivative, thought to act via the inhibition of IL-1B. Its effect on symptoms is minimal (ES 0.24, 0.08–0.39), with considerable heterogeneity between trials. Diarrhoea is a significant side effect, especially at higher doses.[9] Diacerhein may slow the progression of joint space narrowing in the hip over a 3 year treatment period,[42] but because of its side effects it is not a widely accepted treatment for hip OA.

Bone as a target of structure modification?

Although historic studies have focused on hyaline cartilage as the main target of structure-modifying therapies, the subchondral bone may be a target for treatment in OA, as subchondral bone abnormalities seen on MRI have been associated with pain[43] and progression of cartilage loss. Histological studies have demonstrated

altered trabecular structure within these areas[44,45] and there is also evidence of increased bone turnover in OA.[46] A large, multinational trial of a bisphosphonate, risedronate, noted that urinary levels of C-terminal cross-linking telopeptide of type II collagen (CTX-II), a marker of cartilage degradation, were reduced with risedronate but despite this, there was no reduction in radiographic structural progression or symptoms at 2 years.[47] However a recent trial using zoledronic acid (ZA) vs placebo infusion in people with MRI bone marrow lesions (BMLs) demonstrated that the ZA group had a reduction in total BML area and a small improvement in pain compared with the placebo group at 6 months. At 12 months, the total BML area was still significantly lower in the ZA group but this was not associated with any reduction in pain compared to the placebo group.[48]

There is evidence that oral salmon calcitonin, strontium ranelate, the selective oestrogen receptor modulator levomeloxifene, and oestrogen replacement therapy also lower CTX-II levels,[49–51] and preliminary results from recent trials have suggested structure modification for both strontium ranelate and calcitonin[52,53] in OA of the knee. Strontium demonstrated a reduction in joint space narrowing compared to placebo over a 3 year period, as well as an improvement in clinical symptoms.[53] Although the study using calcitonin in 1200 knees did not show a difference in reduction in joint space narrowing over 2 years, there was an increase in cartilage volume of 5% compared to 2.5% in the placebo group, suggesting potential structure-modifying effects of calcitonin.[52]

Treatment of hand osteoarthritis

Despite the high prevalence of symptomatic hand OA,[54] current therapies for hand OA are limited and there is a lack of high-quality RCTs for assessing treatments for hand OA.[55] As with the knee and hip, treatments can be divided into non-pharmacological and pharmacological, and general information and advice with regard to joint protection and exercises, both to improve range of motion and local strengthening exercises (forearm strengthening) should be provided to all people with hand OA. People with hand OA with hand pain and difficulty in performing everyday tasks should be referred to occupational therapy for assessment, advice and if needed, the provision of splints and devices to help with activities of daily living (e.g. tap turners). Simple treatments which the patient can initiate includes local application of heat (e.g. hot pack, paraffin wax); although there are no trials to support this, it may be effective and is very safe.

Aid and devices

The use of a splint for base of thumb (first carpometacarpal (CMC)) OA is a safe and effective therapy recommended in current management guidelines. A recent RCT assessed the use of a thumb base splint vs usual care and demonstrated that by 12 months, those using a splint had significantly reduced pain and disability.[56]

Oral analgesics

Paracetamol is the first oral pharmacological treatment of choice as recommended by current management guidelines; however, there are no placebo-controlled trials of paracetamol in hand OA, and paracetamol is recommended (at doses of up to 4 g per day) because of its previously good safety profile, low cost, and data showing some effectiveness (albeit small ES) in OA trials of other

joints. There are few placebo-controlled trials of NSAIDs in the short-term treatment of hand OA, which show that oral NSAIDs are effective in the short-term at reducing pain in hand OA (ES 0.4, 0.2–0.6)[57] and could be used for those who have pain despite paracetamol and topical NSAIDs. However, potential side effects must be noted before prescribing, and NSAIDs should be used at the lowest effective dose and for the shortest possible time period. Opioids such as tramadol may be considered for those with persistent severe symptoms,[6] although side effects may limit its use, particularly in elderly people. There is very little data for the use of glucosamine, chondroitin, ASU, or diacerhein in hand OA. To date, there are no trials of diacerhein or ASU in hand OA.[57]

Topical therapies

Topical NSAIDs are an effective treatment for relieving pain in hand OA (ES 0.77, 0.32–1.22) and appear to have no more GI side effects than placebo.[57] Their effect size is higher than that for oral NSAIDs and the side-effect profile is much better. Topical NSAIDs could be used as an alternative or in addition to paracetamol for people who still have symptoms, although patients may need to be reminded that regular application may be required for the maximal effect. Two short-term (4 weeks) studies of topical capsaicin (0.025% four times a day) for hand OA have demonstrated that it is a useful treatment.[57] It may be a particularly useful therapy for those who are intolerant or at high risk of adverse events from oral analgesics, although it is relatively expensive. Patients should be warned of the potential redness or irritation, which occurs in around 40%, and that the drug must be used for several consecutive days to achieve maximum benefit.

Intra-articular therapies

There is one placebo-controlled RCT of IA corticosteroid to the first CMC joint in hand OA, which failed to show any benefit above placebo, although the study terminated early because of difficulty in recruitment.[58] Open-label studies have shown a short-term reduction (up to 6 weeks) in pain after IA corticosteroid to the first CMC joint[59–61]; the ACR management guidance did not support the use of IA corticosteroid due to the lack of clinical trials,[6] although other guidelines have supported the use of this therapy. IA CS to the base of thumb could be considered for those with persistent symptoms despite a trial of oral or topical analgesia. There is no well-designed RCT of HA in CMC OA.

Treatment of foot osteoarthritis

OA of the first metatarsophalangeal (MTP) joint is extremely common, but there is increasing evidence that midfoot OA is also common. Using a newly developed foot atlas, an Australian community cohort study (n = 197) showed radiographic OA was significantly more prevalent at the midfoot (60%) than the first MTP joint (42%) using anteroposterior and lateral foot views.[62]

Most of the available data for treatment of MTP OA pertains to surgical intervention and there is very little data for any other treatments. There is a lack of RCTs or systematic reviews that assess the effectiveness of either corticosteroid or HA injections to the OA foot. A recent trial noted that IA HA is no more effective than placebo in improving the symptoms of first MTP OA.[63] In clinical practice, injecting a small amount of corticosteroid into an osteoarthritic foot joint may provide some short-term relief but there is

little evidence to support this.[64] A recent month-long investigation of functional foot orthoses highlighted that midfoot OA was associated with adverse biomechanics and that in-shoe orthoses have the potential to improve in foot pain and walking function in midfoot OA.[65] Further studies are needed to confirm this.

Surgical treatments for osteoarthritis

The wide variety of surgical interventions and their indication cannot be adequately covered in this chapter. Some common procedures are therefore briefly overviewed.

Joint replacement

Total knee arthroplasty involves the removal of the distal portion of the femur, proximal part of the tibia, and the anterior cruciate ligament and replacement of the damaged surfaces with metal prostheses, either with or without cement. Total hip arthroplasty involves replacing the acetabulum and the head and neck of the femur with prostheses. These operations are becoming increasingly common, with over 160 000 total hip and knee joint replacements performed in England and Wales last year. Hip resurfacing has been developed as an alternative to total hip replacement and consists of placing a metal cap over the head of the femur while a matching metal cup is placed in the acetabulum. This replaces the articulating surfaces of the hip but removes less bone than with a total joint replacement and may be considered for younger, active males.[66]

Total joint replacement is a safe and effective but irreversible treatment option for which a patient should be referred when a combination of non-pharmacological and pharmacological treatments has been tried and the patient still has significant symptoms that are substantially impacting on their life. Ideally, referral should be made before pain becomes severe or before an individual has longstanding functional difficulties, and patient factors such as obesity, smoking, or other comorbidities should not be a barrier to referral. A recent international study has demonstrated that there is no specific level of either pain or function that indicates the need for a joint replacement,[67] hence the decision for surgery should be made after discussion with the patient and clinician, and cannot rely on currently available scoring tools.

Studies note a significant reduction in pain and improvement in function after total joint replacement, with pain improving in particular in the first 3–6 months after surgery.[68] Revision rates at 10 years after total joint replacement have been reported as 7% for the hip and 10% for the knee.[69,70]

Unicompartmental knee replacement

This may be a treatment option for those with just one compartment of the knee affected (around 30% of those with knee OA), with similar outcomes for pain and function improvement.[9,71] The medial compartment is most commonly replaced, although the lateral compartment may also be suitable. In selected patients with patellofemoral compartment disease and no tibiofemoral OA, a patellofemoral replacement, although infrequently performed and usually only at specialist centres, may be an option.[71]

Arthroscopic lavage and debridement for knee osteoarthritis

A recent systematic review noted that there is no evidence for any benefit of arthroscopic lavage and debridement for the OA knee

above placebo.[9] Referral for arthroscopy should be reserved for those with a clear history of mechanical locking of the joint, suggestive of a meniscal tear or other loose body within the joint. The presence of loose bodies on imaging is not a reason to refer for an arthroscopy unless there is associated locking. Locking should not be confused with gelling of the joint, which is stiffening of a joint with rest (e.g. after sitting in a fixed position for a period of time).

Osteotomy

Osteotomy involves cutting and reshaping the tibia in order to alter the biomechanics of the knee joint in order to transfer the load-bearing area from the damaged to the normal compartment of the joint. The best evidence is for a high tibial osteotomy for medial knee OA, whereby a wedge of lateral tibia is removed. Although a systematic review noted that osteotomy results in improved pain and function, it is not known whether an osteotomy is better than no treatment at all, or which surgical technique is best.[72] Osteotomy may be considered for younger patients to delay the need for arthroplasty.[73]

Joint distraction

This is a technique whereby the bony ends of a joint are gradually separated over a period of time, using an external fixator to unload the joint. Preliminary studies of joint distraction have shown promising results, with improved pain scores and structural modification in both the ankle and knee,[74,75] but this technique is not yet in clinical use and needs further validation.

Surgery for hand osteoarthritis

Surgery should be considered for people with severe thumb base OA who are not responding to other treatments. Surgical options include arthrodesis, osteotomy, total joint replacement or trapeziectomy, with or without synthetic or biologic interpositions. A Cochrane review has shown that a combination of surgical procedures (e.g. trapeziectomy with ligament reconstruction) is no better than a single procedure (e.g. trapeziectomy) and single procedure was associated with fewer side effects. The ES for pain reduction was −0.17 (−0.57–0.24).[76]

Surgery for foot osteoarthritis

There are several new surgical techniques for minimally invasive correction of hallux valgus, which may have shorter recovery and rehabilitation times. However, at present, there is inadequate data (due to the heterogeneity of clinical trials) to be able recommend the use of minimally invasive techniques over routine management.[77]

Emerging treatments of osteoarthritis

The concept of targeting bone for symptom and structure modification has been mentioned above. As there is increasing evidence for inflammation within the OA joint,[78] other anti-inflammatory therapies have been trialled in OA. Case reports of anti-TNF medications note an improvement in symptoms in OA,[79,80] although this was not evident in a recent large study,[81] and methotrexate, a disease-modifying drug which is widely used in inflammatory arthritis, has also been trialled in OA to some effect, although data is limited.[82,83]

Increased nerve growth factor (NGF) expression has been noted in the OA joint, and a number of humanized monoclonal

antibodies are in development that bind and inhibit NGF. One of these, tanezumab, showed good analgesic efficacy and an improvement in function in a study of 450 people with knee OA, compared to placebo.[84] However, despite this initial promising data, trials in OA were temporarily suspended due to concerns over accelerated rate of progression to total joint replacement. The anti-NGF FDA committee has recently voted to continue developing anti-NGF drugs as long as certain safety criteria are observed. Anti-NGF therapies may have a role in the future for reducing OA pain.

As well as peripheral sources of OA pain that may be targeted for analgesic treatments, there are new treatments for OA that target central pain in OA. Recently trialled therapies include centrally acting drugs such as duloxetine, a serotonin–noradrenaline reuptake inhibitor, for which there is growing evidence. Short-term (10 week) studies of duloxetine vs placebo, in over 500 people demonstrated a significant improvement in pain and function for people with painful knee OA (pain >4/10) already taking NSAIDs.[85] A 13 week, placebo-controlled study of 250 people also noted a significant reduction in pain and improvement in function scores in those taking duloxetine compared with placebo.[86] Side effects of duloxetine included nausea, dry mouth, and constipation, which may limit its use.

Novel opioid drugs are also in development, for example tapentadol, a centrally acting mu-opioid receptor agonist and noradrenaline reuptake inhibitor. A study of over 1000 people with chronic low back pain or OA pain, comparing tapentadol with the traditional opioid oxycodone, noted that both drugs provided sustained pain relief but that tapentadol was better tolerated with fewer side effects. Despite this, 22% of participants withdrew from the study due to side effects of tapentadol, although this was lower than the 37% who withdrew from the oxycodone group.[86a]

Side effects of opioids remain a major disadvantage of this class of drug. Opioid drugs formulated as extended-release preparations may have fewer side effects and these are undergoing phase 3 clinical trials, with two-thirds of patients noting good to excellent pain relief with extended-release oxycodone, with 22% discontinuing treatment due to adverse events.[87]

To date there are no studies assessing the use of pregabalin in people with OA, although one study has suggested decreased pain sensitivity in a rat model of OA.[88] The cannabinoid receptors, present in the central and peripheral nervous system, glutamate, a major central nervous system (CNS) neurotransmitter, the mu-opioid receptor, and the bradykinin-2 receptors[89] are also potential targets for pain relief and are under review.[90] As yet, these treatments remain in clinical trial stage.

Conclusion

OA is a common, painful and functionally limiting condition. All people with OA should be offered a combination of pharmacological and non-pharmacological treatments and the psychological effects of OA should also be considered. A range of treatments is available, although for many the ES is small, side effects limit the use of common pharmacological treatments, and there is very limited data to judge which people may respond better to a certain therapy than another. Ongoing research into optimal use of existing therapies and new treatments is needed to enable improved management of this common condition.

Gout

Nicola Dalbeth

Introduction

Gout is the most common inflammatory arthritis affecting men. The central biochemical feature of gout is hyperuricaemia (elevated serum urate concentration) which leads to formation and deposition of monosodium urate monohydrate (MSU) crystals within the joint and soft tissues. Gout most often presents as recurrent, self-limiting episodes of severe acute arthritis. In the presence of prolonged hyperuricaemia, some patients also develop chronic tophaceous disease and joint damage. Gout is frequently associated with comorbid conditions such as chronic kidney disease, hypertension, diabetes, and dyslipidaemia; these comorbid conditions may add further complexity to the presentation and management of gout. Long-term management with urate-lowering therapy (ULT) using a treat-to-target approach is essential to promote dissolution of MSU crystals, suppression of acute gout attacks, and regression of tophi.

Definitions

The central feature of gout is deposition of MSU crystals. This crystal deposition may lead to acute inflammatory arthritis, chronic gouty synovitis, and/or chronic tophaceous disease. The gold standard for diagnosis of gout is identification of MSU crystals within tissue or synovial fluid (Figure 141.1). MSU crystals may be present in patients with gout and poorly controlled hyperuricaemia in previously unaffected joints.[1] Classification criteria that include clinical history, physical examination, laboratory tests, and radiography, exist for epidemiological studies of gout.[2] However, these criteria have relatively poor specificity and sensitivity for acute gout.[3] For this reason, crystal diagnosis should be attempted wherever possible for clinical diagnosis.

Epidemiology

In the United Kingdom adult population between 2000 and 2007, the incidence of gout per 1000 person-years was 2.68 (4.42 in men and 1.32 in women).[4] Most recent prevalence estimates of gout in the United States are 3.9% among adults in 2007–2008 (5.9% in men and 2.0% in women).[5] Similar prevalence data have been reported in the entire New Zealand population, with an estimated prevalence in the adult population in 2009 of 3.8% (6.0% in men and 1.8% in women).[6] The prevalence of gout in the United States has increased by 1.2% from the 1988–1994 period to the 2007–2008 period.[5]

Analysis of cross-sectional studies has demonstrated a number of factors associated with gout in the general population. These factors include male sex, increasing age, socio-economic deprivation, and ethnicity.[6] In particular, Polynesian ethnicity is associated with a 3–4-fold increased risk of gout.[6] Medical conditions associated with gout include obesity, chronic renal impairment, renal transplantation, cardiovascular disease, type 2 diabetes, hypertension, heart failure, hypertriglyceridaemia, and psoriasis.[5,7,8] Diuretic and cyclosporine use are also associated with gout.[7,9] The relationship between various comorbid conditions and gout is complex, and there is ongoing debate about the influence of hyperuricaemia and gout on development of comorbid conditions, and vice versa (Table 141.1). Nevertheless, in the general population, gout is associated with increased total mortality and cardiovascular mortality, even after adjusting for traditional cardiovascular risk factors.[10]

Analysis of large longitudinal cohort studies has shown that a number of dietary factors are associated with development of gout (Table 141.2); these factors include high intake of beer and spirits, sugar-sweetened soft drinks, fructose, meat, and seafood.[11–14]

Table 141.1 Relationship between development of gout and comorbid conditions

Comorbid condition	Prevalence in patients with gout	Refs	Risk of developing gout if comorbid condition is present	Refs	Risk of developing/ having comorbid condition if gout is present*	Refs
Obesity	22–67%	22,78	RR 2.33 for obesity RR 1.99 for weight gain	15	NA	–
Type 2 diabetes	29–33%	8,22	RR 0.67	90	RR 1.34	91
Hypertension	60–89%	8,22	RR 2.31	15	HR 1.81 (if hyperuricaemia present) NA for gout	92
Coronary artery disease	25–37%	8,22	NA		OR 1.26	93
Peripheral vascular disease	NA	–	NA	–	OR 1.33	94
Nephrolithiasis	27%	95	RR 1.05 (not significant)	96	RR 2.12	96
Chronic kidney disease	47%	8	RR 3.61 including those on diuretics RR 4.60 excluding those on diuretics	15	NA	–
Diuretic use	33%	7	RR 1.77	15	–	–

HR, multivariate adjusted hazard; NA, data not available; OR, multivariate adjusted odds ratio; RR, multivariate adjusted relative risk ratio.

Weight gain and obesity in younger life are strongly associated with development of gout.[15] Other dietary factors such as low-fat dairy products, coffee, and vitamin C are associated with reduced risk of developing gout.[11,16–18] Dietary intake of diet-sweetened soft drinks, wine, tea, high-fat dairy products, and vegetable purines does not appear to influence the development of gout.[11–13,16]

Clinical features

The first attack of gout most often presents as rapid onset of acute inflammation affecting the first metatarsophalangeal (MTP) joint or other joint in the lower limb. Triggers for gout flares include heavy alcohol intake, dehydration, joint trauma, medical illness, surgery, and intake of high-purine diet. In patients with established gout, commencement of ULT may also trigger a gout flare. Patients describe severe joint pain with difficulty walking and performing daily activities. Examination of the affected joint shows the cardinal features of inflammation; erythema, heat, tenderness, swelling, and loss of joint mobility. In the case of a severe gout attack, patients may also be systemically unwell with fever. The acute gout attack typically resolves spontaneously after 7–10 days.

In the presence of persistent hyperuricaemia, recurrent flares occur, with increasingly frequent and prolonged attacks which may affect numerous joints including those in the upper limbs. Chronic synovitis may also develop. In some patients, tophaceous gout develops, leading to cosmetic problems, ulceration and superimposed infection, mechanical obstruction of joint movement, bone and cartilage damage, and musculoskeletal disability. In a minority of patients, gouty tophi may be the initial manifestation of disease. This is particularly the case in elderly women with chronic kidney disease who are taking diuretics.[19] Chronic gout has an important impact on health-related quality of life and musculoskeletal function. In particular, recurrent gout flares, the presence of joint inflammation and tophi are associated with disability and poor health-related quality of life.[20] Work productivity is also reduced in patients of working age with severe gout, with an estimated mean work day loss of 25.1 days per year.[21]

In addition to the joint disease, patients with gout frequently have additional comorbid conditions such as type 2 diabetes, chronic kidney disease, hypertension, dyslipidaemia, and cardiovascular disease (CVD).[8] These comorbid conditions may impact on gout management; for example, thiazide diuretic use in patients with hypertension may increase serum urate concentrations and predispose individuals to gout, chronic kidney disease may limit the use of non-steroidal anti-inflammatory drugs (NSAIDs) and/or colchicine for management of acute flares, and blood sugar control may be difficult in patients with coexistent diabetes receiving corticosteroids for management of acute gout. The majority of patients with gout are at high risk for CVD events,[22] and a presentation with gout should be viewed as an opportunity to address musculoskeletal health, and also cardiovascular and metabolic risk factors.

Diagnosis of gout is confirmed by identification of MSU crystals in synovial fluid or tophus. MSU crystals may be present in joints previously unaffected by clinically apparent episodes of gout,[23] and crystal diagnosis should be attempted in all patients. In acute gout, synovial fluid analysis typically shows an inflammatory picture with high concentrations of neutrophils. During the acute flare, blood testing typically shows signs of acute inflammation with neutrophil leucocytosis and high acute phase reactants. Measurement of the serum urate concentration is essential in patients with gout. Most patients with untreated gout will have elevated serum urate concentration, above saturation concentrations (>0.41 mmol/L). However,

Table 141.2 Dietary factors and development of gout

Dietary factor	Risk of developing gout	Relative risk for developing gout[a]	References
All alcohol	Increased	2.53	12
Beer	Increased	2.51	12
Spirits	Increased	1.6	12
Wine	No effect	1.05	12
Meat	Increased	1.41	11
Seafood	Increased	1.51	11
Purine-rich vegetables	No effect	0.96	11
Low-fat dairy products	Reduced	0.58	11
High-fat dairy products	No effect	1.0	11
Coffee	Reduced	0.41 in men, 0.43 in women	16,18
Decaffeinated coffee	Reduced	0.73 in men, 0.77 in women	16,18
Tea	No effect	0.82 in men, 1.55 in women	16,18
Vitamin C	Reduced	0.55	17
Sugar-sweetened soft drinks	Increased	1.85 in men, 2.39 in women	13,14
Diet soft drinks	No effect	1.12 in men, 1.18 in women	13,14
Fructose-rich fruits	Increased	1.64 in men	13
Fruit juice	Increased	1.81 in men, 2.42 in women (orange juice)	13,14
Free fructose	Increased	2.02 in men, 1.62 in women	13,14

[a]Multivariate relative risk, typically comparing highest quintile of intake with referent group (no intake or lowest quintile of intake).

during an acute gout flare, serum urate concentration drops into the normal range in approximately 40% of patients.[24] In this situation, repeat measurement of the serum urate concentration in the convalescent period is required.

Imaging has a role in diagnosis and assessment of disease severity and complications. Most often plain radiographs are normal, particularly in patients with recent presentation of gout. In patients with established disease, typical plain radiographic features are asymmetric soft-tissue masses (tophi) and well-corticated bone erosions with overhanging edges. Ultrasonography has the ability to detect erosion, synovitis, and tophi in affected joints. The 'double-contour' sign on ultrasonography—hyperechoic enhancement of the superficial margin of the hyaline cartilage—has high specificity for gout.[25] MRI is able to detect bone erosion, synovitis, and tophus deposition with high sensitivity, but is not usually required in clinical practice. MRI may have a particular role in detecting complications of gout, such as tendon rupture or superimposed infection; bone marrow oedema is not usually a major feature of uncomplicated gout, but is strongly suggestive of concurrent bone infection in patients with gout.[26] Conventional CT allows excellent visualization of tophi and bone erosion.[27] A further development in CT imaging of gout is dual-energy CT (DECT)—a system with two X-ray tubes scanning at 80 kbp and 140 kbp, which allows for colour identification of urate and calcium. DECT has the potential to allow non-invasive diagnosis of gout, and also measurement of total body urate burden, through three-dimensional volume assessment of tophi (Figure 141.2).[28] DECT scanners are not yet in widespread use,
Fig. 141.2 Dual-energy CT scan of the foot affected by tophaceous gout, demonstrating collections of MSU crystals (shown in red)

and further information is required about the sensitivity and specificity of this method before it can be accepted as a tool for gout diagnosis.

Aetiopathogenesis

A number of key checkpoints exist for pathogenesis of gout (reviewed by Choi et al.[29]). The central biochemical feature of gout is hyperuricaemia. Urate is primarily derived from the catabolism of purines formed in the de-novo biosynthesis of nucleic acids and to a lesser extent from breakdown of dietary purines. Plasma urate is completely filtered at the glomerulus and almost totally reabsorbed by proximal tubule. Tubular secretion accounts for almost all urinary uric acid. Hyperuricaemia can be due to either an increase in endogenous biosynthesis of purines or reduction in renal excretion of uric acid or both.

Most dietary risk factors for gout are also associated with hyperuricaemia. Beer, red meat, and seafood have high purine content. Similarly, fructose increases urate production by increasing hepatic ATP degradation to AMP, a urate precursor, and high intake of fructose-sweetened beverages has been associated with hyperuricaemia.[30] Although genetic variants such as hypoxanthine-guanine phosphoribosyltransferase (HPRT) deficiency and PRPP synthetase (PRS) superactivity are been associated with urate overproduction and gout, these variants are rarely associated with gout in the general population.

Renal underexcretion of uric acid accounts for the majority of hyperuricaemia (90%). Renal underexcretion of uric acid may be present due to chronic kidney disease, diuretic use, and high circulating insulin concentrations.[31] Genetic variants in renal urate transporters also play an important role in development of hyperuricaemia and gout (Figure 141.3). Recent genome-wide association studies have identified that the majority of genes associated with hyperuricaemia are transporters implicated in renal transport of urate.[32] Variants in the *SLC2A9* gene contribute most to genetic risk for hyperuricaemia; in addition to its effects on renal uric acid transport, this transporter also transports glucose and fructose.[33] Variants in the *SLC2A9* gene have been associated with gout.[34,35] Other genes associated with both gout and hyperuricaemia in the general population are the renal transporters *ABCG2* and *NPT1*.[32,36]

MSU crystals form in vitro at physiological temperature and pH when urate concentrations rise above supersaturation concentrations of 0.41 mmol/litre (6.8 mg/dL).[37] The majority of individuals with serum urate concentrations above supersaturation concentrations do not develop gout.[38] Therefore, hyperuricaemia is necessary, but not sufficient, for development of gout. Other factors such as debris, proteins, local temperature, and pH within the joint may also influence whether crystal formation occurs.[37,39]

Histological examination of the synovium in acute gout shows lining-layer hyperplasia and intense infiltration of the membrane by neutrophils, monocyte-macrophages and lymphocytes.[40] Acute attacks of gout are often triggered by events such as joint trauma, dehydration, or sudden alterations in the serum urate concentration. These triggers may stimulate de-novo formation of MSU crystals or may promote release of crystals from preformed deposits within the joint.

A number of factors have been implicated in the initiation phase of the acute gout attack (reviewed by Dalbeth and Haskard[41]). These factors include signalling through the Toll-like receptors
Fig. 141.3 Renal transport of uric acid within the proximal tubular cell.

TLR-2 and TLR-4, activation of the complement cascade, and mast cell degranulation. Activation of the NALP3 inflammasome within monocytes/macrophages is central in the initiation of the acute gout attack.[42] NALP3 inflammasome activation leads to release of mature interleukin (IL)-1β. IL-1β leads to endothelial activation and release of IL-8 from non-haematopoietic cells. These events, in turn, lead to an amplification phase with recruitment of neutrophils, monocytes, and other inflammatory cells. Leucocyte recruitment is likely to be enhanced by the local generation of other chemotactic factors such as leukotriene B4, C5a, and S100A8/A9.[41]

Intense infiltration of neutrophils into both synovial membrane and fluid is the central feature of acute gout, and these cells provide the main cellular mechanism of inflammatory amplification in acute gout.[43] The consequences of neutrophil interaction with MSU crystals include the synthesis and release of a large variety of mediators that promote vasodilatation, erythema and pain associated with the acute gout attack. These include reactive oxygen species, nitric oxide, arachadonic acid metabolites, enzymes, IL-1, and chemokines including S100A8, S100A9, and IL-8. Infiltrating monocytes also amplify the inflammatory response in acute gout.[44] Following exposure to MSU crystals, monocytes also become activated, resulting in expression of a number of proinflammatory genes, including IL-1, tumour necrosis factor (TNFα), IL-6, IL-8 and cyclooxygenase-2.[41]

Even in the absence of treatment, the acute inflammatory response in gout is typically self-limiting over 7–10 days. Factors contributing to the resolution phase of the acute gout attack are less well defined, but putative mechanisms include release of anti-inflammatory cytokines such as transforming growth factor (TGF)-β and IL-10, expression of melanocortin receptors, induction of anti-inflammatory signalling pathways such as PPARγ, and alterations in macrophage differentiation.[41]

In some individuals, persistent hyperuricaemia leads to the formation of tophaceous deposits of MSU crystals, typically in subcutaneous and periarticular areas. The tophus represents a complex and organized chronic inflammatory tissue response to MSU crystals involving both innate and adaptive immune cells.[45] Tophi may invade bone, leading to bone erosion and joint damage. Erosive gout is characterized by disturbance of normal bone turnover. Disordered osteoclastogenesis has been implicated, with numerous osteoclast-like cells within the tophus surrounding MSU crystal deposits at the tophus–bone interface.[46] MSU crystals have profound inhibitory effects on primary osteoblast viability, function and differentiation, and there is a relative paucity of osteoblasts at the tophus–bone interface.[47] Production of matrix metalloproteases and other degradative enzymes in response to MSU crystals may also lead to cartilage and bone matrix damage in tophaceous gout.[48]

Management

Gout management is separated into three key therapeutic goals: treatment of acute gout flares, prophylaxis against acute gout flares (usually at the time of initiating ULT), and long-term preventive treatment of chronic gout with ULT (Table 141.3). The European League Against Rhematism (EULAR) and the British Society for Rheumatology (BSR) have published gout treatment guidelines in the last decade,[49,50] and American College of Rheumatology (ACR) gout treatment guidelines were released in 2012.[51,52]

Treatment of acute gout

The goal of treating acute gout is resolution of pain and inflammation in the affected joint. Treatment should be commenced as soon as possible after development of symptoms. Management of the acute gout flare includes rest, icing of the affected joint, and analgesia. A number of pharmacological agents are effective in the management of acute gout. NSAIDs are first-line treatment in patients without contraindications. These drugs are most effective when used in a fast-acting preparation and at full dose (e.g. naproxen 500 mg twice daily, indomethacin 50 mg three times daily). Following treatment with NSAIDs, more than 50% patients

Table 141.3 Summary of gout management

Therapeutic goal	Pharmacological treatment options	Adjunctive treatment
Treatment of acute gout	NSAIDs Colchicine Prednisone/prednisolone Intra-articular corticosteroids ACTH IL-1 inhibitors[a]	Rest Ice Analgesia
Prophylaxis against acute flares	NSAIDs Colchicine IL-1 inhibitors[a]	Gradual up-titration of urate-lowering therapy
Urate-lowering therapy	Xanthine oxidase inhibitors: allopurinol, febuxostat Uricosuric agents: probenecid, sulphinpyrazone, benzbromarone Recombinant uricase: pegloticase, rasuricase[a]	Vitamin C Losartan, fenofibrate, amlodipine, atorvastatin Dietary modification Weight loss

ACTH, adrenocorticotropic hormone; NSAIDs, non-steroidal anti-inflammatory drugs.

[a]In development/not currently approved for use in gout.

experience a major clinical response within 2 days, and 80% after 5 days.[53] Compared with non-selective NSAIDs, COX-2 inhibitors such as etoricoxib (120 mg daily) and lumiracoxib (400 mg daily) have similar efficacy in treating acute gout, although COX-2 inhibitors are generally better tolerated.[53,54]

Colchicine has been used for centuries for treatment of acute gout. A recent clinical trial of oral colchicine showed that a low dose of colchicine (1.8 mg total over 1 hour) was as effective as a high dose (4.8 mg total over 6 hours), with substantially less toxicity.[55] In this study, clinical response (≥50% pain reduction at 24 hours without rescue medication) was observed in 38% of patients in the low-dose colchicine group, 33% in the high-dose colchicine group, and 15% in the placebo group. This study has led to United States Food and Drug Authority (FDA) recommendations that colchicine dosing for acute gout should be 1.2 mg stat followed by 0.6 mg in 1 hour (total 1.8 mg in the first 24 hours). Concomitant use of P-gp and moderate-strong CYP3A4 inhibitors (such as ciclosporin, clarithromycin, ketoconazole, ritonavir, verapamil, diltiazem, erythromycin) may cause severe drug interactions due to accumulation of colchicine, and dose reduction is recommended when these drugs are coadministered to avoid colchicine toxicity.[56] The dose of colchicine should also be reduced in patients with renal or liver disease.

Intra-articular corticosteroid injection of the affected joint leads to rapid improvement in pain and inflammation, and avoids the systemic complications of orally administered therapies. Oral prednisolone is particularly useful for treatment of acute gout in patients with medical comorbidities and/or concomitant medication that preclude the use of NSAIDs and colchicine. Two randomized controlled trials (RCTs) have demonstrated that oral prednisolone (30 mg or 35 mg daily for five days) is as effective as full-dose NSAIDs for treatment of acute gout.[57,58] This treatment protocol is at least as safe as NSAID therapy in patients with acute gout, with one study reporting fewer adverse events in the prednisone-treated group.[58] Adrenocorticotropic hormone (ACTH) injection is also effective in treatment of acute gout; typical doses are 40 IU.[59] The beneficial action of ACTH may occur through adrenal corticosteroid release and also activation of the melanocortin type 3 receptor (MC3R).[60]

The identification of the central role of IL-1β in initiation and amplification of the acute inflammatory response in gout has raised the possibility of cytokine-targeted treatment of acute gout. In an RCT of acute gout, a single 150 mg subcutaneous dose of canakinumab, a fully human anti-IL-1β monoclonal antibody, led to greater reduction in pain than 40 mg intramuscular triamcinolone.[61] At present, these therapies are not approved for treatment of acute gout.

Gout prophylaxis

Gout prophylaxis refers to the use of anti-inflammatory agents to prevent flares in patients with intercurrent or chronic gout. Prophylaxis is particularly relevant when commencing ULT, as this period is frequently associated with increased number and severity of flares. In the absence of prophylaxis, up to three-quarters of patients will have an acute flare following initiation of ULT.[62] Patients with high urate burden are at greater risk of recurrent gout flares, and prophylaxis may be required for longer in patients with tophi. Gout flares can be prevented, in part, by gradual up-titration of ULT.

Low-dose colchicine (0.5–1.5 mg daily) is the most frequently used prophylactic treatment for gout. Several RCTs have reported benefit of colchicine in patients commencing ULT, at doses of 0.6 mg twice daily and 0.5 mg three times daily.[62,63] Both of these studies reported increased adverse events in the colchicine group, most frequently diarrhoea which may limit the use of this medication particularly in patients with renal impairment. When used for gout prophylaxis, colchicine dose should be reduced in patients taking P-gp and moderate-strong CYP3A4 inhibitors and in those with renal impairment.[56]

Oral NSAIDs are frequently used in clinical practice and clinical trials for gout prophylaxis.[64] The role of NSAIDs specifically for gout prophylaxis has not been extensively studied. Renal impairment and poorly controlled hypertension are frequently present in patients with gout, and for this reason regular NSAIDs may be contraindicated.[7]

IL-1β inhibitors may also play a role in gout prophylaxis. In a clinical trial of patients commencing allopurinol, canakinumab at a single dose of ≥50 mg was superior to daily colchicine 0.5 mg daily for prevention of gout flares at 16 weeks.[65] Similar findings were observed in the RCT of canakinumab for treatment of acute gout, where canakinumab-treated patients experienced fewer gout flares 8 weeks after injection.[61] At present, anti-IL-1 therapies are not approved for gout prophylaxis.

Urate-lowering therapy for chronic gout

Long-term ULT is recommended for all patients with recurrent gout flares (more than one flare per year), gouty tophi, chronic gouty arthropathy, and/or radiographic erosions. A serum urate concentration below 0.36 mmol/litre (6 mg/dL) is recommended by EULAR as a treatment target for patients with gout.[49] This is the concentration that corresponds to that required to ultimately achieve resolution of MSU crystals within the joint, suppression of acute gout attacks and resolution of gouty tophi.[66–68] Lower serum urate concentrations lead to more rapid dissolution of tophi, and an even lower target of less than 0.30 mmol/L has been recommended by the BSR.[50] ULT should be tailored to each individual, in order to achieve this target. A number of urate-lowering agents are available. These agents can be separated into three main groups; the xanthine oxidase inhibitors, uricosuric agents, and recombinant uricase. The sites of action of these agents are shown in Figure 141.4.

Adjunctive therapies that have a modest urate-lowering effect include dietary modification (e.g. avoidance of beer, sugar-sweetened beverages, and large purine loads; increase in consumption of low-fat dairy, and coffee), and weight loss. Vitamin C at 500 mg-1000 mg daily has a modest urate-lowering effect and may a useful adjunct for those wishing to take supplementary therapies.[69] However, most patients with gout are unable to reduce their serum urate to target (<0.36 mmol/L) with adjunctive treatment alone, and in this situation, specific ULT is indicated.

Xanthine oxidase inhibitors

Xanthine oxidase is a critical enzyme in the metabolism of purines to urate, which catalyses the conversion of hypoxanthine to xanthine and xanthine to urate (Figure 141.4). Two agents that inhibit this enzyme currently used as ULT for patients with gout are allopurinol and febuxostat.
Fig. 141.4 Summary of purine degradation and urate clearance, including sites of action of urate-lowering therapy.

Allopurinol

Allopurinol is first-line ULT. This drug inhibits xanthine oxidase, a critical enzyme in the metabolism of purines to urate, which catalyses the conversion of hypoxanthine to xanthine and xanthine to urate. Allopurinol is a structural analogue of hypoxanthine, and its active metabolite oxypurinol is a structural analogue of xanthine. Both allopurinol and oxypurinol inhibit xanthine oxidase, thereby reducing the production of urate. In comparison to allopurinol which has short half-life ($t_{1/2}$~1 hour), oxypurinol has a much longer half-life ($t_{1/2}$~23 hours). Oxypurinol is largely eliminated unchanged by the kidneys and thus its half-life is dependent on renal function. Allopurinol is effective in reducing serum urate, resorption of tophi, and reducing the number of gout flares. Allopurinol may also have a beneficial effect on renal function, CVD, hypertension and mortality.[70–73]

Although allopurinol is well tolerated in most patients, adverse events may occur. Approximately 2% of patients develop a mild rash. Allopurinol can be associated with a rare but potentially life-threatening allopurinol hypersensitivity syndrome (AHS) which is characterized by rash (e.g. toxic epidermal necrolysis, exfoliative dermatitis), eosinophilia, leucocytosis, fever, hepatitis, and progressive renal failure. The true incidence of AHS is unknown although it is estimated to be around 0.1%. Some cases of AHS occur as a result of T-cell-mediated immune reactions to oxypurinol. A number of studies have reported that renal impairment, diuretic use, and recent commencement of allopurinol therapy are risk factors for the development of severe AHS. *HLA B*5801* has been identified as an important risk factor for toxicity, particularly in Asian populations.[74] The mortality associated with AHS is as high as 27%. There is no cure for AHS and early recognition and drug withdrawal are important. Management consists of supportive care, and although corticosteroids and dialysis have been used, their role is controversial. Desensitization has been used successfully for patients with mild cutaneous hypersensitivity reactions, but is contraindicated for patients with life-threatening AHS.[75]

The role of allopurinol dosing in AHS was highlighted by Hande and colleagues who reported that most of the patients in their institution and literature review with AHS had pre-existing renal impairment and were treated with full doses of allopurinol (≥300 mg daily).[76] This observation, together with studies of oxypurinol clearance in patients with renal impairment, lead to the development of dosing guidelines, recommending that allopurinol doses should be adjusted according to creatinine clearance. These guidelines are of great practical relevance, as renal impairment is a frequent finding in patients with gout.[7] However, adherence to these dosing guidelines for long-term prescribing of allopurinol results in suboptimal control of hyperuricaemia in the majority of patients with gout.[77] A recent report has described the safety and efficacy of gradual dose escalation of allopurinol in patients established on renally-adjusted doses.[78] Using this strategy, 89% of patients achieved a target serum urate concentration <0.36 mmol/L in 12 months, without serious toxicity.

Gout is common in solid organ transplant recipients and azathioprine is a commonly used immunosuppressive agent in these patients. 6-Mercaptopurine, the active metabolite of azathioprine, is partly inactivated by xanthine oxidase and therefore allopurinol may increase serum concentrations of 6-mercaptopurine with resultant myelosuppression. It is recommended that the dose of azathioprine be reduced by 50–75% before commencing allopurinol and that the starting dose of allopurinol be lower than normal. However, despite dose adjustment bone marrow suppression with this combination may occur after months or even years of therapy.[79] Therefore, azathioprine and allopurinol must be coprescribed with great caution and with careful blood monitoring for the duration of combination therapy.

Febuxostat

Febuxostat is a recently developed xanthine oxidase inhibitor that was approved by the European Medicines Agency in 2008 (at doses up to 120 mg daily) and by the FDA in 2009 (at doses up to 80 mg daily) for management of hyperuricaemia in patients with gout. Febuxostat is a potent and specific non-purine inhibitor of xanthine oxidase. Febuxostat is metabolized by hepatic conjugation and oxidation, and has at least three pharmacologically active metabolites: 67M-1, 67M-2, and 67M-4.

RCTs have demonstrated that febuxostat has superior urate-lowering efficacy compared with fixed-dose allopurinol. For example, in a phase 3 randomized, double-blind, 52 week trial of patients with gout and no significant renal impairment (as defined by creatinine clearance <50 mL/min), serum urate less than 0.36 mmol/litre (6 mg/dL) at the last three monthly measurements was achieved in 21% of those on 300 mg allopurinol, 53% of those on 80 mg febuxostat, and 62% of those on 120 mg febuxostat.[80] Gout flares were more common in the 120 mg febuxostat group in the first 8 weeks of treatment. However, other adverse event and serious adverse event rates was similar in the three treatment groups. The most common treatment-related adverse events for all groups were liver function test abnormalities, diarrhoea, headache, and musculoskeletal signs and symptoms. Similarly, in another large phase 3 randomized, double-blind, 28 week trial comparing the safety and efficacy of febuxostat with allopurinol, serum urate less than 0.36 mmol/litre (6 mg/dL) at the final visit was achieved in 42% of those on allopurinol (300 mg or 200 mg/day, based on renal function), 45% of patients treated with febuxostat 40 mg, and 67% of those on 80 mg febuxostat.[81] In those patients with mild/moderate renal impairment, serum urate less than 6 mg/dL was achieved in 50% of patients treated with febuxostat 40 mg, 72% of

those on 80 mg febuxostat, and 42% of those on allopurinol. Rates of adverse events and serious adverse events did not differ across treatment groups. Long-term extension studies have shown that serum urate-lowering persists during treatment with febuxostat, with associated resolution of gout flares and tophi.[82]

In summary, febuxostat is an effective urate-lowering agent. A dose of 40 mg/day may be effective in achieving a target serum urate below 0.36 mmol/litre. However, a higher dose of 80 mg or 120 mg/day may be required to achieve this target. Febuxostat appears to be well tolerated and does not require dose adjustment in patients with mild–moderate renal or hepatic impairment. Liver function tests should be monitored while patients are taking febuxostat. Intensive prophylaxis against gout flares should be prescribed for up to 6 months when commencing febuxostat. To date, drug–drug interaction studies between febuxostat and azathioprine or 6-mercaptopurine have not been reported. This combination should be avoided because of the risk of significant toxicity.

Febuxostat should be considered for those patients with gout who have failed to achieve a target serum urate below0.36 mmol/litre on an adequate dose of allopurinol. Febuxostat may be particularly useful in the context of renal impairment, where allopurinol dosing is most complicated and carries the greatest risk of toxicity. However, clinical experience of febuxostat in patients with severe renal impairment, severe liver disease, and transplantation is very limited, and the safety of febuxostat in these situations is unknown. Similarly, the use of this drug in the paediatric context is not well recognized. While febuxostat has been shown to be more effective than fixed-dose allopurinol for reduction of serum urate, it is not yet known whether this drug is superior to allopurinol when a treat-to-target serum urate approach is employed with allopurinol. Although this agent has been recommended in the United Kingdom for patients who are intolerant to allopurinol or have contraindications to it,[83] the experience of this agent in patients with previous severe allopurinol reactions is limited; in a case series of 13 such patients treated with febuxostat, one patient developed a hypersensitivity-type cutaneous vasculitis early in febuxostat treatment.[84] Thus, use of febuxostat in such patients requires caution, careful dose escalation, and close monitoring.

Uricosuric drugs

Uricosuric drugs increase uric acid excretion through interactions with various urate transporters (Figure 141.3). Due to the higher uric acid concentrations in the renal tract, these drugs have the potential to promote urate stone formation, and should be avoided in patients with nephrolithiasis. Liberal fluid intake is recommended for patients taking uricosuric agents, and urine alkalinization should also be considered when commencing these agents, using sodium bicarbonate (3–7.5 g daily) or potassium citrate (7.5 g daily).

Probenecid has been used for more than 60 years as a uricosuric agent. This agent promotes urate excretion through interactions with various renal tubular urate transporters including URAT1, NPT4, the organic anion transporters OAT1, OAT2, and OAT4, and multidrug resistance protein MRP4 (Figure 141.3). In patients without severe chronic renal impairment (defined as CrCl <30 mL/min) who have not achieved normouricaemia (defined as serum urate ≤0.30 mmol/litre) with fixed-dose allopurinol, target serum urate below 0.36 mmol/litre was achieved in 68% patients treated with probenecid.[85] In additional to use

as monotherapy, probenecid in combination with allopurinol leads to excellent serum urate lowering with up to 95% patients achieving serum urate concentrations of less than 0.30 mmol/litre.[86] Probenecid is typically commenced at 250 mg twice daily, increasing to 1 g twice daily depending on serum urate concentrations and tolerance. Patients with chronic kidney disease may have less response to probenecid, particularly those with CrCl <30 mL/min. Probenecid is generally well tolerated, but may cause gastrointestinal intolerance in up to 23% of patients.[85] Headache, hypersensitivity reactions, nephrotic syndrome, hepatitis, and anaemia are rare complications.

Sulphinpyrazone has similar urate-lowering efficacy to probenecid, and is also most effective in patients with normal renal function. This agent promotes uric acid excretion through interactions with renal tubular urate transporters such as OAT4 and MRP4. Typical starting doses are 100–200 mg daily, increasing up to 600 mg daily in divided doses as needed to achieve serum urate target. Sulphinpyrazone is contraindicated in patients with active peptic ulcer disease, severe renal disease, and severe liver disease. Sulphinpyrazone may potentiate the action of sulphonylureas, insulin, salicylates, and anticoagulants. Gastrointestinal intolerance is the most common adverse event, but other serious side effects are skin rash and blood dyscrasia such as anaemia, agranulocytosis, and thrmobocytopenia. Monitoring of the full blood count is essential throughout treatment.

Benzbromarone is a potent uricosuric agent with documented efficacy in patients with gout. It interacts with a number of renal urate transporters including SLC2A9 and URAT1. Benzbromarone is particularly beneficial for patients with renal impairment who are intolerant to allopurinol or have an insufficient response to recommended doses of allopurinol. RCTs have demonstrated that benzbromarone has superior efficacy over standard doses of allopurinol and is also more effective than probenecid in patients who have failed allopurinol treatment (due to inadequate serum urate lowering or intolerance). For example, in patients who had not achieved normouricaemia (defined as serum urate ≤0.30 mmol/litre) with fixed-dose allopurinol, target serum urate below 0.36 mmol/litre was achieved in 92% patients treated with benzbromarone.[85] Typical starting dose is 50 mg daily, increasing to 100 mg daily. Occasionally 200 mg daily is required to achieve normouricaemia. Benzbromarone was widely used in Europe until 2003 when it was withdrawn after reports of fulminant hepatitis leading to death in two patients. It appears that hepatotoxicity is extremely rare and was not reported in the clinical trials of benzbromarone. The EULAR gout treatment guidelines have endorsed the use of benzbromarone as an alternative to allopurinol, particularly in patients with renal impairment.[49] Close monitoring of liver function tests is required in patients receiving this drug.

Case history 1

A 78 year old woman presents with extensive gouty tophi affecting the hands and feet. These tophi are discharging and cause difficulty with gripping, toileting, and putting on shoes. She has treated heart failure and hypertension. Her medications include furosemide 80 mg twice daily. She is intolerant to allopurinol which caused blistering skin rash, eosinophilia, and raised creatinine. Examination shows extensive tophi but no synovitis.

Serum urate is 0.68 mmol/litre, creatinine 119 μmol/litre, and creatinine clearance 37 mL/min. Radiographs show gouty erosions. Swab of a discharging tophus confirms MSU crystals. What are the treatment options?

Comments: This patient has chronic tophaceous gout, likely due to chronic kidney disease and diuretic use. She has major musculoskeletal disability and radiographic damage due to her gout. Management is further complicated by intolerance to allopurinol. Serum urate lowering below 0.36 mmol/litre (and ideally lower) is required to achieve dissolution of MSU crystals and regression of tophi. Depending on drug availability, benzbromarone or cautious use of febuxostat would be appropriate first-line therapies. Probenecid could be trialled but may not be effective because of the degree of her chronic kidney disease. Allopurinol desensitization is contraindicated because of the severity of her allopurinol drug reaction.

Recombinant uricase

Uricase (urate oxidase) converts urate to 5-hydroxy isourate and H_2O_2, with subsequent formation of allantoin. Allantoin is soluble and is readily eliminated by the kidney. Unlike most other mammals, humans lack a functional uricase gene; the absence of uricase is a major contributor to elevated serum urate concentrations in humans compared with other species. Administration of recombinant uricase leads to profound reductions in serum urate concentrations, often to undetectable levels. Rasburicase, an agent used in the oncology setting for management of tumour lysis syndrome, has been described as a potent urate-lowering agent in patients with severe refractory gout.[87] Use of rasburicase for long-term management of gout is limited by the relatively short half-life, high cost, and risk of hypersensitivity reactions with repeated infusions.

Pegloticase is a recombinant mammalian uricase modified by polyethylene glycol which was approved in the United States in 2010 for treatment of chronic gout that is refractory to conventional therapy. In two phase 3 clinical trials, intravenous administration of 8 mg pegloticase every 2 or 4 weeks lead to higher numbers of patients achieving target plasma urate concentrations below 0.36 mmol/litre after 3 and 6 months of treatment; overall, this target was achieved in 42% of the fortnightly pegloticase group, 35% of the monthly pegloticase group, and 0% of the placebo group.[88] After 6 months of treatment, patients treated with pegloticase on a fortnightly basis had greater regression of tophi, fewer gout flares, fewer tender joints, less disability, improved physical function, and less pain compared with the placebo-treated group. Overall adverse event rates were similar between the pegloticase and placebo groups, but more serious adverse events were observed in the pegloticase groups, primarily due to greater frequency of infusion reactions in pegloticase-treated patients. Infusion reactions occur in up to one-quarter of patients treated with pegloticase, and may present as chest discomfort, chest pain, dyspnoea, erythema, flushing, rash, and urticaria. To reduce the risk of infusion reactions, premedication with antihistamines and corticosteroids is recommended, and patients should be closely monitored for infusion reactions during and after drug administration. Importantly, loss of urate-lowering efficacy precedes development of infusion reactions in most patients with infusion reactions, and should be viewed as an important warning sign of potential drug reaction. In those patients with loss of urate-lowering efficacy on two consecutive treatments, pegloticase should be discontinued. The recommended dose of pegloticase is 8 mg administered as an intravenous infusion over at least 2 hours, every 2 weeks.

Management of comorbid conditions
