John Isaacs

Ulf Müller-Ladner

OXFORD

UNIVERSITY PRESS

Preface

The science of rheumatology has progressed enormously since the third edition of the *Oxford Textbook of Rheumatology* was published in 2004. There have been major developments in all the major sub-specialities of rheumatology and rheumatologists are enjoying the fruits of the biotechnology revolution, with a cornucopia of biological agents in routine clinical practice or in development.

In keeping with a new editorial team the content of the book has been thoroughly revised, while retaining the broad structure of the previous editions which were a distinctive feature of the book. The number of chapters has increased from 126 to 173, reflecting the increasing breadth of knowledge. New chapters have been written reflecting the changing face of rheumatology. We have expanded the imaging section to include separate chapters on each of the main modalities, and chapters on therapeutics cover the new biologic agents including areas that we foresee becoming mainstream during the life of the book.

Textbooks of this size are often viewed in the modern electronic age of rapid revision as being ossified and out of date before publication. We, however, believe, as do our publishers Oxford University Press, that textbooks still have a valuable place. Much of the corpus of knowledge contained within textbooks changes quite slowly; principles and practice of examination, clinical features of disease and assessment. Chapters on pathogenesis and treatment become outdated more quickly and we are planning a regular cycle of updates. In addition to completely revising text, we have introduced colour throughout the book.

Electronic books have become widespread since the last edition and in addition to a print edition we are producing an online version, which is not merely the print version reproduced but has enhanced functionality with direct links to references, video images, and links between relevant sections. The ability to use video enables use of multislice MR and CT to be available and real time ultrasound.

We owe a huge debt to the editors of the previous editions—David Isenberg, Peter Maddison, Patricia Woo, David Glass, and Ferdinand Breedveld—who assembled and produced three splendid editions. They felt that the time had come, nearly a decade after the writing of the third edition, that a fresh editorial team was needed.

CHAPTER 1

The child patient

Lori B. Tucker

Introduction

Musculoskeletal complaints in children are very common, and most are generally inconsequential and self-resolving. However, it is important to differentiate children with minor problems from those who have developed a more serious musculoskeletal problem possibly associated with long-term illness. This is frequently challenging to the clinician, as the differential diagnosis of conditions associated with musculoskeletal complaints is broad and children present special circumstances to consider. The spectrum of childhood rheumatic diseases is shown in Table 1.1. A full discussion of childhood rheumatic diseases is beyond the scope of this chapter; summaries of many of the important diseases are provided in later chapters or other sources.[1]

Table 1.1 The spectrum of childhood rheumatic disease

JIA	
SLE	SLE
	Neonatal LE
Juvenile dermatomyositis	
Scleroderma	Limited or localized: morphea, linear, generalized cutaneous
	Systemic sclerosis
Vasculitides	Kawasaki disease
	Henoch–Schonlein purpura
	Granulomatous polyangiitis
	Takayasu's arteritis
	Polyarteritis nodosa
Granulomatous disease	Sarcoidosis
Acute rheumatic fever	
Autoinflammatory diseases	Periodic fever syndromes
	CRMO

CRMO, chronic recurrent multifocal osteomyelitis; JIA, juvenile idiopathic arthritis; LE, lupus erythematosus; SLE, systemic lupus erythematosus.

Classifications of rheumatic disease in children

The classification of arthritis and other rheumatic diseases in children has posed significant challenges, and until recently, the use of different classification systems for the most common rheumatic condition, arthritis, resulted in inability to compare research around the world.

Classification of childhood arthritis

The classification of childhood arthritis has evolved over the past 10 years since the publication of the International League of Associations for Rheumatology (ILAR) criteria for juvenile idiopathic arthritis (JIA) in 2002.[2] These criteria were developed by an international committee of paediatric rheumatologists, using expert opinion, as well as a consensus process and evidence-based modifications. Before these criteria were developed, children were diagnosed using either the American College of Rheumatology (ACR) criteria for juvenile rheumatoid arthritis[3] or the European League Against Rheumatism (EULAR) criteria for juvenile chronic arthritis;[4] the use of these differing criteria sets led to difficulty in comparing patient cohorts across different countries and publications (Table 1.2).

Table 1.2 Comparison of criteria for chronic arthritis in childhood[2–4]

ILAR criteria (JIA)	ACR criteria (JRA)	EULAR criteria (JCA)

Oligoarthritis
  Persistent
  Extended
	Pauciarticular	Pauciarticular

Polyarthritis RF–	Polyarticular	Polyarticular RF–
Polyarthritis RF+		Polyarticular RF+
Systemic arthritis	Systemic	Systemic
Psoriatic arthritis		Psoriatic
Enthesitis-related arthritis		Ankylosing spondylitis
Undefined arthritis		

JCA, juvenile chronic arthritis; JIA, juvenile idiopathic arthritis; JRA, juvenile rheumatoid arthritis; RF, rheumatoid factor.

There is now more widespread adaptation of the ILAR criteria for childhood arthritis worldwide. The overall term juvenile idiopathic arthritis (JIA) is defined as definite arthritis occurring before the 16th birthday, persisting for at least 6 weeks and of unknown cause. There are seven categories of JIA defined by the ILAR criteria (Table 1.3). Of importance, the ILAR criteria include a category of enthesitis-related arthritis (ERA) which encompasses children

Table 1.3 ILAR criteria for the classification of juvenile idiopathic arthritis[2]

Category	Definition	Exclusions
Oligoarthritis	Arthritis in less than 5 joints during the first 6 months of disease Persistent: never more than 4 joints Extended: more than 4 joints after the first 6 months of disease	1, 2, 3, 4, 5
Polyarthritis RF+	Arthritis in 5 or more joints during the first 6 months of disease, with positive RF test (X2)	1, 2, 3, 5
Polyarthritis RF−	Arthritis in 5 or more joints during the first 6 months of disease, with negative RF test	1, 2, 3, 4, 5
Systemic arthritis	Arthritis with fever of >2 weeks' duration, documented to be quotidian for at least 3 days, and accompanied by one or more of: (a) evanescent, non-fixed rash (b) hepatomegaly or splenomegaly (c) serositis (d) generalized lymphadenopathy	1, 2, 3, 4
Psoriatic arthritis	Arthritis and psoriasis, *or* Arthritis with one or more of: (a) dactylitis (b) nail pitting or onycholysis (c) psoriasis in a first degree relative	2, 3, 4, 5
ERA	Arthritis and enthesitis, *or* Arthritis or enthesitis with one or more of: (a) sacroiliac joint tenderness and/or inflammatory lumbosacral spinal pain (b) HLA B27 positivity (c) acute symptomatic uveitis (d) first-degree relative with HLA B27 associated disease (e) onset of arthritis in a boy over the age of 8 years	1, 4, 5
Undefined arthritis	A child with arthritis who meets criteria for more than one category or for no category	

ERA, enthesitis-related arthritis; RF, rheumatoid factor. Exclusions:
1. Psoriasis in the patient or first-degree relative.
2. Arthritis in an HLA B27 positive male with onset after 8 years of age.
3. Anklyosing spondylitis, enthesitis-related arthritis, sacroiliitis with inflammatory bowel disease, Reiter's syndrome, or acute anterior uveitis in a first-degree relative.
4. Presence of IgM RF on at least two occasions more than 3 months apart.
5. The presence of systemic JIA.

previously described as having spondyloarthropathy, seronegative enthesitis and arthropathy, and juvenile ankylosing spondylitis. There has been controversy regarding the use of a family history of psoriasis as an exclusion criteria for some subtypes, and some difficulties of classification in the subtypes of psoriatic, ERA, and unclassified JIA.[4]

Classifications of other childhood rheumatic conditions

The only diagnostic criteria which have been developed specifically for classification or diagnosis of childhood rheumatic diseases are those for acute rheumatic fever[5] and for Kawasaki disease.[6] Both of these criteria sets have reasonably high sensitivity but lower specificity. Specifically, strict application of the Kawasaki disease criteria will exclude children who have what is described as 'atypical Kawasaki disease'. These children do not fulfil the published criteria, but are at high risk for development of coronary artery aneurysms and poor outcome.

Criteria for the diagnosis of most other chronic rheumatic diseases of childhood have generally been adopted in whole or part from classification criteria for adults. For example, the classification criteria for systemic lupus erythematosus (SLE)[7,8] and dermatomyositis[9] are used in general practice for the diagnosis of these conditions in children. However, recent work has been done to examine the validity of classification criteria for systemic vasculitides such as Henoch–Schonlein purpura, polyarteritis nodosa, Takayasu arteritis, and granulomatous polyangiitis (formerly known as Wegener's granulomatosis[10]) for children. In 1990, consensus criteria definitions were proposed by a group of expert rheumatologists from the ACR for these vasculitis conditions.[11,12] In 2008, an international paediatric rheumatology consensus conference was convened to validate and finalize paediatric vasculitis diagnostic criteria; using standard consensus formation methodology and patient case data, finalized classification criteria were published which demonstrated high sensitivity and specificity in these exercises.[11,13]

Epidemiology of childhood rheumatic diseases

It is a common misconception that rheumatic diseases are rare in childhood. In fact, chronic arthritis is one of the most common chronic conditions of childhood associated with disability. In addition, a significant percentage of patients with autoimmune diseases such as SLE have developed the onset of disease in childhood. Some rheumatic diseases such as dermatomyositis and localized scleroderma are more frequent in children and adolescents than in adults. Some diseases such as oligoarticular JIA with uveitis, systemic JIA, acute rheumatic fever, Henoch–Schonlein purpura, and Kawasaki disease occur almost exclusively in childhood. Conversely, there are a number of rheumatic diseases that rarely occur in childhood, including gout, calcium pyrophosphate deposition disease, polymyalgia rheumatica, and primary osteoarthritis.

Accurate data demonstrating the incidence and prevalence of childhood arthritis is surprisingly sparse. Much of the data available has come from paediatric rheumatology-based clinic populations or registries, which may result in under-reporting of the true frequency of disease. The most current information

suggests that the prevalence of JIA is between 10 and 400 per 100 000 children, depending on geographic location and case definitions.[14] Of interest, a population-based study by Manners and Diepeveen[15] suggests that the prevalence of chronic arthritis in 12-year-old Australian children was actually much higher than expected (400/100 000). Reported incidence of JIA ranges from 1 to 2 per 100 000 children, with most reports coming from clinic-based studies in Europe or North America.[16] A surveillance-based study from Canada done in 2007–2009 found a calculated incidence rate of 4.3 per 100 000 children;[17,18] however this is likely to be an underestimate as cases were reported by paediatricians only.

Accurate frequencies of the other childhood rheumatic diseases, such as SLE, dermatomyositis, scleroderma, and vasculitis, are even more difficult to find. Population-based studies using administrative data have not been done in these populations.

Age and sex distributions of the rheumatic disorders of childhood differ by disease. For example, SLE is more common in girls than in boys, and far more frequent in children over age 10 years. Oligoarticular JIA is more common in girls younger than age 6 years, and ERA more common in boys over age 6 years. However, these 'rules' are not hard and fast, and clinicians need to be aware that rheumatic disease can present in children as young as 1 year of age.

Ethnic variation occurs in some childhood rheumatic diseases. JIA is found around the world, but the distribution of disease subtypes has been reported to differ in different countries. For example, JIA subtype distribution in India is quite different from that in North America.[19,20]

Interaction of growth and development with childhood rheumatic disease

Physical growth

One of the major differences between childhood-onset and adult-onset rheumatic disease is the potential effect of having a chronic inflammatory disease on the normal growth of the affected child. The presence of active inflammation can stunt the linear growth of an affected child. Additionally, treatments used for chronic inflammatory diseases, most notably corticosteroids, have profound negative effects on growth. Careful documentation of the height and weight of a child with rheumatic disease should be made at each medical encounter, and compared to growth curves for healthy children of the same sex and age. It is important to consider the child's genetic background and parental heights in assessing growth rates for an individual child. Serial measurements ensure that growth velocity over time is normal. Growth rates may increase to allow catch-up growth once disease is controlled; for example, a child with poorly controlled JIA may have a growth spurt once disease is controlled using methotrexate. However, some children will have permanent growth stunting from the combination of severe active disease and the requirement for high doses of corticosteroids.

Motor development

Young children who develop a rheumatic disease may have delayed motor development due to their disease. For example, a very young child who develops JIA may not learn to walk or jump at the appropriate times due to pain and inability to move joints normally. Recognition of the range of normal development in young children is essential for interpretation of findings on the physical examination and functional assessment. There is considerable variation in the age at which individual developmental milestones are achieved. The dates in Table 1.4 should be used as a guideline only.

Delay in achieving motor milestones may occur in a child with any chronic disease, but this may be more evident in the child with a disease affecting the musculoskeletal system, the function of which is the basis for the estimation of developmental stages. Although there may be a delay in the chronically ill child, milestones are eventually achieved over time.

Psychosocial development

Chronic illness can have a major impact on the quality of life of the family, as well as the child, throughout their development. A significant number of children with JIA have disability that interferes with full functioning at some times during childhood and adolescence, and children with serious systemic rheumatic conditions such as systemic lupus, vasculitis, or dermatomyositis may have major interference with regular functioning. For children with rheumatic disease, care needs to be family focused, and is best delivered by a multidisciplinary paediatric rheumatology team which often includes social workers and psychologists.

Educational considerations

The school is one of the child's most important environments, and participation in the school environment is a strong influence on healthy development. Attention to school performance, both academic and social, is critical to promoting healthy development. Children with rheumatic disease should be expected to participate fully in school, with modifications if necessary to account for their physical considerations, physician visits, or treatments. An assessment of school attendance, participation, limits and concerns should be a part of every follow-up visit. Direct contact between the medical team and the child's teachers or counsellors is often beneficial in educating school personnel about the child's condition and designing modifications that are appropriate. For example, the use of a laptop computer for taking notes and tests may

Table 1.4 Normal developmental gross motor milestones in children

Age (months)	Milestones achieved by this age
7	Independent sitting
10	Crawling
12	Cruising, walking with one hand held
15	Walking alone, crawling up stairs
18	Running stiffly
24	Running well; walking up and down stairs one step at a time
30	Jumping
36	Walking up stairs alternating feet, rides tricycle
48	Hopping on one foot
60	Standing on one foot; skipping

be important for the child with arthritis involving the hands and wrists. Children with rheumatic disease should be encouraged to participate in physical activity at school, such as physical education, playtime, or sports teams; routine proscription from activity is not helpful for treatment and leads to social isolation and generalized poor conditioning.

As children move into adolescence, the developmental trajectory begins to include issues relating to self-esteem, sexuality, peer relationships, educational and vocational goals, and independence. Having a chronic rheumatic illness offers unique challenges to the adolescent and their parents, and the support and guidance of a knowledgeable subspecialty team is very important through this time. The timing of transition from the paediatric to the adult healthcare setting varies with the patient, family, physician, and healthcare setting. In general, adolescents will be cared for by the paediatric rheumatology team until the time of completion of secondary education, and entering the workforce or post-secondary education. In some settings, transition clinics have been developed to care for youth with rheumatic disease. The goals of these transition programs are to promote youth independence in health care, educate youth about their disease and needs, and prepare them to move to the adult healthcare setting.[21,22]

Sexual maturation

Chronic inflammatory disease can result in a delay in sexual maturation. Complete genital maturity (Tanner 5) may occur before the age of 13 years, but may not occur until age of 18 years.[23] Menarche occurs at an average of 12–13 years in North America and Europe. The onset of menstruation may be delayed in girls with active inflammatory disease; also, menses may become irregular or cease in a girl who has previously had a regular menstrual pattern.

A delay in sexual maturation may be a source of anxiety for adolescents, and often these patients may not be comfortable raising issues of concern regarding sexuality with the medical team, especially in the presence of their parents. It is useful to have some part of the medical visit with the adolescent alone, and the physician or nurse should directly address issues of sexual maturity and functioning at that time, while reassuring the adolescent of the confidentiality of the conversation. Care should be taken to be certain that the adolescent understands the critical aspects of conversations around medications and teratogenicity or impact on fertility. For example, the comment 'You can't get pregnant while taking cyclophosphamide' may be interpreted to mean that the adolescent does not need to use birth control, rather than being extremely careful to avoid pregnancy.

Assessment

History and physical examination

The history and physical examination provide most of the diagnostic information in children with rheumatic diseases; laboratory tests provide little help. The history should be obtained from the child's usual caregiver if possible (parent or other adult), and the child. Even a young child may be able to provide important information relating to the history of their symptoms or the degree of functional difficulty experienced.

Rheumatic diseases are systemic disorders, and therefore a complete physical examination should be performed in every case, during which the child's comfort, modesty, and dignity must be respected. Children should be offered appropriate-size gowns or shorts, and should be given a private space for changing clothes. The approach to the physical examination of the child requires expertise in understanding how to approach children of different ages. Frequently, providing an explanation to the child of what will occur during the examination is helpful, and reassurance that the examination will not continue if it causes pain. In most cases, examination of painful areas should be left to the last. For small children, the examination may begin by observing the child at play or moving around the room. An apprehensive young child may need to have the physical examination performed while sitting on a parent's lap. In most cases, the skilled examiner will be able to perform a complete examination of even the youngest child.

Age-related normal variations in physical examination must be taken into account:

◆ *Position and range of motion:* In full-term newborns, the elbows, knees, and hips do not fully extend. In the young child, or even the adolescent, hyperextension at the knees and elbows is often greater than in years of age. Asymmetry of range at any age should be considered abnormal. Many children have flat feet resulting from the distribution of fat and limited muscle development until the age of 5 or 6 years. In the absence of symptoms, no investigation or treatment is required.

◆ *Muscle strength:* Evaluation of muscle strength in the young child may be difficult due to difficulty in the child's ability to cooperate in the examination of individual muscle groups. A well trained paediatric physiotherapist is often best able to completely assess a child's muscle strength reliably.

◆ *Ambulation:* In order to be able to assess gait in children, it is critical to know the normal developmental trajectory of ambulation (see Table 1.4). Children who develop arthritis during the time they are learning to walk frequently present with a delay in achieving ambulation, regression in motor milestones, or an abnormal ambulation pattern. Specific physiotherapy may be required to correct poor ambulation habits which persist even after active joint disease is well-controlled. A limp (asymmetry of gait) may result from structural asymmetry, pain, muscle weakness, or arthritis. Although it is helpful to differentiate between a painful and a non-painful limp, it is important to note that some children with active arthritis in the lower extremity may not have pain. Some common causes of limp, by age of the child, are listed in Table 1.5.

Diagnosis of childhood rheumatic diseases

The child with musculoskeletal pain

Many children with rheumatic disease will present to the physician with pain; however, it is important to note that not all children with musculoskeletal pain will have a rheumatic disease, and in fact, some children with arthritis and other rheumatic conditions do not have pain. Therefore, the important job of a physician evaluating a child complaining of musculoskeletal pain is to consider the broad differential diagnosis, and use clinical clues and physical examination to come to the appropriate diagnosis.

Localization of pain to the bone, joint, or soft tissues may help in guiding appropriate investigations, particularly in the context of length of time pain has been present, severity of pain, or history of trauma. Very severe pain in the context of an ill child with fever, or

Table 1.5 Common or significant causes of limping according to age[24]

Toddler/preschool
Infection (septic arthritis, osteomyelitis—hip, spine)
Mechanical (trauma and non-accidental injury)
Congenital/developmental problems (e.g. hip dysplasia, talipes)
Neurological disease (e.g. cerebral palsy, hereditary syndromes)
JIA
Malignant disease (e.g. leukaemia, neuroblastoma)
5–10 years
Mechanical (trauma, overuse injuries, sport injuries)
Transient synovitis 'irritable hip'
Legg–Perthes disease
JIA
Tarsal coalition
Complex regional pain syndromes
Malignant disease
10–17 years
Mechanical (trauma, overuse injuries, sport injuries)
Slipped capital femoral epiphysis
JIA
Idiopathic pain syndromes
Osteochonditis dissecans
Tarsal coalition
Complex regional pain syndromes
Malignant disease (leukaemia, lymphoma, primary bone tumour)

JIA, juvenile idiopathic arthritis.

Table 1.6 Pain in children and adolescents

Scheurmann's disease
Diffuse pain syndrome
Pain in the sacroiliac joints
Septic sacroiliitis
Spondyloarthropathy (arthritis)
Pain in the pelvis
Osteomyelitis
Chronic recurrent multifocal osteomyelitis
Tumour (usually osteogenic sarcoma or Ewing's sarcoma)

Table 1.7 Red flags for evaluation of back pain in children and adolescents

Systemic features: fever, night sweat, weight loss
Night pain
Neurologic symptoms or signs
Gait change
Change in bowel or bladder habits
Focal lower extremity muscle weakness
Painful scoliosis

the child who does not allow movement of a joint or limb, should be investigated for fracture, bone or joint infection, or malignancy. Joint pain in a single or multiple joints, more prominent in the mornings, with gradual difficulty in movement, may be more suggestive of arthritis. Pain after sports activities or exacerbated by sport activities may be mechanical or orthopaedic in nature.

Pain in young children may be particularly challenging to assess. Parents may note a child change how they use a limb, and only when an area is stressed or examined carefully will the child complain. Some young children may refuse to use an arm or leg, or regress in motor milestones as a manifestation of musculoskeletal pain. For example, a child who has been walking but stops walking, limps, or holds the foot in an abnormal position may have arthritis or other problems. Young children often localize pain poorly, and the physician must carefully identify the area of discomfort by palpation and observation of the child's behaviour. The child may withdraw the limb or become anxious when the affected area is examined. Some young children are able to use a pain scale utilizing faces to score their pain.

Pain and dysfunction may be a sign of a chronic idiopathic pain syndrome, not a rare condition in adolescents. These adolescents present with either a very localized area of pain and inability to use a limb or a diffuse pain in many areas of the body associated with disability and fatigue. In patients with localized pain syndrome, an arthritis cannot be demonstrated, and often a bone scan may show decreased blood flow to the area; this condition is similar to reflex sympathetic dystrophy and should be treated aggressively with physiotherapy. Young people with diffuse pain syndrome may have soft tissue tender points similar to those seen in patients with fibromyalgia, as well as fatigue and inability to participate in normal activities. These patients may be challenging to treat, as they require a multidisciplinary team including physiotherapy, occupational therapy, and psychology for treatment.

The child with back pain

Back pain is an uncommon complaint in childhood, particularly in young children, as compared with adults. Persistent complaint of back pain should always be thoroughly investigated, as the underlying cause could be serious and require prompt treatment. When evaluating a child with back pain, one should consider that back pain can be referred from other areas; for example, from the back to the thigh, from the sacroiliac joint to the buttock. Important causes of back pain in children and adolescents are shown in Table 1.6. Red flags which should prompt clinician concern for serious disease are shown in Table 1.7.

The child with monoarticular arthritis

The differential diagnosis of monoarticular arthritis in the child or adolescent is broad. Children with a new presentation of monoarticular arthritis should be evaluated promptly, because potentially serious causes may not present in the 'typical' manner seen in adults. Some of the more common causes of monoarticular arthritis in children are shown in Table 1.8.

The child or adolescent who presents with isolated hip pain often presents a diagnostic challenge from several aspects. First, it is critical to examine all the joints and axial skeleton carefully, with a view to differentiating the hip pain from the possibility of referred pain from other areas. Hip pain as the sole presenting feature of JIA is relatively rare, and therefore the clinician should consider the possible causes of hip pain as listed in Table 1.9.

Chronic asymmetric joint inflammation in the developing child can result in localized growth disturbances. In general, the bones adjacent to an inflamed joint grow more rapidly, and in consequence, the affected digit or limb is longer. If this occurs in a single knee, a measurable inequality of the legs can result. Monitoring for localized growth disturbances is an important part of the assessment

Table 1.8 Monoarticular arthritis in children and adolescents

Acute monoarthritis	Chronic monoarthritis

Infection
    Septic arthritis
    Osteomyelitis
	Infection
	    Osteomyelitis
	    Chronic septic arthritis (i.e. TB)

Trauma: minor, ligament injury, Fracture	JIA
Malignancy	Inflammatory bowel disease Orthopaedic: osteochondritis dissecans, loose body Synovial chondromatosis Pigmented villonodular synovitis Osteoid osteoma

JIA, juvenile idiopathic arthritis; TB, tuberculosis.

Table 1.9 Causes of persistent hip pain in children and adolescents

Condition	Age range/considerations
Congenital hip dysplasia	Usually found in infancy but can be missed
Transient synovitis	3–10 years
Legg–Perthes disease	5–10 years; boys>girls
Slipped capital femoral epiphysis	10–15 years; boys>girls
Idiopathic chondrolysis of the hip	10–16 years; girls>boys
Acute chondrolysis of the hip	10–16 years
JIA—ERA	Any age, usually >8 years
Reactive arthritis	Any age
Osteonecrosis	Any age

ERA, enthesitis-related arthritis; JIA, juvenile idiopathic arthritis.

of a child with arthritis, and may indicate need for more aggressive treatment.

The child with muscle weakness

Muscle weakness is common in children with inflammatory musculoskeletal conditions. Some children with JIA may present with apparent muscle weakness as their main symptom, and only a complete physical examination will demonstrate the findings of arthritis. In addition, a number of rheumatic conditions present in childhood or adolescence with weakness; these include juvenile dermatomyositis, mixed connective tissue disease, and SLE.

The evaluation of the child with muscle weakness may be challenging, particularly when the child is young. It may be difficult to do standard manual muscle testing in a young child, because of the child's short attention span or difficulty following instructions. Careful observation of the child at play, the manner in which they get up from sitting or lying or walk in the examination room or hallway, or their ability to stand on tiptoes and heels, or squat, may provide the best information about the child's level of weakness. For example, the child with weakness of trunk and neck muscles, as seen in dermatomyositis, may have to roll over on their side or abdomen to sit from a supine position. The child with weakness of the hip girdle may be unwilling to squat or stand from a squat without showing Gower's sign. Observation of the gait for a wide-based or Trendelenburg sign may suggest weakness of the hip girdle muscles. Assessment of muscle strength should also include a detailed neurological examination. Asymmetric weakness is not likely to result from an inflammatory myositis such as dermatomyositis, or from a primary myopathy. With patience and experience, the physician or physiotherapist can demonstrate muscle weakness by formal testing in the child over 3–4 years of age. The application of a standardized valid muscle scoring scale, the Childhood Myositis Assessment Scale, is helpful in determining the functional level of weakness, and to follow changes over time.

Dermatomyositis is suggested by the presence of symmetrical proximal muscle weakness; the presence of the classical cutaneous changes and elevated serum muscle enzymes will confirm the diagnosis and differentiate it clinically from primary myopathies. Weakness of one limb or muscle may indicate a peripheral neuropathic lesion or inflammation of an adjacent joint or joints. Severe weakness of the hip girdle or thighs can result from inflammatory sacroiliitis or greater trochanteric enthesitis.

The child with fever of unknown origin

Determining the cause of fever of unknown origin (FUO) in a child can be challenging, and frequently the assistance of a paediatric rheumatologist is sought. The consultant must first ascertain that the child in fact does have persistent unexplained fever, and then must think broadly across the differential diagnosis. To be certain that there is fever, actual documentation by a medical professional, sometimes in an in-patient setting, may be required. This observation period may be helpful as well to determine the fever pattern, which may give a clue to the ultimate diagnosis.

The most frequent aetiology of FUO is infectious, and overt or occult infection must be sought. A basic work-up including complete blood count, inflammatory markers such as erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), liver and kidney function testing, chest radiographs, and abdominal ultrasound may

be required. Blood, urine, and other bacterial cultures must be performed to rule out occult sepsis or bacterial endocarditis. A technetium bone scan may be indicated. It is also important to consider and exclude malignancy early in the work-up of a child with FUO; this may require a bone marrow biopsy. Fever with weight loss, the presence of erythema nodosum, arthritis or arthralgia, with or without gastrointestinal symptoms, may suggest the possibility of inflammatory bowel disease. In such instances, there may be anaemia, hypoalbuminaemia, and elevation of the ESR. Definitive diagnosis may require endoscopy of the colon or small bowel with biopsies; more recently, MRI of the bowel has been used as a diagnostic test.

Among the rheumatic conditions to be considered in the child with FUO are systemic arthritis, systemic vasculitis, SLE, or autoinflammatory syndromes.

The onset of systemic arthritis may be characterized by fever and rash before the development of joint disease. It is unusual, however, for arthritis to lag more than a few weeks after the onset of the systemic features of the disease; in addition, a diagnosis of systemic JIA in the absence of arthritis should be considered tentative. One should be aware, however, that arthritis may present in somewhat unusual patterns: for example, the child with neck pain and torticollis, fever, and rash may have arthritis in the cervical spine and the diagnosis of systemic JIA. The fever of systemic JIA is specifically quotidian, and the rash is evanescent and macular; the additional presence of systemic inflammatory features of serositis, splenomegaly, anaemia, leucocytosis, and markedly raised ESR are helpful markers of disease.

Children with vasculitis may present with fever and elevated inflammatory markers without objective physical signs. In Takayasu's arteritis, there may be a prolonged phase of disease prior to detection of deficiencies of peripheral pulses, making diagnosis challenging. Kawasaki's disease is usually diagnosed in children early in their fever course (within the first 10 days); however, there may be children in whom this diagnosis is missed. Signs of renal disease, such as hypertension or haematuria, should be sought in children with FUO. In polyarteritis, the presence of painful subcutaneous nodules, characteristically in the calf or sole of the foot, provides the opportunity for excisional biopsy.

Laboratory investigations

The laboratory evaluation of a child with presumed rheumatic disease serves three functions: to provide or exclude evidence of inflammation, to provide diagnostic evidence, and to exclude non-rheumatic diseases.

In screening for evidence of inflammation, the white blood cell count and differential, haemoglobin, platelet count, and ESR or CRP generally suffice. Some clues from this simple battery of tests may be helpful. A low platelet count in the presence of an elevated ESR should prompt consideration of an underlying malignancy. In acute Kawasaki's disease, the platelet count may exceed 10^6; children with very active systemic onset JIA may also have extreme elevations in platelet counts. Decreased serum albumin in a child with arthritis may suggest the possibility of inflammatory bowel disease.

Tests that have diagnostic specificity for rheumatic diseases are few in number. Although anti-nuclear antibody (ANA) is present in many children with a wide variety of rheumatic diseases, it occurs in non-rheumatic disease and healthy children as well.[25] In the context of a child with arthritis or other symptoms strongly suggestive of a rheumatic condition, the antigenic specificity of the ANA should be determined and may be helpful. Antibody to double-stranded DNA or extractable nuclear antigens such as SSA/Ro, SSB/La, and Sm are highly suggestive of a diagnosis of SLE. Antibodies to cardiolipin and other phospholipid antigens can be seen in patients with SLE, but can be found in children with other rheumatic and non-rheumatic conditions as well. Elevated levels of von Willibrand factor antigen often occur in patients with inflammation of blood vessels, such as Takayasu's arteritis, but also are frequently elevated in children with juvenile dermatomyositis when disease is active. Highly elevated serum ferritin can be seen in children with active systemic JIA, and may be a marker of haemophagocytic syndrome, a potentially fatal complication of this disease. Antineutrophil cytoplasmic antibodies (ANCA) are useful markers of vasculitides in children such as granulomatous polyangiitis (formerly called Wegener's granulomatosis), microscropic polyangiitis, and polyarteritis nodosa.

The presence of a rheumatoid factor (RF) in a child with musculoskeletal pain is generally not helpful in making the diagnosis of arthritis. Studies of the sensitivity and specificity of RF in children have shown that it has little value as a diagnostic test.[26]

Some laboratory investigations are useful in excluding rather than diagnosing disease. Normal white blood cell and platelet counts, ESR, and CRP make the possibility of a rheumatic, malignant, or infectious disease less likely. Normal radiographs may be helpful in excluding some conditions; however, recent-onset pathology cannot be excluded. Technetium bone scans can be very useful in this situation, and a normal three-phase bone scan virtually excludes bone or joint disease in a child with undiagnosed musculoskeletal pain.

CHAPTER 2

Young people and transitional care in rheumatology

Janet E. McDonagh and Helena Gleeson

Introduction

Adolescent rheumatology is increasingly being recognized as a vital bridge between paediatric and adult rheumatology. Advances in neuroscience has revealed ongoing brain development into the mid twenties, further highlighting the need for both paediatric and adult rheumatology professionals to develop adolescent specific expertise. In so doing, we will ensure all young people at this stage of their life course receive developmentally appropriate rheumatology health care irrespective of which setting they are seen in.

Transitional care is an integral part of adolescent rheumatology and has long been recognized as a key quality indicator of health care for young people with childhood onset disease. Despite being listed in guidance documents for many years, the universal implementation and objective evaluation of transitional care remains underdeveloped.[1–4] Furthermore, transitional care should no longer be perceived as a stand-alone process alongside routine rheumatology care but part of the developmentally appropriate care for all young people. The aims of this chapter are to describe the implications of adolescent development on rheumatic disease; present the current evidence base for effective transitional care and highlight the key quality criteria for young person friendly rheumatology health services.

Adolescence and rheumatic conditions

Disease spectrum in adolescent rheumatology

Musculoskeletal symptoms are the third most common presentation of young people to primary care.[5] Adolescence is also the time of onset of many long-term rheumatic conditions including systemic lupus erythematosus (SLE), certain subtypes of juvenile idiopathic arthritis (JIA), and inflammatory bowel-associated arthritis. Other adolescent-onset rheumatic conditions include chronic idiopathic pain syndromes, anterior knee pain syndrome, Scheuermann's, non-specific mechanical back pain, and idiopathic Raynaud's.[6] Greater effects on measures of mental health, health service use, school, work, and home activities have been reported in adolescents with chronic rheumatic conditions compared to individuals without chronic disease or those with other chronic disease.[7]

Outcome of adolescent rheumatic disease into adulthood

In spite of advances in therapy, JIA can continue into adulthood. Approximately a third of adolescents with JIA had an increase in disease activity after transfer to adult care.[8] Only 35% of young people were in remission at mean follow-up of 16.2 years.[9] Skarin et al. reported that 49% of young people with JIA associated uveitis still had active uveitis at 24 years follow-up.[10] Time will tell whether the newer biologics will influence long-term outcomes. The significant burden and cost of JIA in adulthood is recognized in the literature[11] but considering reports of up to 52% loss to follow-up (JIA),[12,13] the true extent of this burden, whether medical, psychosocial, and/or vocational, may not be fully realized.

A shared concern of paediatric and adult rheumatologists is reduced bone mass accrual, leading to osteoporosis and increased risk of fractures.[14–16] French et al. reported adolescent predictors of low bone mineral density in adults with JIA: reduced calcium intake, smoking, functional disability, and lack of participation in sports.[17]

Despite average or above average educational achievement, there are reports of higher levels of unemployment in UK JIA populations[18,19] although studies elsewhere have reported better outcomes, albeit only in early adulthood.[20] One prospective study reported that although young people with a range of chronic conditions were socially successful in adulthood, this was not matched with vocational success compared to their healthy counterparts with lower odds of graduating from college and/or being employed and higher odds of having a lower income and/or being on public assistance.[21]

There are also particular concerns regarding outcome of adolescent-onset disease. For example, adolescent-onset juvenile systemic lupus erythematosus (JSLE) has been reported to have an increased risk of mortality compared to adult SLE.[22] Whether this is related to pubertal changes, adolescent development and/or health care provision is as yet unknown.

Adolescent development

Adolescence is a bio-psycho-social development process (Table 2.1) leading to adult life. Adolescence can be broadly divided into early (10–13 years), mid (14–16 years), and late stages (17–19 years) in keeping with the World Health Organization chronological definition of 10–19 years.[23] An additional phase of 'emerging adulthood' (19–mid twenties) is now also recognized.[24]

Biological development includes sexual maturation, growth, and bone mass accrual. Longitudinal neuroimaging studies demonstrate that the adolescent brain continues to mature into the third decade although empirical evidence linking neurodevelopmental processes and adolescent real-world behaviour remains limited at present.[25]

In contrast to the biological and psychological changes (Table 2.1), which are fairly universal, the social changes of adolescence are culturally determined. In Western cultures, the social 'tasks' of adolescence are concerned with establishing relationships outside the family, achieving independence from parents, and establishing financial (i.e. vocational) independence. Many of these tasks are shifting into the third decade of life and well beyond the usual age criteria of transfer to adult health care, with more young people staying in education before employment and remaining in the parental home for longer.

Impact of chronic rheumatic disease during adolescence

Many of the challenges in the management of rheumatic conditions during adolescence are not unique to rheumatology. Chronic illness and adolescent development have reciprocal effects on each other. A chronic condition may retard adolescent development, producing pubertal and growth delay, delayed social independence, poor body, sexual and self image, and educational and vocational failure. As well as delaying development, a chronic condition can appear to accelerate development. For example, 18–30-year olds with diabetes are more likely to self-classify themselves as adults earlier than their healthy counterparts, with adult self-classification positively related to glycaemic control.[26]

On the other hand, the imperatives of adolescent development (the search for identity and independence, immature abstract thinking, experimentation, etc.) make chronic illness management challenging for young people, their caregivers, and healthcare providers alike. Experimentation can lead to risk behaviours, which have been reported to be more common in adolescents with chronic conditions compared to the general population.[27] such young people have been described as being in a 'double whammy' situation;[28] as well as the risks of such behaviours which face any young person, young people with chronic conditions have additional risks from their condition

Table 2.1 Bio-psycho-social development during adolescence

	Biological	Psychological	Social
Early adolescence	Girls: Breast bud and pubic hair development (Tanner stage II) Initiation of growth spurt Boys: Testicular enlargement, beginning of genital growth (stage II)	Thinking remains concrete but with development of early moral concepts Progression of sexual identity development: Development of sexual orientation, possible homosexual peer interest Reassessment and restructuring of body image in face of rapid growth	Realization of differences from parents Beginning of strong peer identification Early exploratory behaviours (smoking, violence)
Mid adolescence	Girls: Mid to late puberty (stage IV–V) and completion of growth Menarche (stage IV event) Development of female body shape with fat deposition Boys: Mid puberty (stage III–IV) Spermarche and nocturnal emissions Voice breaking Initiation of growth spurt (stage III–IV)	Emergence of abstract thinking although ability to imagine future applies to others rather than self (self seen as 'bullet-proof') Growing verbal abilities; adaptation to increasing educational demands Conventional morality (identification of law with morality) Development of fervently held ideology (religious/political)	Establishment of emotional separation from parents Strong peer group identification Increased health risk behaviours Heterosexual peer interests develop Early vocational plans Development of an educational trajectory; early notions of vocational future
Late adolescence	Boys: Completion of pubertal development (stage V) Continued androgenic effects on muscle bulk and body hair	Complex abstract thinking Post-conventional morality (ability to recognize difference between law and morality) Increased impulse control Further completion of personal identity Further development or rejection of ideology and religion—often fervently	Further separation from parents and development of social autonomy Development of intimate relationships—initially within peer group, then separation of couples from peer group Development of vocational capability, potential

and/or therapy. An awareness of these inter-relationships between adolescent development and the chronic condition is vital for their appropriate management of these young people.

Transitional care in rheumatology

Principles of transition

Transition is most usefully defined, as 'a multi-faceted, active process that attends to the medical, psychosocial and educational/vocational needs of adolescents as they move from child to adult centred care'.[29]

The aims of transition are to:

- provide high quality, coordinated, uninterrupted health care that is patient-centred, age and developmentally appropriate, culturally competent, flexible, responsive and comprehensive with respect to all persons involved
- promote skills in communication, decision-making, assertiveness and self-care, self-determination and self-advocacy
- enhance the young person's sense of control and interdependence
- provide support for the parent(s)/guardian(s) of the young person during this process
- maximize lifelong functioning and potential.[30]

It is important to acknowledge that transition is a process, whereas transfer is only one event within the much longer process of transition. Timing of events within transition (including transfer) will depend on many variables and must be individualized to the young person concerned (Box 2.1).

Evidence base for transitional care

The evidence base for transitional care has evolved significantly since the last edition of this textbook.[1,31,32] A multicentre study involving 10 UK paediatric rheumatology centres was the first objective evaluation of an evidence-based transitional care programme in any chronic illness.[33] In this study, significant short-term improvements were reported in health-related quality of life, patient and parent satisfaction, disease knowledge,

vocational readiness, and documentation of adolescent health issues.[33,34]

The content of the rheumatology programme cited in the previous paragraph has since been further validated by subsequent research elsewhere.[31,32] Lugasi et al. reported that the following aspects determined successful transition:

- the meaning given to transition by patients
- their expectations about transition and adult care
- their level of knowledge and skills
- transition planning and environment.[31]

In a systematic review, the most commonly used strategies in successful programmes were reported to be (1) patient education and skills training and (2) specific clinics such as combined paediatric and adult clinics and/or dedicated young adult clinics within adult services.[32]

Key elements of a transitional care programme in rheumatology

In spite of the advances in research and publication of national standards for transition,[4,35,36] implementation in clinical practice is not yet universal.[4,37] Various models for transition have been reported,[32,38] including a young adult clinic[32,39,40] which particularly addresses the developmental needs of late adolescence and emerging adulthood.[39] Irrespective of which model is employed, there are key elements common to all (Box 2.2).

Intrinsic to effective transitional care is planning, which should actively involve the young person and their parents and start ideally by early adolescence at the latest.[2,4,33,35,37] Lack of planning has been reported as a major reason for failure of successful transition.[41] The unpredictability of many chronic illnesses can further

---

Box 2.1 Factors to consider in the timing of transition and transfer

- Chronological age
- Physical maturity
- Cognitive maturity
- Current medical status
- Adherence to therapy
- Independence in healthcare
- Preparation
- Readiness of the young person
- Readiness of the parent/caregiver
- Availability of an appropriate adult rheumatologist
- Readiness of adult rheumatology service
- Adolescent expertise within adult rheumatology team

Box 2.2 Key elements of a transitional care programme in rheumatology

- Written transition policy agreed by all members of the multidisciplinary team and target adult rheumatology services
- Individualized patient-centred planning
- A preparation period and education programme, involving knowledge and skills training for patient and parents, starting in early adolescence
- Informational resources of transition process and of the adult service
- Flexible policy on timing of events
- Network of relevant local agencies
- Primary health care and social care involvement
- Interested and capable adult services
- Liaison personnel in paediatric and/or adult teams
- Key person identified for each individual patient
- Staff training in transitional care and core principles of adolescent health care
- Administrative support

accentuate the negative effects of deficient planning. If transition is 'forced' at a time when the young person is ill prepared, their perceived lack of control and choices is further accentuated.

The role of a transition coordinator is well established in the literature,[42] and their potential in determining successful transition is highlighted in a systematic review.[32] In the rheumatology multi-centre study ,the local coordinator role was considered better than paper-based resources by the adolescents themselves.[43] A key role for such personnel is that of bridging the gap between the paediatric and adult service, both for the patient and for the multidisciplinary teams. Their other major role is preparing the young person and their family for the many differences between paediatric and adult care.[44]

Effective links with local adult rheumatologists are vital.[44] In several studies of different chronic diseases, including JIA, young people have reported a preference for meeting adult doctors prior to transfer,[45–47] which in turn is associated with positive outcomes.[47]

Adequate administrative support for transitional care must not be underestimated, facilitating effective communication between all the many professionals involved. Young people and their parents have expressed specific fears regarding the actual transfer of information to adult services.[46] A medical summary was considered to one of the top five aspects of transition, according to adult gastroenterologists.[48] In view of the concerns regarding lapse of care at transfer,[13,14] a mechanism to track young people into adult care is a further aspect of administrative support but not yet universally available.[49,50]

Parents of young people with chronic rheumatic conditions

One of the basic tenets of transitional care is that it is inclusive of the family. Parental issues have been reported to be significant during transition,[46,51,52] including some reports that transition is more difficult for parents than for the young people themselves.[51]

Parents can be helped to encourage involvement of their son/daughter in decision-making from early age, to ensure attainment of functional living skills and development of autonomy and self-advocacy skills similar to their peers. A shared leadership approach should be encouraged with the parent moving from providing all the care in early childhood, to managing it with the young person participating during late childhood and, as their son/daughter becomes competent, for the parent to take the role of supervisor as the young person takes over the management, eventually becoming their own supervisor with the parental role evolving into that of consultant.[53]

Knowledge and skills for young people

Knowledge and skills were one of five factors associated with successful transition in a metasummary of the qualitative research literature.[31] Stinson et al. reported that young people with JIA describe a desire to acquire appropriate knowledge and skills to manage their disease including listening to and challenging care providers, communicating with doctors, pain management and managing emotions.[54] The wide range of skills required of a young person to take over the care of their condition is detailed in Box 2.3.

Knowledge deficits, inaccuracies, and misunderstandings have been reported in young people with JIA[55] as in many other conditions.[56–58] Berry et al. also reported that adolescents with JIA were still at the concrete operational stage of cognitive development rather than the more adult abstract stage,[55] a factor which

---

Box 2.3 Key skills to address in adolescent rheumatology clinics

Health

- Seeing health professionals independent of their parents
- Effective health information-seeking behaviours, including cybersafety issues
- Accessing healthcare independently, including booking own appointments, contacting medical team for advice, refilling prescriptions, registering with a new doctor, etc.
- Awareness of own health: recognition of a flare, taking temperatures
- Self-management of their condition
- Adherence to therapy, appointments
- Pain management skills, including procedural pain management
- Fatigue management skills, including pacing
- Emergency strategies
- Practical skills, e.g. urine/blood testing

Psychosocial

- Independent living skills:
  - Chores
  - Meal preparation
  - Self-care
  - Mobility, including travel away from home
  - Driving
  - Hobbies and leisure activities
- Peer support, including independent social life
- Social competencies

Education/vocational

- Communication skills
- Work experience
- Part-time job
- Disclosure of condition to others including teachers, employers

---

must be considered by professionals providing disease education. Young people have also expressed the wish that there should be no gate-keeping of information.[46] In a study of young people with congenital heart disease, Clarizia et al. reported a positive impact of knowledge acquisition during transition, with more knowledgeable young people being more likely to independently respond to the health professional's questions and more likely to understand implications of transition.[59] Multiple methods for health literacy education need to be developed,[46,60] and technologies including the internet and SMS text messaging have great potential in this area.[61–64]

Skills training in addition to health literacy is also core to transition. Independent visits and self-medication practices were reported

as baseline predictors of improvement in health-related quality of life after 6 months and 12 months respectively of participation in a transitional care programme.[34] Similarly, in a larger study including young people with JIA, independence during consultations was identified as an important predictor of transition readiness.[65]

A core skill for any individual with a long-term health condition is adherence. Data shows that in JIA populations adherence to medication and physiotherapy varies from 55–95% and 46–86% respectively.[66]

In any discussion regarding adherence, it is important to reflect on what young people with rheumatic conditions face day-to-day. They often have long-term therapeutic regimens which require regular monitoring. The benefit of therapy is not immediately apparent and they have to continue therapy even when they feel well. All of these factors potentially lead to restrictions on leisure time, spontaneity and peer interactions. Non-adherent behaviour may be the only control mechanism open to the young person and be a simple wish to be heard and to take an active role in the decision-making process.

Addressing adherence in the clinic setting should never be about identifying 'poor' adherence. The most important strategy is to decriminalize non-adherence and giving the young person opportunity to disclose difficulties that they are experiencing. 'When was the last time you forgot to take ….' Is a much more effective question than 'Do you remember to take …. every day?'. Adherence is multifactorial and assessed as such in terms of health beliefs, previous experiences (first- or second-hand), disease duration, reality factors in terms of inter-relationships with the rheumatology team members, maturity, etc.[66] One of the common misunderstandings in dealing with non-adherence is that explanation about the rationale of therapy will suffice. Demonstrating how the young person can become an active partner in self-management is imperative. Finally, the quality of the relationship between the health professional and the young person—the therapeutic alliance—is an important, yet often underestimated, determinant of adherence.

New technologies offer potential for addressing self-management needs in a youth friendly manner. Several such programmes have already been reported in the rheumatology literature, e.g. Teens Taking Charge: Managing Arthritis Online,[61] Rheumtogrow.org.[62] Other generic tools are similarly useful, such as 'My Health Passport'.[66] There however remain many unanswered questions regarding the efficacy of such interventions.[64]

Adolescent healthcare in transitional care programmes

Developmentally appropriate communication skills, verbal and nonverbal, are integral to adolescent health.[67] Adolescents are reported to be worse at reading facial expressions and body language, than children or adults.[68] Clinical encounters with adolescents are opportunities to nurture their communication, negotiation, problem solving, decision-making, information-seeking, and disclosure skills.

Motivational interviewing techniques are ideal for use with adolescents as they address resistance and/or ambivalence as well as emphasizing self-responsibility in changing or modifying one's behaviour.[69] Brief intervention strategies are useful in time constrained clinics. The 5As of brief intervention strategies are Ask, Assess, Advise, Assist, and Arrange.[70] However, in a study of

rheumatology professionals, 45% did not assess the young person's understanding of units of alcohol when discussing the risks of alcohol and methotrexate use.[71] In a study of paediatricians, only 44% assessed the adolescent's readiness to quit and only 16% assisted them in quit strategies.[70] Very low or low perceived skill in addressing sexual health, drugs, smoking, and alcohol issues was reported by 27%, 45%, 18%, and 18% respectively of rheumatology professionals.[72]

Barriers to appropriate counselling amongst adolescents with JIA have been described and include availability of time, discomfort, and ambivalence of the rheumatologist and the perceived lack of applicability.[73] The importance of the act of simply asking the right questions should not be underestimated, even when the young person is reluctant to answer. Brown et al. reported that if consultations included discussion of a sensitive health topic, young people involved were more likely to have a positive perception of the provider, have their worries eased, be allowed to make decisions, and report taking responsibility for treatment.[74]

Specific needs of young people with rheumatic disease and a learning disability should also be acknowledged and addressed.[75] Although the developmental milestones are likely to be delayed, assessment during adolescence remains important in order to ensure they meet their full potential. A proactive, anticipatory approach to adolescents with or without learning disabilities is required. Psychosocial screening tools such as HEADSS (see Table 2.2) are useful in this regard: as well as acting as a risk assessment for behaviours, they also assist in engaging the young person, identify protective and resilient factors, and provide information useful in future interventions and management.[76] They can be readily integrated into adolescent rheumatology consultations.[21,33,34,46,69,70,71,73,77–92]

Key criteria for young person friendly rheumatology services

Adolescent rheumatology services should provide age and developmentally appropriate health care for young people with rheumatic conditions.[93] In the UK, the 'You're Welcome' quality criteria for services friendly to young people have been developed and endorsed by the World Health Organization (Box 2.4).[94] The task now is that of implementation. Criteria not previously discussed in this chapter will now be considered.

Accessibility

Young people are in effect 'new users' of rheumatology services that were previously accessed on their behalf by their parents. It is important that young people have the confidence and skills to see professionals independently if they so choose. Only 21% of young people were seen independently of their parents by doctors in rheumatology clinics,[95] although young people report valuing such opportunities.[46] Such opportunities were considered best practice and feasible in most UK hospitals by rheumatology professionals, young people, and their parents.[96] Furthermore, such autonomy has been reported to be the key determinant of attendance at the first adult cardiology clinic appointment,[97] and associated with improved health-related quality of life in adolescents with JIA.[33] In a large study of 954 adolescents with chronic conditions, 48% of total variance in transition readiness was explained by their perceived self-efficacy in skills for independent hospital visits and

Table 2.2 Adolescent HEADS for adolescent rheumatology clinics

		Evidence of importance to adolescent rheumatology	Strategies for use in adolescent rheumatology clinics
H	Home	Early incorporation of a child with disabilities into household chores is key for fostering competence and responsibility[77]	Ask questions regarding home life, e.g: – who they live with – who they talk to about what – what they do to help around the home
E	Education	School absence is reported to predict health-related quality of life in JIA[78] Although social success is now being reported in young people with long-term conditions, vocational success is still concerning[21] Improved vocational readiness with transitional care programmes[33]	Address information needs of teachers, particularly head of year and physical education Explore the impact of a long-term condition in specific areas with respect to the school day: – education – environmental considerations – medical needs and – activities of daily living[79] Assessment particularly important at transfer from junior to high school and from high school to further education or employment. Assess vocational readiness in terms of – educational achievement – prior work experience – knowledge of resources – psychological aspects including self-esteem – expectations of the young person, their family, their teachers
E	Exercise	Inactivity in young people with rheumatic disease can lead to – deconditioning – disability – decreased bone mass – reduced quality of life – increased mortality in adulthood[80,81]	Normalize exercise regimes into typical day, e.g. weekly visit to local gym with peers rather than the physiotherapy department Consider less traditional exercise opportunities, e.g. dance, martial arts
A	Activities and peers	Factors which disrupt peer support networks[46,82,83] include Intrinsic: – pain, fatigue – poor self-esteem, reduced self-confidence, impaired body image – limited knowledge and/or inaccurate beliefs about their condition Extrinsic: – hospitalization and clinic appointments – overprotection by family members, bullying – limited transport	Explore interests, hobbies and leisure activities with young person—important considerations when planning management regimens and interventions in order to ensure adherence Ask about friends, both in and out of school Enquire about teasing and/or bullying, particularly with young people with visible impairments or growth restriction[84] Ask about participation in extracurricular activities at school, particularly trips away—excellent opportunities to foster independent skills including self-medication Ask about use of public transport and/or driving—key skills to support an independent social life
D	Drugs	Neglected area in adolescent rheumatology clinics[34,71,73,85] Reported association of substance misuse with non-adherence[86] Smoking is specifically important for young people with lung disease, Raynaud's, SLE, vasculitides or on long-term steroid therapy[85,87]	Ideally young person should be seen independently of parents for such discussions with appropriate assurances of confidentiality to facilitate disclosure Ask whether friends are using substances in order to assess risk, even if young person denies substance use Consider the use of brief intervention, motivational interviewing, and harm reduction strategies[69,70]

(continued)

Table 2.2 (*Continued*)

		Evidence of importance to adolescent rheumatology	Strategies for use in adolescent rheumatology clinics
S	Sexual health	Many young people are sexually active before transfer to adult rheumatology care[88]	Ideally young person should be seen independently of parents for such discussions with appropriate assurances of confidentiality to facilitate disclosure. Use of gender-neutral language should always be advocated[89] and cultural and religious beliefs respected. Discussions regarding potential teratogenicity of disease-modifying drugs should emphasize protection against sexually transmitted infections as well as avoidance of pregnancy
S	Suicide and emotional well-being	Frustration and depression were rated by adolescents with JIA as their biggest psychological problems[90]	Useful questions include: *How do you feel in yourself at the moment on a scale of 1 to 10?* *What sort of things do you do if you are feeling sad/angry/hurt?* *Is there anyone you can talk to? Do you feel this way often?*
S	Sleep	Sleep disturbance and fatigue are prevalent among young people with rheumatic diseases[91]	Enquire about sleep routine
S	Safety	Young people with disabilities who engage in risky behaviours experience are at increased risk for medically attended injury[92]	Assess safety strategies, e.g. around substance use, sexual health, internet use

independence during consultations, their attitude towards transition, and their involvement in discussions about transition.[65]

Accessibility issues have important implications for all members of the multidisciplinary team. This includes secretarial and reception staff who are frequently the first point of contact. Accessing advice from the rheumatology team using forms of communication familiar to this age group, including text messaging and email, can also help foster healthcare utilization skill development.[98]

An important aspect of accessibility is timing of clinics. Late afternoon and early evening clinics enable young people to avoid missing school, college, or the first year in their first ever job. Drop-in clinics are another solution to facilitate open access for times of relapse and/or concern.

Publicity

Information regarding the rheumatology service is important to provide in formats suitable for young people as well as for parents. The opportunity to be seen and to access the service independently of parents should be detailed for a young person before their first visit to the service and reiterated the first time they visit the clinic.

The first encounter with the rheumatology service may be the letter informing the patient of their first appointment. However, often this letter is addressed to the parents and fails to include the young person as an addressee—a missed opportunity for respect and engagement of the young person. The copying of clinic letters for young people can help engagement and facilitate disease education and self-management skills training. The implications of sending copies of clinic letters direct to young people need to be carefully considered, however, with particular reference to confidentiality and comprehension.

Confidentiality

Confidentiality is an important attribute of any adolescent-friendly practice.[93,94] Confidentiality, including its limits, needs to be routinely explained to every young person (and their parents). Posters detailing the policy should be clear in the waiting room and included in the service's informational resources.

Clinic environment

Adolescent-focused clinics, wards, and waiting areas have been called for by young people in rheumatology who report finding paediatric environments 'patronizing', adult environments 'distressing', and both isolating.[46] Dedicated adolescent environments were one of three components of transitional care considered to be best practice but feasible in only a few UK centres.[96]

Waiting times are a concern of patients of all ages. Prolonged waiting can be perceived as a lack of respect, and also increases anxiety and boredom.[46] Ensuring there are age-appropriate activities within the waiting area can deflect some of these negative feelings. The waiting area is an opportunity for peer support activities, and is optimized if there is a separate waiting area for young people distinct from their parents and younger children.

Staff training, skills, attitudes, and values

Lack of training in transitional care and/or adolescent health has been reported as a major barrier for service delivery by several authors.[99–101] In a national survey, 43% of rheumatology professionals reported unmet training needs.[99] Rheumatology professionals knowledgeable in transitional care were considered best practice but only feasible in a few hospitals in a UK Delphi study.[96] Provider characteristics were more important determinants of adolescent satisfaction with transitional care in rheumatology than process and/or environmental characteristics.[102]

There is evidence that training in adolescent health is beneficial. Sustainable, improvements in knowledge, skill, and self-perceived competency were reported in a randomized controlled trial,[103] and in rheumatology, screening for risk behaviours improved with training.[73]

Transitional care is an excellent model to use in problem-based learning to highlight such aspects of health care as triadic consultations, cross-boundary and multidisciplinary working, ethics of consent and confidentiality, or holistic care. There are online resources to support teachers (www.euteach.com) and online transition modules which can be accessed individually or used in small group work (www.e-lfh.org.uk).

Joined-up working

Adolescent rheumatology and transitional care is multidisciplinary. In a UK-based Delphi study, consultant rheumatologists (paediatric and adult) considered delivery of transitional care by a multidisciplinary team as less feasible than their allied health professional counterparts, reflecting the challenges of commissioning such services currently.[96]

Adolescent rheumatology clinics require a minimum of two trained health professionals to facilitate concurrent visits for parents and young person in addition to chaperone availability. Continuity of these professionals is of importance both to young people[46,104,105] and to their parents[46] in the building of a therapeutic alliance, vital for confidentiality and engagement.

An integral aspect of joined-up working is effective communication, including written communication. Unfortunately, in a national audit of case notes of recently transferred young people to adult care, there was limited documentation of key transitional care issues. Documentation significantly improved following centre participation in a transitional care research project.[34] Effective communication with other teams such as ophthalmology, orthopaedic surgery, nephrology, and primary care, is important to ensure coordination. Poor intra-agency and interagency coordination was reported by rheumatology professionals in a UK survey of transitional care needs for young people with JIA.[99]

Monitoring and evaluation and involvement of young people

Research has identified differences between the views of young people and the adults close to them, suggesting that adults cannot be used as proxies.[105] Actively involving young people in decision-making promotes citizenship and social inclusion, important for the health of the community. Moreover, strategies for enhancing participation will develop self-esteem and personal development. Guidance on strategies that rheumatology teams can use to involve young people in service delivery, development, evaluation, and research is now available.[106]

Conclusion

Adolescent rheumatology and transitional care have come far since the last edition of this textbook. On reflection, perhaps identifying transitional care as a defined entity was a mistake and it is now time to redefine it as an integral component of the wider concept of adolescent rheumatology. Once we consider the interdependence of adolescent medicine, chronic disease self-management, and the structure of rheumatology service provision and training, we will have a real chance of getting transitional care right.[107] There is now a growing evidence base to support further development of adolescent rheumatology. However in these times of financial restraint, developments will also require professionals to be as imaginative and creative as the young people in their care and to start looking beyond the limits of rheumatology to areas of potential sharing in adolescent health, both interspecialty and interagency. They are, after all, young people first and foremost who happen to be living in the 21st century with a chronic condition. As one young person in the original rheumatology research states 'It's not about arthritis, it's about living with it'.[46]

CHAPTER 3

The adult patient

Paul Thompson

Introduction

This chapter is for the rheumatologist in training. While inevitably coloured by the author's experience and bias, the text will be evidence-based and refer to published reviews as much as possible. Clinical vignettes will be used to stimulate thought and discussions. In the age of the internet, YouTube and Twitter reference will be made to relevant sites, although it should be noted that in a rapidly changing world new and important sites may be missed. The reader is encouraged to surf the net for additional material.

Rheumatic diseases constitute a wide range of conditions and an inclusive approach is taken here. While many rheumatologists will concentrate their practice on the inflammatory arthritides, others will see patients with regional and widespread pain syndromes. A knowledge of the complex interaction of physical and psychological factors in, for example, patients with chronic disabling back pain, will serve the clinician well in any aspect of practice.

The International Statistical Classification of Diseases and Related Health Problems 10th Revision (ICD-10) lists those conditions considered to be diseases of the musculoskeletal system and connective tissues.[1] Not all the conditions will be covered here, but the chapter will concentrate on patients presenting with arthritis, regional pain syndromes, polymyalgia, and connective tissue diseases.

Principles

Some consideration of how to collect the relevant information to help make a diagnosis and, perhaps more importantly, to understand the person's problem in the context of their beliefs, social, and economic environment, is pertinent.

Recommendations for taking a history and performing a clinical examination relevant to musculoskeletal problems are available (see Woolf and Akesson[2] for a recent review), but it is assumed that the reader has the basic competencies of a trainee specialist.

There are a number of ways in which to approach a patient but in practice physicians use a combination of pattern recognition and hypothetical-deductive methods for most decision-making and extract elements of the full history and examination in selected ways.[3] The rheumatologist makes use of all clues—from the referral letter and the appearance and behaviour of patient and carers, to the formal examination—making hypotheses and testing them with direct questions and specific examination techniques.[4] Use of the 'GALS' locomotor screen, as a brief musculoskeletal

assessment, is recommended and can be incorporated into a systemic review.[5]

Arthritis

For the purposes of this section three separate presentations of arthritis (mono-, oligo-, and polyarthritis) are considered. It will be seen that a specific diagnosis may present in more than one way, or evolve from monoarticular to oligoarticular or oligoarticular to polyarticular, but rarely from more to less joints. Of particular note is that many patients presenting in any of the categories never fulfil the criteria for a specific diagnosis. These 'undifferentiated arthritis' conditions frequently resolve spontaneously.

Monoarthritis

> **Case history**
>
> Early in the evening, a 50-year-old man presents to the Emergency Department with a 24-hour history of pain and swelling in his right knee. He denies recent trauma. He has no prior history of joint disease or joint surgery and has no history of arthritis. His medical history includes hypertension, for which he takes hydrochlorthiazide and metopralol. He drinks three beers per day.[6]
>
> What is the differential diagnosis? What questions would you ask him? What clinical signs would you look for? What initial investigations would you perform? How would you manage this case?

In a review of four studies of monoarthritis, Ma and colleagues[6] listed gout (15–27%), septic arthritis (8–20%), osteoarthritis (5–17%), rheumatoid arthritis (11–16%) and reactive arthritis (0–19%) as the most common diagnoses, but pointed out that the cause was not ascertained in a significant number of patients (16–36%). Other rare causes included pseudogout, psoriatic arthritis, tuberculosis, and spontaneous haemarthrosis.

Although there are no specific studies to ascertain the most useful clinical features, experienced rheumatologists have published the points summarized in Box 3.1.[7,8]

Some presentations are pathognomic of conditions such as podagra, acute gout of the great toe, or a sausage digit in patients with reactive arthritis, but acute monoarthritis is often non-specific

- The history should include the mode and time course of presentation, trauma, previous history of joint disease, family history, prodromal and concurrent illnesses, medications, sexual history, tick bites, alcohol and intravenous drug use, occupation, and recent travel.

- In particular, a family history of gout; recent diarrhoea and vomiting; symptoms of urethritis in the patient or their sexual contacts indicating possible reactive arthritis (or rarely gonococcal arthritis); prolonged use of thiazide diuretics in elderly women predisposing to tophaceous gout; intravenous drug use in septic arthritis; tick bites suggesting Lyme disease; and fevers, rigors, and malaise in septic arthritis.

- Examination should focus on the involved and contralateral joints, and surrounding areas, examination of other joints (the GALS method is useful as a quick and reliable screen test), looking for systemic manifestations of disease.[7]

and clinical evaluation alone is usually not enough to make a diagnosis.

The most important investigation is arthrocentesis. Observation of the fluid may be enough to differential a non-inflammatory condition (clear viscid fluid), acute haemarthrosis (heavily blood stained), and infection (frank pus), but crystal arthopathies and reactive arthritis fluid can look the same as sepsis. Urgent Gram stain, examination of the fluid under polarized light for uric acid or pyrophosphate (a skill which every rheumatologist should acquire) will help with the acute management. Subsequent culture and additional tests such as rheumatoid factor and anti-citrullinated peptide (anti-CCP) antibodies will be helpful in a few cases. It should be noted that despite these diagnostic assessments a definitive diagnosis is reached in only two-thirds of patients[9] and a significant number of those not diagnosed will have a benign outcome.

Oligoarthritis

Case history

A 45-year-old male born in Suriname was admitted with relapsing fever for one and a half weeks, muscle weakness, and fatigue. Physical examination revealed temperature of 38.8°C, arthritis of the second metacarpophalangeal joint of the right hand, right knee, and both ankles, and erythema nodosum on both lower legs.[10]

What is the most likely diagnosis? What tests would you order?

Laboratory testing showed leucocytes of 13.8×10^9/Litre and an erythrocyte sedimentation rate (ESR) of 128 mm/h. IgM-RF and anti-CCP antibodies were negative. On a chest radiograph, infiltration of the lingula of the left lung was observed. Radiographs of the ankles, hands, and feet showed no abnormalities.

What is the significance of the infiltration of the lingula?

Standard cultures and cultures for tuberculosis (TB) in blood and mucus were negative. Analysis of synovial fluid of the right knee and both ankles revealed leucocytes between 4.0 and 8.2×10^9/Litre and no crystals. Standard and cultures for TB of all obtained synovial fluid samples were negative.

What treatment would you give?

Because of the infiltration of the lingula, treatment with clarithromycin and amoxicillin/clavulanic acid was started. The general condition improved but the arthritis persisted. A radiograph performed 8 weeks after admission showed that the infiltration had not changed. Additional investigations were performed including bronchoscopy to obtain specimens for histology and culture. After 4 weeks one culture of bronchial mucous revealed *Mycobacterium tuberculosis*, and Poncet's disease was diagnosed. Therapy with isoniazid, ethamutol, pyrazinamide, and rifampicin was started, after which the arthritis resolved in a few days.

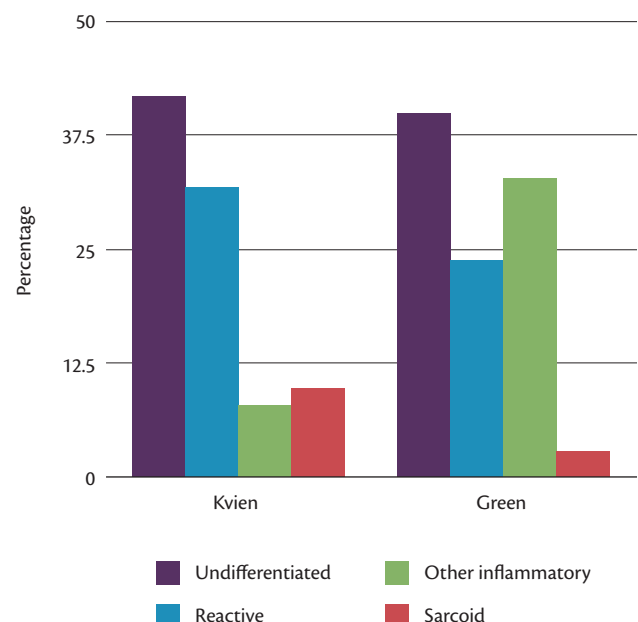
Oligoarthritis is characterized by observed swelling of only a few joints. Definitions are varied and range from two to four joints or less than six and can be considered acute, subacute, or chronic. The term encompasses a group of diseases including reactive arthritis, psoriatic arthritis, and undifferentiated arthritis in addition to rheumatoid arthritis in evolution.[11] The incidence in adults below 60 years of age is at least of the same magnitude as rheumatoid arthritis. Data on outcome in these patients demonstrate a variable rate of persistence. Longitudinal cohort studies have shown that a surprisingly large proportion of patients do not develop into a recognizable condition (Figure 3.1) with those patients with undifferentiated arthritis either resolving spontaneously after a few months or going


Fig. 3.1 The incidence of four diagnoses made in two longitudinal cohorts of patients presenting with oligoarthritis.

on to a more persistent arthritis after 24 weeks, not fulfilling the case definitions of reactive arthritis or any other clinical rheumatic diagnosis[12] despite treatment with intra-articular corticosteroids.[13] Many of these patients have evidence of subclinical synovitis when examined by ultrasound and might be better classified as having polyarthritis.[11]

Reactive arthritis is so called because many cases follow shortly after an identified infection although the joint inflammation is aseptic. The clinical picture of a systemic illness associated with inflammation of a few, usually large joints, is typical but a proportion of patients will have minimal symptoms of infection so careful questioning and appropriate testing should be carried out. In general there are two subtypes with a number of rare conditions such as in our case history here. Reactive arthritis occurring after a proceeding infection of the urogenital tract with *Chlamydia trachomatis* or after an infection of the gut with enterobacteria are considered to be part of the spondyloarthropathies.[14] Patients carry the HLA B27 antigen in about 50% of cases and some have features of enthestitis, sacroileitis, and uveitis. Affected joints have a dusky appearance and are extremely painful, warm, and swollen. The synovial inflammation may be intense and mimic sepsis or acute gout/pseudogout. Synovial fluid looks turbid and is packed with polymorphonuclear leucocytes but Gram stain is negative and crystals are absent on polaroid light microscopy (essential investigations in the Emergency Department). Sausage digits are not unusual, reminding us of the overlap with psoriatic arthritis.

Poststreptococcal reactive arthritis is often considered to be a condition of children but the age distribution is bimodal with peaks in early teens and late twenties.[15] The clinical presentation is heterogeneous but appears different from rheumatic fever and the HLA B27-associated reactive arthritides. In most cases arthritis is non-migratory, involves one or a few joints, and resolves within a few weeks, although it may recur with further infections.[15]

Sarcoidosis is a heterogeneous multisystem granulomatous disease that primarily affects the lungs and lymphatic system, which is characterized by its pathological hallmark, the non-caseating granuloma. Arthritis is found in 15–25% of patients and is usually acute and transient. Löfgren described the triad of arthritis, bilateral hilar lymphadenopathy, and erythema nodosum but the latter is not always present. The arthritis is usually symmetrical in the large joints of the lower limbs. The ankles are affected in almost all patients and there may be a dusky discolouration around the ankle. One-third of patients will have evidence of enthestitis, usually of the achilles tendon.[16]

Other rheumatic conditions that may present as an oligoarthritis include rheumatoid arthritis or psoriatic arthritis (which may present without skin manifestations of psoriasis—psoriatic arthritis sine psoriasis—but there may be a family history),[17] gastrointestinal disease, in particular inflammatory bowel disease (Crohn's disease and ulcerative colitis), coeliac disease which is usually not associated with HLA B27, and Whipple's disease (probably an infective arthritis a part of a systemic infection with *Tropheryma whippelii*).[18] The careful rheumatologist will bear these conditions in mind when clinically evaluating the patient.

Polyarthritis

Polyarthritis is the bread and butter of the rheumatologist. Recent major advances in the diagnosis, prediction of outcome, and drug therapies linked to new ways of managing patients (systematic monitoring using outcome targets and escalation protocols leading to tight control) of rheumatoid and psoriatic arthritis have revolutionized the management of these conditions and the achievement of remission is in many patients a realistic goal. However, it is clear from cohort studies of early synovitis clinics that not all patients with polyarthralgias have rheumatoid or psoriatic arthritis and perhaps one-third of these patients will resolve without long-term sequelae. So how will the rheumatologist manage patients who may present in a very similar way but have very different outcomes?

Case history

A 45-year-old white woman was referred to the early synovitis clinic by her GP. She had gradually developed painful wrists over 2 months and consulted her doctor when the pain and early morning stiffness stopped her from doing the housework. The pain spread into her fingers and knees, and she developed some discomfort in her toes on walking. She was taking paracetamol and ibuprofen but her symptoms had prevented her working and she was becoming tearful and depressed (Thompson, personal communication).

What is the differential diagnosis? What questions would you ask her? What clinical signs would you look for? What initial investigations would you perform? How would you manage this case?

The hands shown in Figure 3.2 appear to show swelling of all the small joints and a possible nail dystrophy on the left ring finger. Swelling of the metacarpophalangeal joints (MCPs) and proximal interphalangeal joints (PIPs) is typical of rheumatoid arthritis while swelling of the distal interphalangeal joints (DIPs) is more suggestive of nodal osteoarthritis or psoriatic arthritis. This patient had early rheumatoid arthritis (RA).[19]

RA is a chronic inflammatory disease characterized by joint swelling, joint tenderness, and destruction of synovial joints, leading to severe disability and premature mortality. Given the presence of autoantibodies, such as rheumatoid factor (RF) and anti-CCP antibody, which can precede the clinical manifestation of RA by many years, RA is considered an autoimmune disease. The accepted means of defining RA is by use of classification criteria to provide the basis for a common approach to disease definition that can be used to compare across studies and centres and recruit to clinical trials. The most widely used classification criteria are those published by the American Rheumatism Association in 1988.[20] These used seven criteria: morning stiffness, arthritis of more than three areas, arthritis of the hands, symmetrical arthritis, rheumatoid nodules, serum RF, and radiographic change. A patient is said to have RA if at least four of the criteria have been present for at least 6 weeks.

However, these criteria are limited because they were derived to discriminate patients with established RA from those with a combination of other definite rheumatological diagnoses. They are not helpful in identifying patients who would benefit from early effective intervention to prevent them from reaching the chronic, erosive disease state. In view of this a joint working group from the American College of Rheumatology and the European League Against Rheumatism developed a new

Fig. 3.2 Hands and wrists of a patient presenting with polyarthritis. Note that all joints appear to be swollen and there is a possible nail dystrophy on the left ring finger.

Box 3.2 The 2010 American College of Rheumatology/European League against Rheumatism classification criteria for RA

Target population (Who should be tested?): Patients who

1. have at least one joint with definite clinical synovitis (swelling)

2. with the synovitis not better explained by another disease

Classification criteria for RA (score-based algorithm: add score of categories A–D; a score of ≥6/10 is needed for classification of a patient as having definite RA)

A.	Joint involvement	
	1 large joint	0
	2–10 large joints	1
	1–3 small joints (with or without involvement of large joints)	2
	4–10 small joints (with or without involvement of large joints)	3
	>10 joints (at least 1 small joint)	5
B.	Serology (at least 1 test is needed for classification)	
	Negative RF *and* negative ACPA	0
	Low positive RF *or* low positive ACPA	2
	High-positive RF *or* high-positive ACPA	3
C.	Acute-phase reactants (at least 1 test is needed for classification)	
	Normal CRP and normal ESR	0
	Abnormal CRP or normal ESR	1
D.	Duration of symptoms	
	<6 weeks	0
	≥6 weeks	1

approach to classifying RA.[21] The work focused on identifying, among patients newly presenting with undifferentiated inflammatory synovitis, factors that best discriminated between those who were and those who were not at high risk for persistent and/or erosive disease. In the new criteria set, classification as 'definite RA' is based on the confirmed presence of synovitis in at least one joint, absence of an alternative diagnosis better explaining the synovitis, and achievement of a total score of 6 or greater (of a possible 10) from the individual scores in four domains: number and site of involved joints (range 0–5), serological abnormality (range 0–3), elevated acute-phase response (range 0–1), and symptom duration (two levels; range 0–1) (Box 3.2) and a classification tree can be used.

The classification criteria can be applied to any patient as long as two mandatory requirements are met. First, there must be evidence of currently active clinical synovitis defined as 'swelling' in at least one joint as determined by an expert assessor. All joints of a full joint count may be assessed for this purpose with the exception of the DIPs, the first metatarsophalangeal (MTP) joint and the carpometacarpal (CMC) joint of the thumb, since these joints are typically involved in osteoarthritis. Second, the criteria may be applied only to those patients in whom the observed synovitis is not better explained by another diagnosis. For example, conditions that should be considered and excluded include systemic lupus erythematosus, psoriatic arthritis, and gout.

It should be noted that joint involvement, as used for the determination of the pattern of joint distribution, differs from the definition of synovitis in one joint needed for eligibility in that it refers to any joint with swelling or tenderness on examination that is indicative of active synovitis. Tenderness is included as an equally important feature as swelling for the determination of joint involvement, particularly for the second to fifth MTP joints. Furthermore, any joints with known recent injury that could contribute to swelling or tenderness should not be considered. Additional evidence of joint activity from other imaging techniques (such as MRI or ultrasound) may be used for confirmation of the clinical findings.

Psoriatic arthritis may present in a polyarticular pattern which may mimic RA in addition to an oligoarthritis or axial disease.

Nail dystrophy is usual and psoriatic plaques on the elbows may indicate the diagnosis. For a review of the clinical features see Cantini et al.[22]

Nodal osteoarthritis is one of several clinical presentations of osteoarthritis, typically occurring after 40 years of age in women and affecting the DIPs, PIPs, and thumb base although the MCPs are not infrequently affected. Inflammatory forms may mimic RA or psoriatic arthritis. For a recent consensus report on diagnosis see Zhang et al.[23]

Regional soft tissue and myofascial pain

In the evaluation of the patient with regional pain, the prudent rheumatologist will appreciate the difference between the specific soft tissue conditions such as tennis elbow and frozen shoulder, the myofascial syndromes with local trigger points, and the nonspecific disorders often related to occupational factors.

Two examples will be used here to illustrate the approach to these multifaceted problems: back pain and shoulder/arm pain.

Back pain

Low back pain will be studied in more detail but the principles may be applied to patients presenting with neck pain, and have many

features in common with regional myofascial pain syndromes. Isolated thoracic pain is less common and has a greater chance of reflecting more serious pathology (see 'Red flags').

Case history

Mr JT, a 52-year-old drayman, was referred to the rheumatology services with back pain. He said that he often had low backache. 'We all get back pain from time to time because of lifting those barrels, it's part of the job.' While he was being investigated for an unrelated gastrointestinal problem by his GP an abdominal radiograph was reported as showing, 'degenerative changes in the discs and facet joints at several levels'. The GP told Mr T that he had severe arthritis of his spine and should not lift. He turned from a person with a manageable problem to a patient with a disease and never worked again (Thompson, personal communication).

Back pain ranks second only to upper respiratory tract infections as a symptomatic reason to visit a GP. About 70% of adults have back pain at some time but only 14% have an episode that lasts more than 2 weeks and about 2% of these have features of sciatica. Most cases of back pain respond to symptomatic and physical treatments but some are surgically remedial and some are systemic diseases such as cancer, infection, or spondloarthropathies requiring specific therapy, so careful diagnostic evaluation is essential. Furthermore, psychosocial factors are important in chronic back pain disability.

Since a specific cause frequently cannot be identified, diagnostic efforts are often disappointing. Instead of seeking a precise cause in every case of back pain it is more useful to answer three basic questions. (1) Is there a serious systemic disease causing the pain? (2) Is there neurological compromise that may require surgery? (3) Is there social or psychological distress that may amplify or prolong pain? These questions can generally be answered on the basis of history and examination alone, a minority of patients requiring further diagnostic testing.[24]

Red flags

The initial clinical history taking should aim at identifying 'red flags' of possible serious spinal pathology.[25] Red flags are risk factors detected in low back pain patients' past medical history and symptomatology and are associated with a higher risk of serious disorders causing low back pain compared to patients without these characteristics. If any of these are present, further investigation (according to the suspected underlying pathology) may be required to exclude a serious underlying condition, e.g. infection, inflammatory rheumatic disease, or cancer. Red flags are features in addition to low back pain (Box 3.3).

Cauda equina syndrome is likely to be present when patients describe bladder dysfunction (usually urinary retention, occasionally overflow incontinence), sphincter disturbance, saddle anaesthesia, global or progressive weakness in the lower limbs, or gait disturbance. This requires urgent referral.

Yellow flags

Psychosocial 'yellow flags' are factors that increase the risk of developing, or perpetuating chronic pain and long-term disability,

---

Box 3.3 Red flags: risk factors in patients with low back pain associated with an increased chance of underlying systemic disease

- Age of onset less than 20 years or more than 55 years
- Recent history of violent trauma
- Constant progressive, non-mechanical pain (no relief with bed rest)
- Thoracic pain
- Past medical history of malignant tumour
- Prolonged use of corticosteroids
- Drug abuse, immunosuppression, HIV
- Systemically unwell
- Unexplained weight loss
- Widespread neurological symptoms (including cauda equina syndrome)
- Structural deformity
- Fever

---

including work loss, associated with low back pain.[26] Identification of yellow flags should lead to appropriate cognitive and behavioural management. However, there is no evidence on the effectiveness of psychosocial assessment or intervention in acute low back pain.

Examples of yellow flags are:

- Inappropriate attitudes and beliefs about back pain (e.g. belief that back pain is harmful or potentially severely disabling, or high expectation of passive treatments rather than a belief that active participation will help)
- Inappropriate pain behaviour (e.g. fear avoidance behaviour and reduced activity levels)
- Work-related problems or compensation issues (e.g. poor work satisfaction),
- Emotional problems (e.g. depression, anxiety, stress, tendency to low mood, withdrawal from social interaction).

For an in-depth discussion about the assessment of the back pain patient with the available evidence base see the European guidelines for the management of acute non-specific low back pain in primary care.[27]

Shoulder/arm pain

Shoulder pain is a significant cause of morbidity; the prevalence is estimated to be between 16% and 26% and it is the third most common cause of musculoskeletal consultations in primary care. The cause can be difficult to diagnose because of the complex anatomy, the wide spectrum of organic pathologies, and the overlap with regional myofascial pain. Clinical evaluation by specialists can rule out the presence of a rotator cuff tear but more detailed investigations including MRI and ultrasound are often needed to arrive at a firm diagnosis.[28]

A recent review of the literature described over 100 tests for examining the shoulder. The authors concluded that the key steps are as follows: (1) rule out stiffness by checking passive external

rotation; (2) evaluate external rotation and supraspinatus power and impingement signs for rotator cuff tears; (3) O'Brien's sign for superior labral anterior posterior lesions; (4) modified cross arm sign/modified O'Brien's sign for acromioclavicular pain; and (5) instability tests if there is a positive history.[29]

Soft tissue musculoskeletal disorders of the neck and upper limb comprise a heterogeneous group of conditions. At one end of the spectrum are relatively clear-cut specific upper limb conditions such as de Quervain's tenosynovitis, lateral epicondylitis, rotator cuff tendonitis, and carpal tunnel syndrome, but at the other end of the spectrum are non-specific regional pain syndromes, e.g. forearm pain, with few objective physical findings and little in the way of demonstrable pathology.

Many of these upper extremity disorders are attributed to occupational factors but, despite a substantial body of epidemiological and scientific publications, this is a field beset by controversy. For a detailed discussion of the problems see Walker-Bone and Cooper[30] and Harald et al.[31]

Myofascial pain syndrome

Myofascial pain is characterized by local areas of muscle tension and spasm which can often be felt as tender nodules forming the basis of the condition long described as 'fibrositis'. It occurs commonly around the shoulder girdle with pain felt in the neck, shoulder blade, axilla, and upper chest. Myofascial pain may occur as a primary phenomenon or complicate other soft tissue conditions. It is associated with psychological factors such as depression, stress, fatigue, and anxiety. Trigger points (irritable foci within skeletal muscles and their ligamentous junctions that produce characteristic referred pain when palpated) are considered important in the diagnosis of the syndrome, although the reliability of detection has been questioned.[32]

Although myofascial pain syndromes have been described in the medical literature for over a century they are often overlooked as a cause of a patient's symptoms, leading to unnecessary investigations and inappropriate treatments. Myofascial pain can be a useful explanation for a patient's symptoms and a diagnosis on which to logically introduce exercise and other self-management strategies. The utility of other treatment techniques such as trigger and tender point injection remains controversial. The clinician will understand the complex interactions between soma and psyche and make a diagnosis of myofascial pain a positive one, rather than just the absence of organic pathology. For a history see Wikipedia and reviews by Bennett, Gerwin, and Delago et al.[33–35]

Polymyalgia

Case history

Ms HG, aged 72 years, went to her GP complaining of generalized pain and stiffness for 6 months but in particular around her shoulders and thighs. She said the symptoms came on gradually over a few weeks and were eased by taking ibuprofen. The symptoms were bad at night with morning stiffness and her sleep was disturbed. She felt tired, weak and generally unwell. On examination her body mass index (BMI) was 34. She had difficulty rising from a chair without using her arms. There were diffuse tender points around her neck and lower back. Cervical and lumbar movements were full but uncomfortable. Temporal arteries appeared normal and there was no obvious muscle wasting or fasciculation. General examination was normal. Her ESR was 44 mm/h with normal blood count (Thompson, personal communication).

What is your diagnosis? What further tests would you perform? How do you think she would respond to a trial of glucocorticosteroids?

The main differential diagnoses are polymyalgia rheumatica (PMR), fibromyalgia (FMS), and polymyositis (PM) with lymphoma, metastatic disease, and hypothyroidism important disorders needing consideration.

Polymyalgia rheumatica

The British Society of Rheumatology guidelines on the management of PMR recommend evaluating four core inclusion criteria: (1) age over 50 years, duration greater than 2 weeks, (2) bilateral shoulder or pelvic girdle aching, or both, (3) morning stiffness duration of greater than 45 min and, (4) evidence of an acute-phase response. They recommend further investigations and a trial of glucocorticosteroid treatment as the response to treatment is an important part of the diagnostic triage.[36]

In Ms G's case she fulfils the first two criteria but we are unsure of the duration of morning stiffness. How reliable is this as a symptom? Finally, does she have evidence of an acute-phase response? At first sight an ESR of 44 mm/h seems pathological and would be reported as such in the author's hospital where the upper limit of normal is 12 mm/h. However, the ESR is a composite measure affected by circulating acute-phase proteins, paraproteins, fibrinogen, and red cell size and shape. The ESR is higher in women than in men, and goes up linearly with age. A formula has been suggested:[37]

ESR = [age +10 (women)]/2.

For our patient this means an ESR of up to 41mm/h would be considered within the normal range. In addition to age changes, obesity is associated with an increased ESR. Differences of up to 20% have been reported, making an ESR of 41 mm/h in our case an unreliable marker of an acute-phase response.

A trial of modest doses of oral or intramuscular glucocorticosteroids would be expected to result in a dramatic and sustained improvement in symptoms within a few days, helping to confirm the diagnosis.

Fibromyalgia

Chronic, widespread pain is the defining feature of FMS, but patients may also exhibit a range of other symptoms, including sleep disturbance, fatigue, irritable bowel syndrome, headache, and mood disorders.

The introduction of the American College of Rheumatology (ACR) fibromyalgia classification criteria 20 years ago began an era of increased recognition of the syndrome. The criteria required tenderness on pressure (tender points) in at least 11 of 18 specified sites and the presence of widespread pain for diagnosis. A major revision of the criteria for diagnosis has turned the disorder into one of symptoms. The new criteria are based on patient-reported pain, the widespread pain index, and a symptom severity index consisting of self-reported fatigue and unrefreshed waking, and

a wide range of cognitive and systemic symptoms all scored 0 to 3. Patients no longer need to be examined or investigated to make the diagnosis, although a caveat that 'the patient does not have a disorder that would otherwise explain the pain', has been introduced.[38]

In the recent European League Against Rheumatism (EULAR) recommendations for the treatment of FMS there was a negative recommendation for the use of glucocorticosteroids, based on expert opinion that appears to rely on the lack of evidence rather than the evidence of lack of efficacy.[39]

In Ms G's case, while we do not have the detailed self-reported severity scale, it seems likely that she would fulfil the diagnostic criteria, provided we did not consider that her symptoms were caused by PMR. A response to glucocorticosteroids would not be expected although a partial, non-specific improvement, particularly to intramuscular injection, is not uncommon in the author's experience.

Polymyositis

The diagnostic criteria for the autoimmune inflammatory myopathies were formulated by Bohan and Peter in 1975. Their system was (1) primary idiopathic polymyositis (PM), (2) primary idiopathic dermatomyositis (DM), (3) PM or DM with malignancy, (4) juvenile DM (or PM) associated with vasculitis and (5) PM or DM with associated collagen vascular diseases. However, they did not recognize inclusion body myositis or other inflammatory myopathies, such as granulomatous and eosinophilic myositis. While new histological techniques have introduced great potential for a classification that helps in management and prognosis, no consensus has yet been reached as to an alternative. The International Myositis Assessment and Clinical Studies Group is currently coordinating a project to produce a new classification that distinguishes inflammatory myositis from other major mimicking conditions and separates the subtypes from each other.[40]

In Ms G's case further investigations will be needed to make the diagnosis and a response to glucocorticosteroid therapy anticipated, although at much higher doses than that needed to control PMR.

Connective tissue diseases

Case history

Mrs CM, a 23-year-old white woman, presented to her doctor with a 3 year history of joint pains and fatigue. She said that the pains were particularly bad in the mornings and were now interfering with her work as a nursery nurse. On direct questioning she said her hands were always cold and white and she developed chilblains on her toes in the winter. Examination revealed a livido reticularis rash on her thighs but no joint swelling or nail fold abnormalities. Her antinuclear factor was weakly positive but her anti-dsDNA antibodies and extractible nuclear antibody screen was negative (Thompson, personal communication).

How would you classify this patient's condition? Are there other tests that might be helpful? How would you treat her? What prognosis would you offer her?

The term connective tissue disease (CTD) refers to a group of autoimmune disorders that are classified among the systemic rheumatic diseases and include systemic lupus erythematosus (SLE), systemic

Table 3.1 Clinical manifestations of connective tissue diseases associated with autoantibody reactivities

Clinical manifestations	Autoantibody reactivities
Malar rash	Anti-dsDNA
Subacute discoid LE	Anti-Sm
Chronic discoid LE	Anti-P protein
Skin sclerosis	Anti-Scl70
Heliotrope rash	Anti-centromere
Gottron's papules	Anti-La/SSB
Erosive arthritis	Anti-Jo1
	Anti-Mi2

LE, lupus erythematosus.

sclerosis (SSc), polymyositis-dermatomyositis (PM-DM), primary Sjögren's syndrome (pSS), primary anti-phospholipid syndrome (APS), and mixed connective tissue disease (MCTD). Classification of CTDs depends on a patient developing some disease-specific manifestations, e.g. Gottron's papules in DM, or a cluster of non-specific but characteristic findings associated with autoantibody reactivities considered to be specific for a definite CTD (Table 3.1).

The sharing of immunogenic features in these conditions may be why patients present with common clinical features. Taken together they can often represent the onset of a classifiable CTD; remain 'undifferentiated' but associated with a positive anti-nuclear antibody (ANA) suggesting a true autoimmune condition; or remain unclassifiable—for example, many patients presenting with arthralgias and primary Raynaud's phenomenon will have no other features of a CTD and be autoantibody negative. There is considerable debate as to whether those patients have an incomplete or undifferentiated CTD or have more in common with pain syndromes such as fibromyalgia. For a more detailed discussion see Doria et al.[41]

The elderly patient

Fraser Birrell and Janice O'Connell

Introduction

Rheumatological diseases are among the most common causes of disability in older people.[1] In the most recent United States National Health Interview Survey (2007–9), 50% of adults 65 years or older reported an arthritis diagnosis, of whom 42% had activity limitation attributable to the arthritis.[2] The prevalence continues to rise with age, even in the elderly population: by the age of 85, the lifetime prevalence of arthritis diagnosed by the GP in the UK is 65%.[3] Preservation of motor function is key to the maintenance of independent living in old age, with loss or decline in the ability to walk often being the deciding factor in determining the need for supportive or institutional care. It is clear, therefore, that the rheumatologist has a vital role to play in terms of diagnosis and management of musculoskeletal problems in older people.

Rheumatological practice in old age brings with it a number of challenges that set it apart from the treatment of middle-aged adults, not least the paucity of evidence as old age is often an exclusion from clinical trials.[4] Although some conditions are seen in adults of all ages, the clinical presentation and treatment goals will differ in the frail older person with complex comorbidities. Furthermore, there are some specific conditions that are seen mainly in old age, such as polymyalgia rheumatica.

Epidemiology

The prevalence of degenerative and some inflammatory musculoskeletal diseases increase with age. Osteoarthritis is the most common joint disorder seen in Europe and North America.[5,6] The prevalence varies depending on the definition and joint(s) that are considered. A recent cohort study performed in the Netherlands found that 67% of women and 55% of men aged over 55 years had radiographic evidence of osteoarthritis of their hands.[7] However, not all patients with radiographic changes of arthritis are symptomatic and this may result in discrepancies between different studies of the prevalence of osteoarthritis in various joints. While osteoarthritis is the most common form, affecting women more than men (GP notes diagnosis: knee 33%, hip 20%, hand 9% in women vs. knee 27%, hip 13%, hand 5% in men who reach 85 years[3]). Soft tissue problems, including shoulder problems (adhesive capsulitis, rotator cuff disease, bicipital tendonitis), greater trochanter pain syndrome (the equivalent 'rotator cuff disease of the hip' previously thought to be trochanteric bursitis) and axial disease (including neck and back syndromes) are also more common. Back pain has different implications in this age group, with age itself being a key 'red flag' triggering investigation to rule out a differential diagnosis which includes osteoporotic collapse and malignancy.

Rheumatoid arthritis (RA) also becomes more common from middle age onwards, reaching a prevalence of 5% in females at 85, compared to 0.5% of males. This is a key learning point, as RA is often wrongly stated to be most common in middle age. The rising age-specific incidence and rare occurrence of remission determines that prevalence increases progressively with age.

Crystal arthritis is also more common, with incident gout in 4.4 men vs. 1.3 women per 1000 patient-years in the UK, with the highest rate in those over 80 years.[8] Over a 52-year follow up of the Framingham cohort, 200 men (period prevalence 10%) and 104 of women (4%) developed gout, with similar predictors in men and women: increasing age, obesity, alcohol consumption, hypertension, and diuretic use.[9] Calcium pyrophosphate deposition (CPPD) now has agreed terminology and diagnostic recommendations,[10] with risk factors including ageing, osteoarthritis, and metabolic conditions such as primary hyperparathyroidism, haemochromatosis and hypomagnesaemia. The prevalence of CPPD is 7–10% in those aged 60 years—equal in men and women.[11]

The Hordaland Health Study in Norway reported that the prevalence of primary Sjögren's syndrome was approximately seven times higher in the elderly population (age 71–74 years) compared with individuals aged 40–44 years.[12] Reported prevalence rates vary from 0.1% to 2.7%, depending on the population studied and the classification criteria used.[13] Increased survival and higher incidence rates of systemic lupus erythematosus (SLE) contribute to an increasing prevalence of SLE in the elderly population. Most estimates vary from 0.15% to 0.51%, although some based on self-report diagnosis are as high as 1.2%.

Definitions, classification criteria and diagnostic criteria where appropriate

Frailty

The syndrome of physical frailty in old age is easy to recognize, but perhaps more difficult to define. Various definitions of 'frailty' have been proposed, ranging from the social model focusing on functional dependence to descriptions based on medical comorbidities.[14] Frailty certainly encompasses loss of independence in one's

activities of daily living. However, this is a simplistic notion and fails to acknowledge that frailty in the older person is probably a dynamic rather than a static concept. For any individual, there will be a number of different factors that determine if they can still live independently in their own home. This dynamic model of frailty was first described by Brocklehurst,[15] and describes the assets and deficits that help an older person retain their independence in the community. These assets and deficits include a mixture of socio-economic and medical factors. This concept of the dynamic model of frailty is useful to the clinician. In a fit elderly person, their assets will clearly outweigh any concurrent deficits. However, in someone who is more frail, there will be a fine balance between the positive and negative factors that affect independent living. Only a small change in their condition will be required in order to tip the balance in favour of deficits, resulting in loss of independence. This tipping point could be a relatively minor insult that would cause only inconvenience to a younger patient, e.g. a urinary tract infection or monoarticular flare of arthritis.

This view of frailty as a dynamic process is consistent with the decline in physiological reserve that can be recognized with ageing. Ageing is probably best considered as a continuum. The function of most organ systems reaches a peak in the mid-twenties and thereafter a gradual decline may be observed. The process of ageing occurs at a variable rate in different people, influenced by a number of intrinsic (genetic) and extrinsic (environmental and lifestyle) factors. In younger people, organ systems have considerable reserve capacity that is superfluous to normal daily requirements, but is available to respond to any severe physiological stress placed on the individual. Involutional changes with ageing lead to a gradual reduction in this reserve capacity and thus the older person may be unable to mount an adequate response to the additional physiological stresses imposed by acute illness or injury. This rapid decline in functional ability is often witnessed in clinical practice, for example following osteoporotic femoral neck fractures.

Sarcopenia

Changes in the musculoskeletal system with the advancing years are among the most obvious signs of age-related physiological decline. Most people achieve their peak muscle strength in their mid-twenties and in healthy individuals this remains fairly constant up to their fifth decade, at which time decline tends to occur. This age-related loss of muscle mass and strength is termed sarcopenia and is seen in more than 50% of people aged over 80 years. A recent large meta-analysis examined the patterns of loss of muscle strength seen in the general population, confirming the functional decline with age and the acceleration seen after the age of 50 years (0.37kg/yr for hand grip).[16] Sarcopenia is likely to be multifactorial in aetiology, with potential contributory causes including level of physical activity, metabolic, endocrine, and nutritional factors. Moreover, muscle strength is also adversely affected by the presence and duration of inflammatory conditions such as RA.

Age-related changes in bone structure and density are covered in detail elsewhere in this book. However, any discussion of the musculoskeletal system in the older patient must include some consideration of the impact of osteoporosis. Patients with RA, osteoarthritis, and the other conditions mentioned in this chapter are at increased risk of osteoporosis, not only due to their relative immobility but also because many of their prescribed medications can contribute to bone loss. Thus, the role of the rheumatologist

includes consideration of the need for anti-resorptive therapy in all older patients, especially those receiving long-term corticosteroid therapy. This would generally be done after calculation of the 10-year fracture risk using the FRAX website (www.sheffield.ac.uk/FRAX/) or downloadable freestanding app, and linking to the treatment recommendation according to the National Osteoporosis Guideline Group recommendations,[17] in view of ongoing controversy with respect to the NICE technology appraisals[18,19] and in the continued absence of a NICE Clinical Guideline in this area (see Chapter 151).

Clinical features

General principles of disease presentation in old age

Clinical diagnosis in older patients is often fraught with difficulty. Patients may minimize, discount, or ignore relevant symptoms, assuming that these are simply part of the normal ageing process. Furthermore, atypical or non-specific disease presentation is frequent in elderly people. The late Professor Bernard Isaacs first coined the phrase 'geriatric giants' to describe the common clinical presentations seen in older people.[20] The original giants as described by Isaacs were the '4 I s' of Incontinence, Immobility, Impaired intellect (delirium), and Instability (falls). He claimed that, if the physician looked closely enough, all common problems with older people could be related back to one of these giants. In the case of rheumatological disease, there is no doubt that musculoskeletal disease is a major contributor to the risk of immobility and falls in the older person. While the relevance of the other geriatric giants may be initially less obvious, immobility resulting from osteoarthritis could contribute to urinary incontinence and opioid analgesics prescribed for the same condition could cause acute confusion. Indeed, to the original 4 Is described by Isaacs, we should probably add another two: Iatrogenic disease and Inability to look after oneself. The former recognizes the increased likelihood of adverse reactions to medications in older people and the latter the functional decline that often accompanies illness in old age, akin to the syndrome of failure to thrive in children.

Multiple comorbidities

The presence of multiple comorbid illnesses is the norm rather than the exception in older patients. As noted above, disease presentation in old age is often non-specific, with one or more of the geriatric giants. Furthermore, many of the symptoms of rheumatological disease are themselves quite non-specific, for example fatigue, aches, and pains. Patients may find it difficult to describe their current symptoms, especially if they accustomed to some degree of chronic discomfort relating to pre-existing conditions. Diagnosis of musculoskeletal complaints in older individuals with chronic health problems is thus more challenging than in younger patients with symptoms due to a single condition. In the elderly, it is not uncommon for more than one rheumatological illness to coexist in the same person, for example polymyalgia rheumatica and degenerative disease of the cervical spine. In such cases, it may be difficult for the physician to determine the relative contribution of each condition to the patient's overall symptom burden and treatment decisions can be challenging. Moreover, some non-rheumatic conditions that are common in older age groups can present with musculoskeletal symptoms. An example of this is statin-induced myopathy, which can develop after prolonged treatment with HMG CoA reductase

inhibitors for hypercholesterolaemia and may mimic polymyositis.[21] In addition, treatments prescribed for chronic illnesses in other body systems can themselves lead to the development of musculoskeletal conditions. Acute gout is not uncommon in patients given large doses of loop diuretics for congestive heart failure.

Case history

A 72-year-old retired miner with a 7-year history of seropositive (titre 1:320) RA and mild generalized osteoarthritis developed haemoptysis, anorexia, and weight loss. He had a 6-year history of diet controlled, non-insulin dependent diabetes mellitus, hypercholesterolaemia, ischaemic heart disease (myocardial infarction 1978, triple coronary artery bypass grafting 1978 and 1982). He had had right carpal tunnel decompression in 2000 and been diagnosed with emphysema and coal workers pneumoconiosis by the respiratory team 5 years previously. His wife also had RA and they lived in a bungalow with good support from family and friends. He was an ex-smoker of 50 packet-years. Both he and his wife were involved in undergraduate teaching of third-year medical students.

He was taking subcutaneous methotrexate 35 mg weekly, with oral folate, aspirin, omeprazole, paracetamol, iron, simvastatin; and beclomethasone and salbutamol inhalers.

A chest radiograph showed a mass at the right hilum with peripheral consolidation. This was confirmed on bronchoscopy to be a squamous cell carcinoma, but did not respond to radiotherapy and he died 6 months later with metastatic disease of the liver and bones.

Functional and social problems

The presence of multiple comorbidities, together with the propensity of acute illness to manifest in non-specific ways, means that older people often present to healthcare services as a result of a decline in their functional abilities. Terms such as 'social admission' should always be avoided, since in the vast majority of cases underlying illness, injury, drug toxicity, or withdrawal will be diagnosed after appropriate investigation. As mentioned above, relatively minor insults such as constipation, urinary infection, or new joint pain can be sufficient to precipitate a rapid functional decline in a frail older person. Indeed, it is often the combination of several small physiological insults that results in the crisis admission to secondary care.

It is evident that clinical assessment of any older person with a musculoskeletal problem is incomplete without due consideration of the impact of their symptoms on their functional abilities. Evaluation of the patient by history and examination should incorporate inspection of their gait, as is routine in rheumatological practice. However, in the frail older person it is also advisable to assess the safety of their transfers and this can be combined with observation of their gait in the 'get up and go test'.[22] The challenge for the rheumatologist may be to determine the relative contribution of several coexisting problems to the patient's current immobility, for example antalgic gait in an older person with kyphosis, low back pain, and arthritic knees. Clinical assessment of the patient can be supplemented by the use of standardized scales, which quantify the ability of the patient to carry out common everyday tasks or activities of daily living (ADL). The Barthel Index is used commonly in UK clinical practice and assesses the most basic personal ADL such as feeding, dressing, bathing, and toileting.[23] Patients who are dependent in one or more of these ADLs are likely to require daily support from others.

The term 'comprehensive geriatric assessment' is often used to describe the multidisciplinary team approach to the management of the frail older person presenting with a recent functional decline. This assessment should encompass social and functional problems as well as medical and psychiatric issues and the resulting management plan should usually include rehabilitation in addition to medical treatments. The functional issues arising from musculoskeletal illness are not restricted to older patients, as many younger people with rheumatological conditions may also experience difficulties with personal or extended ADLs. Rheumatologists are well placed to recognize such disability in their older patients and are likely to work within established multidisciplinary teams with considerable experience in musculoskeletal rehabilitation. In the older patient, the social and psychological aspects of their condition may be especially challenging. The former may include social isolation, recent bereavement or change in accommodation; the latter is discussed in more detail below.

Depression, delirium, and dementia

Depression is a common accompaniment to many chronic diseases, including musculoskeletal conditions. The aetiology of depression in patients with chronic illness is not well understood, but is likely to be multifactorial; contributory factors may include the patient's emotional response to the diagnosis, the functional limitations imposed by the illness and, especially in the case of many rheumatological problems, the effects of chronic pain. Moreover, the relationship between depression and the coexisting chronic physical illness can complicate the clinical presentation, diagnosis, and management of both conditions. Depression in older people can lead to concordance issues with the treatments prescribed for other illnesses. This can be of particular concern with the use of drugs that require strict adherence to a dosage and monitoring schedule, for example disease-modifying anti-rheumatic drugs (DMARDs) in patients with inflammatory arthropathies. A recent systematic review examined 14 studies of varying interventions in older people with osteoarthritis and depression. Strategies such as cognitive behavioural therapy, integrated depression care management, and exercise therapy were associated with a short-term reduction in depressive symptoms. The long-term benefits of depression management in patients with osteoarthritis are unclear.[24] However, physicians must be alert to the possibility that depression may be contributing to the clinical picture in older patients presenting with musculoskeletal problems, especially when symptoms fail to respond as anticipated to usual treatments. Standardized assessment tools such as the Geriatric Depression Scale[25] may be useful in screening for low mood when there is clinical suspicion.

Delirium or 'acute confusional state' is one of the four geriatric giants originally described by Isaacs. The clinical features include disturbances in consciousness, cognition, and perception. The onset is acute, developing over one or two days, and there is often a pronounced diurnal fluctuation in symptoms. Delirium can be difficult to distinguish from dementia when the time course of symptoms is unclear, particularly since elderly people and those with pre-existing cognitive problems are at increased risk of developing

delirium. The prevalence of delirium amongst hospital in-patients is estimated to be 20–30% on general medical wards and 10–50% on surgical wards.[26] The consequences of delirium are significant both for the individuals affected and for health and social care services. Delirium is associated with longer length of stay in hospital, more frequent complications, higher mortality rates, and increased likelihood of discharge to institutional care. Delirium may be precipitated by acute illness, injury, systemic insult, drug toxicity or withdrawal, and often by a combination of several of these factors. It is particularly common after fractures of the femoral neck in frail older people, who often have an underlying acute illness that contributed to their fall and then require emergency orthopaedic surgery. However, delirium may also occur after elective surgery such as joint replacement and it is important that any preoperative consultation between physician, patient, and carers should include discussion of the possibility of postoperative confusion.[27] A detailed description of the management of delirium is beyond the scope of this chapter. However, rheumatologists need to be aware of the risks of delirium in any of their older patients, particularly when hospitalized with acute illness and including exacerbations of their joint disease. NICE recommends screening all patients aged over 65 years for risk of delirium, and standardized tools such as the Confusion Assessment Method (CAM) can be helpful in this regard. Interventions such as medication review and management of treatable symptoms such as pain, constipation, and dehydration can be helpful in both the prevention and management of delirium in the older patient. In difficult cases, advice may be sought from colleagues in geriatric medicine.

As with musculoskeletal disorders, the risk of developing dementia increases with age. The rheumatologist is therefore likely to encounter patients with coexisting musculoskeletal and cognitive problems. The prevalence of dementia is estimated to be around 10% in people aged over 65 years, rising to more than 20% of those over 80. Alzheimer's disease is the most common form of dementia, accounting for about two-thirds of cases, with other frequent causes being vascular dementia and dementia with Lewy bodies. All types of dementia lead to progressive cognitive deficits, with a resulting decline in functional abilities. Patients with dementia lose the ability to handle new information and may also develop loss of executive function, with difficulties in organization, planning, and sequencing. This will be of concern to clinicians who wish to initiate complex treatment regimens for newly diagnosed illnesses such as RA, but are worried about the patient's ability to adhere to the prescribed treatment. Disorders of speech and language such as dysphasia are not confined to patients with cerebrovascular cognitive impairment, but may also be seen in other forms of dementia. Diagnosis of musculoskeletal complaints may be challenging in patients who have such word-finding difficulties and are unable to provide a clear description of their symptoms. Non-verbal cues to the presence of symptoms like pain assume more importance, and the observations of the patient's carers regarding their recent behaviour can be invaluable. Behavioural changes such as agitation, aggression, and wandering become more prevalent with advancing dementia. Although pain is not the only possible explanation for agitation in a person with dementia, physicians should ensure that adequate analgesia is prescribed for patients with known or suspected musculoskeletal complaints. A recent cluster randomized controlled trial has in fact shown that a systematic approach to the management of pain, using a stepwise protocol starting with paracetamol, resulted in a significant reduction in agitation in nursing home residents with moderate to severe dementia.[28] In the later stages of dementia, the patient may become physically dependent on others and develop dysphagia, leading to difficulties swallowing food, fluids, and medication. In such cases, pragmatic decisions regarding symptomatic treatment of coexisting musculoskeletal complaints should be made in conjunction with the patient's family and general practitioner. In such cases a palliative approach to end-of-life care may be appropriate.

Case history

Edward was a retired teacher with a 10-year history of seronegative RA. His symptoms responded initially to treatment with methotrexate 15 mg weekly, but he could not tolerate a higher dose, which gave him gastrointestinal upset, despite folate supplementation on the other days of the week. This had to be stepped up to triple therapy (adding sulfasalazine and hydroxychloroquine) following a polyarticular flare of his disease that required a short period of in-patient treatment.

There followed a year of clinical stability on his new drug regime, which was monitored with monthly blood tests at the GP's surgery and annual review at the rheumatology nurse clinic. At this appointment Edward's wife reported to the nurse that her husband was becoming forgetful and often needed to be reminded to take his arthritis medication.

Three days after his 75th birthday, Edward was admitted to the acute geriatric assessment unit with delirium and urinary incontinence. His inflammatory markers are raised and he was noted to have a swollen, painful right knee. Joint aspiration excludes septic arthritis and a rheumatology consult confirmed an exacerbation of his inflammatory arthritis. Analgesia was prescribed and his triple therapy continued.

Edward's daughter reported that his wife died 2 months before this admission to hospital and the family were concerned that he had been failing to cope at home because of his poor memory. A full multidisciplinary assessment was undertaken before Edward was discharged from hospital, including supply of a medication dosette box from the community pharmacy. He was also referred to the memory clinic, where a diagnosis of Alzheimer's disease was confirmed.

Three months later, Edward was readmitted to hospital after being found on the floor by his carer. He had fractured his right neck of femur, which required internal fixation under general anaesthesia. After a prolonged period of postoperative delirium, he was transferred to the orthogeriatric ward for rehabilitation. He remained confused, did not regain his previous level of mobility, and could only walk a few metres with a frame. He was discharged to a nursing home. Over the next few months, Edward's condition deteriorated gradually and his verbal output diminished. He had difficulty expressing his needs. The care staff reported to his GP that he sometimes refused his medication. After consulting Edward's daughter and his rheumatologist, the GP stopped the triple therapy and prescribed regular non-oral analgesia and as required intramuscular corticosteroid. Edward was commenced on the Liverpool Care Pathway (LCP) and died peacefully 3 weeks later.

Differences in disease in the elderly

It is worth considering the relevance of new classification criteria and guidelines to musculoskeletal disease in the elderly. These include the new EULAR/ACR classification criteria for RA,[29] which have not yet been validated in any elderly population, but have similar discrimination to previous criteria in younger populations (e.g. Britsemmer et al.[30]). Subtypes of disease have been described, for example benign RA of the elderly[31–33] and remitting seronegative symmetrical synovitis with pitting oedema (RS3PE),[34] both of which have an excellent prognosis. It would be useful for these subtypes to be investigated using current imaging modalities—especially musculoskeletal ultrasound to confirm that synovitis is present, as polymyalgia rheumatica is an important differential diagnosis in the this age group. There are particular challenges for implementing the clinical guidance for RA[35] in this age group, who may not wish to attend hospital so frequently and may be reluctant to start combination regimes of disease-modifying drugs, especially if they are already taking several medications for comorbid conditions.

Osteoarthritis has clear clinical guidance,[36] which explicitly flags that age is no barrier to key non-pharmacological interventions: education, aerobic and strengthening exercise, and weight loss advice. However, there are increased risks drugs such as non-steroidal anti-inflammatories, including cardiovascular and cerebrovascular risks. There is also new data showing that over-the-counter medications like paracetamol are not without risk and have very modest efficacy: 20% of those taking 3 g of paracetamol for knee pain over 3 months had a drop in haemoglobin of 1 g/dL or more.[10,37]

Drugs in older people

Elderly people have a higher frequency of chronic renal impairment of varying degrees, so dose adjustment will often be necessary for drugs like methotrexate, where clearance is by the kidneys. A typical patient with RA might start on methotrexate monotherapy and escalate to 15 or 20 mg orally per week, depending on renal function, compared to the usual target dose of 25 mg (although there are exceptions—see case history). Similarly, colchicine doses should be reduced, so that acute gout attacks, or the introduction of prophylactic therapy can be covered with 500 micrograms once a day, or even alternate days, rather than usual regime of two to three times a day.

The coexistence of cardio- and/or cerebrovascular disease also warrants extreme caution in the prescribing of non-steroidal anti-inflammatory drugs in this age group and preference for naproxen in those who need them. Coprescription of a proton pump inhibitor is even more cost effective than in younger patients in mitigating the upper gastrointestinal risks.

In contrast, dose reduction of leflunomide is not recommended. However, interactions are more common in view of polypharmacy, including consideration of agents such as warfarin, with the potential for life threatening bleeds; or inducers of the cytochrome P450 system, which can have effects on the clearance of many drugs.

Principles of clinical examination in children

Sharmila Jandial and Helen Foster

Background

Musculoskeletal (MSK) presentations in childhood are common and rank highly in the self-reported health problems amongst adolescents.[1] MSK presentations result from a spectrum of causes (Table 5.1),[2] and the majority are benign and self-limiting although it is important to note that MSK symptoms can be presenting features of potentially life-threatening conditions such as malignancy, sepsis, vasculitis and non-accidental injury. Furthermore, MSK features often have associations with many chronic paediatric conditions such as inflammatory bowel disease, cystic fibrosis and psoriasis. Referral pathways for children with MSK problems are often complex, depending on local health care provision and organization. Adult rheumatologists play an important part in the triage of children, are integral to referral to specialist paediatric services, and in many areas of the world continue to have a direct role in management of children and young people with rheumatic disease.

It is increasingly apparent that prompt, accurate diagnosis and specialist management are important to optimize outcomes in many MSK conditions in children and young people. This is especially important with acute conditions such as septic arthritis, osteomyelitis or malignancy (e.g. leukaemia or bone tumour) where delay can incur significant morbidity and indeed mortality, but also applies to orthopaedic conditions (such as slipped upper femoral epiphysis or Perthes' disease) or inflammatory arthritis such as juvenile idiopathic arthritis (JIA) where delay increases the risk of significant joint damage and functional disability. With inflammatory arthritis such as JIA, there has been a marked trend towards early and aggressive management in recent decades, with increasingly effective treatments such as methotrexate and biologicals. The importance of early diagnosis and prompt referral to specialist teams is therefore increasingly relevant.[3–6]

The reported global delay in access to care for JIA and other conditions with MSK presentations such as muscular dystrophy and cancer[7,8], is likely multifactorial but evidence clearly highlights the need to improve MSK clinical skills amongst healthcare professionals to whom children may present. Invariably, children do not present directly to paediatric rheumatologists or paediatric orthopaedic surgeons, but to primary care or paediatricians, who will through their assessment, determine subsequent management and referral pathways to specialist services. Within clinical practice poor documentation of MSK assessment

Table 5.1 Differential diagnosis of musculoskeletal pain in children and adolescents

Life-threatening conditions	Malignancy (leukaemia, lymphoma, bone tumour)
	Sepsis (septic arthritis, osteomyelitis)
	Non-accidental injury
Joint pain with minimal or no swelling	Hypermobility syndromes
	Orthopaedic syndromes (e.g. Osgood–Schlatter disease, Perthes' disease)
	Idiopathic pain syndromes (reflex sympathetic dystrophy, fibromyalgia)
	Metabolic (e.g. hypothyroidism, lysosomal storage diseases)
	Tumour (benign and malignant)
Joint pain with swelling	Trauma (haemarthrosis)
	Infection
	Septic arthritis and osteomyelitis (viral, bacterial, mycobacterial)
	Reactive arthritis (postenteric, sexually acquired)
	Infection-related (rheumatic fever, post-vaccination)
	JIA
	Arthritis related to inflammatory bowel disease
	Connective tissue diseases (SLE, scleroderma, dermatomyositis, vasculitis)
	Metabolic (e.g. osteomalacia/rickets, cystic fibrosis)
	Haematological (e.g. haemophilia, haemoglobinopathy)
	Tumour (benign and malignant)
	Chromosomal (e.g. Down's-related arthritis)
	Auto-inflammatory syndromes (e.g. periodic syndromes, chronic recurrent multifocal osteomyelitis)
	Sarcoidosis
	Developmental/congenital (e.g. achondroplasia)

JIA, juvenile idiopathic arthritis; SLE, systemic lupus erythematosus.

Adapted from Foster H, Tucker LB. Musculoskeletal disorders in children and adolescents. In: Adebajo A (ed.) *ABC of rheumatology*, 4th edn. BMJ Books, London, 2009:98–106).

has been observed in general paediatric medical clerking, even in those children presenting with MSK symptoms,[9] and many doctors in primary and secondary care (including paediatrics, emergency medicine, and even orthopaedics) report poor self confidence in their paediatric MSK (pMSK) clinical skills;[10] such observations may be explained by pMSK clinical skills not being 'core' teaching in medical schools[11] or postgraduate programmes.[12]

Appropriate triage of children requires MSK clinical skills and knowledge to manage patients appropriately, and prompt referral. Acquisition of such 'core' pMSK clinical skills needs to start within undergraduate education as the foundation for further postgraduate training, with MSK assessment being integral to the assessment of all children and especially when a child presents with muscle, joint, or bone pain (with or without fever), limp, functional disability, delayed or regression of motor milestones, and in children with chronic conditions where MSK involvement is well recognized and can cause significant morbidity. Box 5.1 lists themes that are regarded as 'core' for all medical students to acquire by the time of graduation from medical school (S. Jandial, personal communication); this list was derived from using consensus methodology involving paediatricians and primary care doctors as well as specialists in paediatric rheumatology and orthopaedics and comprises generic skills (e.g. knowledge of 'red flags') as well as specific MSK (e.g. knowledge of normal development and indicators of pathology). The evidence-based approach to pMSK clinical examination includes a basic examination (pGALS) and a more detailed regional MSK examination (pREMS) which are described later in this chapter. Interpretation of pMSK assessment must be interpreted in the context of general assessment of the child, especially in the unwell child or in the context of red flags. A comprehensive account of detailed joint examination techniques in children and young people is not given here but suggested texts are provided as further reading.

'Children are not small adults' ... the approach to musculoskeletal clinical assessment in children and young people

The approach to pMSK assessment is quite different from that of adults,[13] needing awareness of age-related growth and development (as described in Chapter 1); this includes normal lower limb alignment, major motor milestones, and gait (Table 5.2), and knowledge and recognition of normal variants (Table 5.3). Indeed, many parental concerns arise from observations that may well be normal, e.g. flat feet in a preschool child. It is important to know that the spectrum of pathology varies with age, such as with the limping child (Table 5.4) and the child must be assessed carefully in the context of knowledge of normal development, and awareness of red flags (such as fever, malaise, anorexia, weight loss, bone pain, persistent night waking, or raised inflammatory markers) suggestive

---

Box 5.1 Core themes of undergraduate learning outcomes for pMSK medicine

Core paediatric skills

◆ Use appropriate behaviour and language, and modify history-taking and examination according to child's developmental stage

◆ Demonstrate an understanding of ways to engage children when examining to maintain cooperation and minimize discomfort.

◆ Outline the principles of managing children with chronic disease (e.g. considering impact on school, play, and family; need for medications and monitoring; and the role of healthcare professionals)

Attainment of clinical skills for pMSK medicine

◆ Recognize the need for extended musculoskeletal history in certain presentations (e.g. limp, pain, rashes, refusing to walk)

◆ Recognize features in the history that may distinguish mechanical from inflammatory musculoskeletal pathology

◆ Perform a basic examination of the musculoskeletal system (e.g. pGALS) understanding that positive findings should lead to more detailed examination incorporating a 'look, feel, move' approach.

Recognition of red flag conditions such as malignancy, infection, or inflammatory disease

◆ Recognize clinical features suggestive of a septic joint and the place of appropriate investigations and referral.

◆ Identify the role of blood tests such as full blood count or acute-phase reactants, and discuss these results in context of musculoskeletal presentations and potential implications (e.g. raised white cell count and possible sepsis)

◆ Describe musculoskeletal presentations of malignancy such as nocturnal bone pain, swelling, systemic features such as weight loss

Understand normal pMSK findings

◆ Recognize that normal children have increased joint flexibility compared to adults and may be hypermobile

◆ Observe and describe principles of gait patterns (e.g. symmetry, leg alignment, presence of pain, limp)

◆ Demonstrate awareness that leg alignment and foot posture changes with age and normal variants within these—knock knees, bow legs, flat feet, intoeing

Table 5.2 Normal variants of lower limb development

	Indications for concern and referral to physiotherapy or paediatric orthopaedics unless specified	Comments
Tiptoe walking Common in healthy young children	Toe walking is persistent or asymmetrical Associated developmental delay Child unable to squat or stand with heels on the floor (tightness of calf muscles) Child >3 years old, and unable to stand from floor-sitting without using hands	Can associate with clubfoot or neurological disease (e.g. muscular dystrophy, cerebral palsy, poliomyelitis). Careful neuromuscular/ assessment required. Check for gastrocnemius contracture and shoes for sole wear. Physiotherapy may help mild cases but surgery may be required
Flat feet Common and normal for babies and toddlers, resolves with development of longitudinal arch usually by 4–6 years of age	Signs of pressure on the foot, e.g. blistering Longitudinal arch does not form normally when the child stands on tiptoe Foot is stiff (i.e. the normal arch does not form when the child stands on tiptoe or the big toe is passively extended)	Persistence often familial, more common in hypermobility Insoles may help but should not be worn all the time—walking in bare feet helps promote foot development A non-flexible flat foot may indicate tarsal coalition (often teens) In newborn, exclude vertical talus
Pes cavus Not common—the opposite of flat feet; the arch is extremely pronounced	Often associated with toe clawing, calluses, heel varus, and pain, with footwear difficult to fit May be physiological (familial—so check parents' feet!), residual from clubfoot abnormality, or associated with neurological abnormalities—paediatric neurology/orthopaedics referral usually needed	Careful neuromuscular/ musculoskeletal assessment required. Neurological conditions to consider include spina bifida, spinal dysraphism, poliomyelitis, Charcot–Marie–Tooth, Friedrich's ataxia Insoles may help and surgery may be required
Curly toes Most resolve by 4 years of age	Surgery rarely needed	Check shoes are well fitting
Knock knees Usually resolve by 6 years of age	Associated with pain or asymmetrical Extreme (>6 cm intermalleolar distance at ankles) or persistent (>6 years)	A gap of 6–7 cm between the ankles is normal (between 2–4 years) Late feature of arthritis of knee (e.g. JIA)
Bow legs Common and normally seen in children until the age of 2 years	Associated with pain or asymmetrical, or the child is short in stature or has other medical problems Extreme (>6 cm intercondylar distance at knees) or persistent (>6 years)	Conditions to exclude include rickets, skeletal dysplasias, syndromes associated with dwarfism (e.g. achondroplasia), Blount's disease Late feature of arthritis of knee (e.g. JIA)
Out-toeing Feet point outwards; usually resolves by 4 years	Recent onset in a teenager—check hips for a slipped upper femoral epiphysis	
Intoeing Feet turning inwards—'pigeon toed' Normal development for many toddlers when just learning to walk, usually resolved by 10 years	Persistence (>10 years) Affecting mobility and function (clumsy, prone to falling) Femoral anteversion and medial tibial torsion; usually resolve by 10 years of age Metatarsus adductus; usually resolve by 5 years of age	Check child's leg alignment when standing Femoral anteversion (90% of cases), patellae pointing inwards Medial tibial torsion (patellae point straight forward) Metatarsus adductus (forefoot abnormal only) Insoles and exercises will not help. Surgery rarely required

JIA, juvenile idiopathic arthritis.

of serious potentially life-threatening conditions such as sepsis or malignancy (see Chapters 13 and 14). Orthopaedic conditions at the hip are commonly present with the well child who is limping, often acutely, and include slipped upper femoral epiphysis (usually the older, often overweight child) and Perthes' disease which may follow a transient synovitis or 'irritable hip' in the younger child. Life-threatening conditions such as acute leukaemia may present with non-specific joint or muscle pain, and in a child with pyrexia of no apparent focus, MSK assessment is important to exclude bone or joint infection. The concept of referred pain from the hip or thigh, for example, must be sought in situations where the child has

knee pain but there is no evidence of localized disease at the knee. The patterns of joint involvement in JIA differ from that of adult rheumatoid arthritis (e.g. oligoarticular JIA most commonly affects a single knee or ankle). A delay in major motor milestones may indicate MSK problems as well as neurological disease. However, *regression* of achieved motor milestones is more likely in acquired MSK disease, such as muscle or joint disease; for example, the child who was happy to walk unaided but has recently refused to walk or resorted to crawling again.

Young children may have difficulty in localizing or describing pain and the history is often given by the parent or carer, based

Table 5.3 Normal gait and musculoskeletal development

Sit without support	6–8 months
Creep on hands and knees	9–11 months
Cruise or bottom shuffle	11–12 months
Walk independently	12–14 months
Climb up stairs on hands and knees	~15 months
Run stiffly	~16 months
Walk down steps (non-reciprocal)	20–24 months
Walk up steps, alternate feet	3 years
Hop on one foot, broad jump	4 years
Skipping	5 years
Balance on one foot for 20 seconds	6–7 years
Adult gait and posture	8 years

Comments:

◆ There is considerable variation in the way normal gait patterns develop—such variation may be familial (e.g. 'bottom-shufflers' often walk later) and subject to racial variation (e.g. African black children tend to walk sooner and Asian children later than average.

◆ The normal toddler has a broad base gait for support, and appears to be high stepped and flat footed with arms outstretched for balance. The legs are externally rotated with a degree of bowing. Heel strike develops around 15–18 months with reciprocal arm swing.

◆ Running and change of direction occur after the age of 2 years, although this is often accompanied by frequent falls until the child acquires balance and coordination. In the school-age child, the step length increases and step frequency slows.

on observations from others (e.g. teacher) and may be rather vague with non-specific complaints such as 'my child is limping'. Symptoms such as pain, stiffness, decreasing ability (e.g. hand skills, handwriting, or sport), and reduced or altered interest in play activities may be observed and caregivers may have concerns about deterioration in behaviour (e.g. irritability, poor sleeping). Assessment of pain is important and may be conveyed through non-verbal signs such as withdrawal, crying, or distress (see Chapter 161).

The key features in the history-taking are described in Table 5.5. It is important to ask open questions and to enquire about mode of onset, site, distribution and nature of the symptoms and observations, features suggestive of multisystem involvement (e.g. rash, abdominal pain, headaches, Raynaud's, fatigue), and red flags that warrant concern. Distinguishing mechanical from inflammatory problems is similar to that in adults: for example, locking and instability of a joint may suggest internal derangement (e.g. meniscal injury) or osteochondritis disssecans (see Chapter 158). It is often necessary to probe for symptoms of inflammatory joint or muscle disease (e.g. asking about the child's mood, 'gelling' after periods of rest such as long car journeys, regression of achieved motor milestones, intermittent limping); a child will often adapt their activities to compensate for joint stiffness, pain, or weakness, and a change in the child's play or reluctance to participate in activities may signify inflammatory joint or muscle disease. It is important to ask about school, as MSK problems such as pain, stiffness, or weakness may create difficulties with school work, physical activity, and socialization; a change in academic performance, bullying, or school refusal can result and impact markedly on the child's global well-being, and enquiry about school and feedback from teachers or school nurse can therefore be revealing.

Table 5.4 Significant causes of limp, by age

	0–3 years	4–10 years	11–16 years
Most common	Trauma (including toddler's fracture)	Trauma Transient synovitis Perthes' disease	Trauma Osgood–Schlatter disease
Conditions requiring urgent intervention	Osteomyelitis Septic arthritis	Osteomyelitis Septic arthritis	Osteomyelitis Septic arthritis
	Non-accidental injury Malignancy (e.g. neuroblastoma)	Non-accidental injury Malignant disease (e.g. acute lymphocytic leukaemia)	Slipped upper femoral epiphysis Malignancy (e.g. bone tumours)
	Testicular torsion Inguinal hernia	Testicular torsion Appendicitis Inguinal hernia	Testicular torsion Appendicitis Inguinal hernia
Other important conditions to consider	Developmental dysplasia of the hip JIA	JIA	JIA
		Metabolic (e.g. rickets)	
		Haematological disease (e.g. sickle cell anaemia)	
		Reactive arthritis	
		Lyme arthritis	

JIA, juvenile idiopathic arthritis.

Table 5.5 Key questions to ask when taking a musculoskeletal history

Questions to parent/carer (and to the child as appropriate)	Points to check for	Comments
What have you or anyone else noticed?	Behaviour, mood, joint swelling, limping, bruising History of trauma	*Limping*, whether intermittent or persistent *always* warrants further assessment. Deterioration in school performance (e.g. sport, handwriting) or avoidance of previously enjoyed activities is always significant. *Joint swelling* is always significant but can be subtle and easily overlooked by the parent (and even healthcare professionals!), especially if the changes are symmetrical. Rather than describing stiffness, the parents may notice the child is reluctant to weight bear, or limps in the mornings, or 'gels' after periods of immobility (e.g. after long car rides or sitting in a classroom). *Trauma*—can be misleading as trauma is a common event in the lives of young children and not necessarily the appropriate explanation for a child's MSK symptoms. Conversely, not all trauma is witnessed by a parent or carer. Repeated episodes of trauma, pattern of injury, or incongruous circumstances or explanation raises concerns about *non-accidental injury*
What is the child like in him/herself?	Irritability, grumpy, 'clingy', reluctant to play, systemic features (e.g. fever, anorexia, weight loss)	Young children in pain may not verbalize pain but may present with behavioural changes or avoidance of activities previously enjoyed. *Systemic features* including red flags to suggest malignancy or infection
Where is the pain? (ask the child to point) and what is it like?	Take a pain history and focus on locality, exacerbating/relieving factors, timescale, pattern	*Asymmetrical persistent site of pain* is invariably a cause for concern *Referred pain* from the hip may present with non-specific pain in the thigh or knee
How is he/she in the mornings and during the day?	Diurnal variation and daytime symptoms (e.g. limping, difficulty walking, dressing, toileting, stairs?)	*Pain on waking or daytime* symptoms suggestive of *stiffness or gelling* (after periods of inactivity), are indicative of inflammatory joint (or muscle) disease
What is he/she like with walking and running? Has there been any change in his activities?	Motor milestones and suggestion of delay or regression of achieved milestone, including speech and language. Avoidance of activities previously enjoyed (e.g. sport, play) are noteworthy. Mechanical problems may be suggested by *locking or giving way*	*Regression of achieved motor milestones*, functional impairment or avoidance of activity (including play, sport, or writing), are more suggestive of acquired joint or muscle disease (and especially inflammatory causes). An assessment of global neurodevelopment is indicated with delay or regression in speech, language or motor skills. *'Clumsiness'* is a non-specific term but may mask significant musculoskeletal or neurological disease
How is he/she at school or nursery?	School attendance (any suggestion of school avoidance, bullying)	*Behavioural problems* in the young child may manifest as non-specific pains (headaches, tummyaches, or leg pains). Sensitive questioning and may reveal stressful events at home or school
Does he/she wake at night with pain?	Pattern of night waking	*Night waking* is a common feature of growing pains (usually intermittent, and often predictable). Conversely, persistent night waking, especially if there are other concerns (such as unilaterality, limping, unusual location, or systemic features) are of concern and invariably necessitate further investigation
Can you predict when the pains may occur?	Relationship to physical activity (including during or after sporting activities)	Mechanical pains tend to be worse later in the day, evenings and often after busy days. Growing pains often follow busy days and are often predictable in their occurrence
What do you do when he/she is in pain?	Response to analgesics, anti-inflammatory medication, massages, and reaction of parent	Lack of response to simple analgesia is a concern. Vicious circle of reinforced behaviour can occur
What is your main concern?	Sleep disturbance, cosmesis, anxiety about serious disease (arthritis, cancer, family history), pain control	*A family history of muscle disease, arthritis, or autoimmune disease* may indicate a predisposition to muscle or joint disease. Observed 'abnormalities' (such as flat feet, curly toes) may be part of normal development. The parent or carer will undoubtedly have anxieties and concerns about the child, may often fear severe illness and both child and parent have an expectation of investigations (e.g. blood tests)

The full medical history with systematic enquiry into family and past history may be helpful, as many chronic conditions will have MSK associations: for example, inflammatory bowel disease can present initially with joint problems, which may be suggested by intolerance to NSAIDS, poor growth, or pattern of joint involvement such as isolated arthritis of the hip. A recent travel history (e.g. travel to an endemic area for Lyme disease) may be informative and a sexual history is important in the adolescent (e.g. reactive arthritis) although this needs to be explored sensitively and with acknowledgment of safeguarding concerns in the young and the need for privacy and confidentiality in the case of an adolescent patient. A medication history (e.g. response to NSAIDS, potential for drug-induced lupus), family history (e.g. autoimmune disease, muscle disease), and social history and family changes may be revealing. The approach proposed by Malleson and Beauchamp[14] incorporates potential diagnoses according to whether pain is localized or diffuse, whether the child is 'well' or not, and the presence of red flags.

It is notable that MSK history-taking in children, especially the very young, can be misleading; even when taken by experienced clinicians, the history alone may not identify sites of joint involvement.[15] It is important, therefore, that in all cases where MSK disease is suspected, physical examination is performed including an MSK basic examination as a minimum to assess all joints (see 'A musculoskeletal basic examination for children: pGALS'). This is exemplified in JIA, where the most common presenting features are joint swelling, limp, and reduced mobility, rather than pain;[16] notably, *the lack of reported pain does not exclude arthritis*. Swelling is the cardinal diagnostic feature of JIA but this can be subtle and easily overlooked by parents and carers and indeed may be missed in clinical examination, especially if the changes are symmetrical (e.g. swollen ankles in the young child) or the assessor is inexperienced. Children with learning disabilities can be more difficult to assess, and joint problems can easily be overlooked in the child with complex needs. There is an association of inflammatory joint disease with chromosomal disorders (such as Down's syndrome or di George syndrome),[17] and many children with complex genetic conditions (such as mucopolysaccharidoses) may present with or develop joint problems.

Non-specific MSK pain in children is common and often labelled as 'growing pains'; a confident diagnosis can be made when applying the 'rules of growing pains' (Table 5.6). Many children with non-specific aches and pains, including growing pains, are often found to have joint hypermobility, although not all hypermobile children are symptomatic.[18,19] It is important in the child with hypermobility to exclude rare but important syndromes (e.g. Marfan's, Stickler's, and Ehlers–Danlos syndromes), as these children are at risk of retinal and cardiac complications. Non-specific aches and pains may be a presenting feature of metabolic bone disease (such as osteomalacia) and in young children, may result in a waddling gait, leg bowing, irritability, and poor growth (see Chapter 150). Similarly, non-specific aches and pains are a feature of idiopathic pain syndromes, albeit typically, but not exclusively seen in older female children or adolescents, often in stressful social environments. Such patients are often markedly debilitated by their pain and fatigue; the pain can be incapacitating, although the child or adolescent is otherwise well and physical examination is normal (see Chapter 161).

The clinical assessment encompasses general evaluation including bodily systems, growth, and development especially if the child

Table 5.6 Growing pains

'Rules' of growing pains	Pains *never* present at the start of the day after waking
	Child does not limp
	Physical activities not limited by symptoms
	Pains symmetrical in lower limbs and not limited to joints
	Physical examination normal (joint hypermobility may or may not be detected)
	Systemically well and major motor milestones normal
	Age range 3–12 years
Indications for concern	Systemic upset (red flags to suggest sepsis or malignancy)
	Abnormal growth (height and weight)
	Abnormal developmental milestones: ◆ *Delay* (especially major motor skills) suggestive of neurological disease or metabolic bone disease, OR ◆ *Regression* of achieved motor milestones (consider inflammatory joint or muscle disease)
	Impaired functional ability (ask about play, sport, schoolwork, 'clumsiness')
	Limping (intermittent or persistent)
	Morning symptoms (other than tiredness after disturbed sleep) or mood changes may suggest inflammatory arthritis
	Widespread pain (such as upper limbs and back)
	School absenteeism

has complex needs or other comorbidities. Table 1.7 summarizes important features of rheumatic disease that can be elicited through a review of the systems. It is always important to assess the parent–child interaction and check for clues that may raise safeguarding concerns. Height and weight and general growth velocity can be assessed from review of growth charts in the parent-held record,[20] if available. Disproportionate limb and trunk growth may suggest dwarfism syndromes, and dysmorphism raises the suspicion of chromosomal or genetic conditions. Indolent presentations of chronic MSK disease can impact on growth (either localized or generalized) and stature, and may be compounded by use of corticosteroids or protracted disease activity from suboptimal treatment. Additional clinical skills that may be required, pending the clinical scenario, include nailfold capillaroscopy or muscle strength testing in suspected connective tissue or muscle disease and musculoskeletal ultrasound, which is increasingly used as an adjunct to clinical examination; these techniques are described elsewhere in the textbook.

A musculoskeletal basic examination for children: pGALS

The paediatric Gait, Arms, Legs, Spine (pGALS) assessment (Figure 5.1) is a simple evidence-based approach to musculoskeletal

pGALS – A basic musculoskeletal assessment for school-aged children

SCREENING QUESTIONS
- Do you have any pain or stiffness in your joints, muscles or your back?
- Do you have any difficulty getting yourself dressed without any help?
- Do you have any difficulty going up and down stairs?

GAIT
- Observe the child walking
- "Walk on your tip-toes / walk on your heels"

ARMS
- "Put your hands out in front of you"
- "Turn your hands over and make a fist"
- "Pinch your index finger and thumb together"
- "Touch the tips of your fingers with your thumb"
- Squeeze the metacarpophalangeal joints
- "Put your hands together / put your hands back to back"
- "Reach up and touch the sky"
- "Look at the ceiling"
- "Put your hands behind your neck"

LEGS
- Feel for effusion at the knee
- "Bend and then straighten your knee" (Active movement of knees and examiner feels for crepitus)
- Passive flexion (90 degrees) with internal rotation of hip

SPINE
- "Open your mouth and put 3 of your (child's own) fingers in your mouth"
- Lateral flexion of cervical spine – "Try and touch your shoulder with your ear"
- Observe the spine from behind
- "Can you bend and touch your toes?" Observe curve of the spine from side and behind

Fig. 5.1 The components of the pGALS musculoskeletal assessment (Table taken with permission, from *Hands On* pGALS—a paediatric musculoskeletal screening examination for children. www.arthritisresearchuk.org/~/media/Files/Education/Hands-On/HO15-June-2008.ashx).

assessment based on the adult GALS (Gait, Arms, Legs, Spine) screen,[21] and has been shown to have high sensitivity in distinguishing abnormal from normal and detecting significant abnormalities.[22] The pGALS examination is aimed at non-specialists in paediatric rheumatology and is increasingly taught at medical schools in the UK and further afield; a full demonstration of pGALS and supportive documents are available as a web-based free resource: (www.arthritisresearchuk.org/health-professionals-and-students/video-resources/pgals.aspx)

pGALS was developed following testing of adult GALS in children which missed significant abnormalities especially at the foot, ankle, and wrist.[22] pGALS incorporates a series of simple manoeuvres, commonly used in clinical practice. pGALS takes an average of 2 minutes to perform and, although validated in the school-aged child, is often useful in younger children, who will often comply—especially if they copy the examiner and see this as a game. Box 5.2 lists simple practical tips to facilitate the examination and it is recommended that, as a minimum, pGALS should be done in all clinical scenarios where MSK disease is a concern. Overt MSK complaints, or a positive response to any of the three pGALS screening questions (Figure 5.1), necessitates a complete detailed MSK history and subsequent physical examination. However, a negative response to these questions in the context of a MSK complaint does *not* exclude significant MSK disease as in children, especially the very young, it is not uncommon to find joint involvement that has not been mentioned[15] as part of the presenting complaint. In other clinical contexts, the pGALS screening questions may be not be socio-culturally relevant (e.g. walking up

Box 5.2 pGALS: practical tips

When performing the pGALS examination
- Check that the child is comfortable, ask about pain, and explain what you intend to do
- Observe the child walking in the room, getting undressed, at play
- Check that the child is adequately exposed (socks, shoes, and exposure of limbs)
- Get the child to copy you doing the manoeuvres
- Look for verbal and non-verbal clues of discomfort (e.g. facial expression, withdrawal) while they get undressed or perform manoeuvres
- Do the full screen, as extent of joint involvement may not be obvious from the history
- Look for asymmetry (e.g. muscle bulk, joint swelling, range of joint movement)
- Consider clinical patterns (e.g. non-benign hypermobility and marfanoid habitus or skin elasticity, and association of leg length discrepancy and scoliosis)

When to perform pGALS in the assessment
- Child with muscle, joint, or bone pain
- Unwell child with pyrexia
- Child with limp
- Delay or regression of motor milestones
- The 'clumsy' child in the absence of neurological disease
- Child with chronic disease and known association with musculoskeletal presentations

and down stairs in environments without steps, or getting dressed and undressed in hot countries where few clothes are worn)[23] and in such circumstances modification of the questions is required (e.g. rise from a squat position).

Key to appropriate interpretation of pGALS is knowledge of ranges of movement in different ethnicity and age groups[24], looking for asymmetry and careful examination for subtle changes. It is essential to perform all parts of pGALS as joint involvement may be apparently 'asymptomatic', symptoms may not be localized, and it is important to check for verbal and non-verbal clues of joint discomfort such as facial expression or withdrawal of limb. It has been shown that pGALS is practical and helpful in acute paediatric practice,[25] but needs to be interpreted in the context of the physical examination elsewhere (e.g. chest, abdomen, neurological examinations). pGALS was developed in the context of detecting inflammatory joint disease in children but has been shown to be useful in identifying other joint problems (e.g. orthopaedic problems at the hip, scoliosis, hypermobility).

Performing pGALS starts with observing the child coming into the room, interaction with the parent or carer, and their interest in play or activities such as using pencils or crayons. The child should ideally be undressed but compromise, patience, and opportunistic

examination is often needed as many children are reluctant to undress—prior request to bring along shorts and T-shirt and provision of privacy to change will facilitate the assessment. As a minimum, the child should be barefoot, the legs exposed to include the knee and thigh and arms to include the elbows. The torso can be exposed to assess the spine in due course.

Observation with the child standing should be done from the front, from behind the child, and from the side. The examination of the upper limbs and neck is best done with the child sitting on an examination couch facing the examiner. The child can copy the various manoeuvres as they are performed by the examiner. The child should then lie supine to allow the legs to be examined and then stand again for spine assessment. Throughout pGALS, the sequence of 'look, feel, move' is followed and it is important to check carefully for symmetry as the changes can be subtle (skin changes, joint swelling and deformity, muscle bulk, and ranges of joint movement) (Figures 5.3 and 5.4). The features of inflammatory arthritis include joint swelling, warmth, loss of movement and tenderness on examination—an isolated hot red joint warrants mandatory investigation to exclude sepsis—however, in a well child with a monoarthritis, in the absence of trauma and sepsis, JIA is the most likely diagnosis.

From the front and back, leg alignment problems such as valgus and varus deformities can be observed. Scoliosis may be suggested by unequal shoulder height or asymmetrical skin creases on the trunk and may be more obvious on forward flexion (Figure 5.2). Subtle abnormalities at the ankle (such as swelling, valgus deformity) are often more obvious from behind the child (Figure 5.3). Leg length inequality may be more obvious from the side and suggested by a flexed posture at the knee; if found, then careful observation of the spine is important to exclude a secondary scoliosis.

Gait is assessed in the context of normal development (Table 5.3). Normal gait follows 'swing', 'stance', and 'toe-off' phases; a painful or antalgic gait leads to shortening of the stance phase on the affected limb, and therefore lengthening of the swing phase. Inability to walk on heels or on tiptoe is a good screening manoeuvre for the ankle and foot, especially as foot or ankle involvement is common in JIA, and enthesitis is a feature of

Fig. 5.3 Limited wrist extension and finger extension on pGALS.

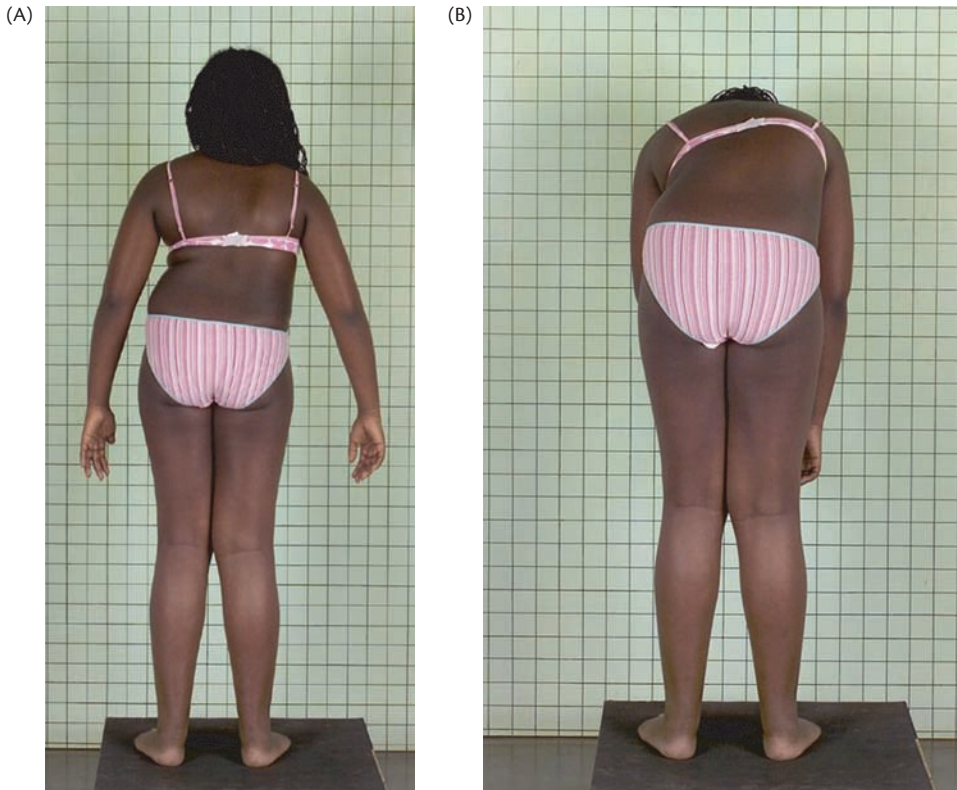
(A)   (B)


Fig. 5.2 Scoliosis.

Fig. 5.4 Swelling of ankles, seen from behind.

enthesitis-related arthritis (ERA; a subtype of JIA). Sever's disease (an osteochondritis of the calcaneum) may also present with a painful heel but the site of tenderness is distal to the enthesis. Flat feet are common as a feature of normal development. Standing on tiptoe should create a normal medial longitudinal arch; inability to do so warrants further investigation (e.g. to exclude tarsal coalition). High fixed arches, pes cavus, and persistent toe walking may suggest neurological disease, but the latter has been reported as a feature of JIA.[26]

The pGALS assessment of the arms examines several joints together with each composite movement (Figure 5.1). The pGALS assessment of the legs with the child supine includes observing for leg length (check that the pelvis is straight to avoid false positives), symmetry of muscle bulk (quadriceps wasting is common with JIA involving the knee), and alignment (looking for valgus or varus deformity). Knowledge of characteristic patterns among the JIA subsets is helpful. For example, in a child with juvenile psoriatic arthritis, there may be asymmetrical joint involvement involving small and large joints, and this may include dactylitis or 'sausage digit' (due to arthritis and associated tenosynovitis). It is important to check the nails and skin for psoriasis as the rash of psoriasis can be subtle and typically follows the onset of the arthritis by several years, in contrast to adults with psoriatic arthritis. Isolated hip joint involvement is unusual as a presentation of JIA

Table 5.7 General examination in the context of musculoskeletal disease

	Features	Context and comments
General observations	Overall impression of the child's well-being Child's appearance, demeanour and interaction with parent or carer Features of dysmorphism (including facies and limbs) Height and weight plotted on a growth chart	An unwell child will require prompt admission and assessment for malignancy or sepsis Local safeguarding policies should be followed if concerned about non-accidental injury or neglect Faltering growth may be a sign of systemic or chronic disease Short stature or localized growth problems are features of chronic untreated disease or dwarfism syndromes
Skin inspection	Look for rashes including scalp and hair Overall feel of skin, including colour and texture	Skin psoriasis often presents on the extensor surfaces, or the natal cleft Malar butterfly rash—observed in JJSLE or JDMS Violaceous heliotrope rash or Gottron's papules on the hands—JDMS Evanescent macular salmon pink rash may be seen in systemic-onset JIA (often occurs with spikes of fever) and may demonstrate Koebner phenomenon Localized scleroderma may present with an isolated patch of pigmented skin (morphoea)—systemic sclerosis is rare in childhood Vasculitis or livedo rash may occur in connective tissue disease (including JSLE or JDMS)
Nail examination	Nail pitting (psoriasis) Nail beds and capillaroscopy—can be aided by magnification using a gel and ophthalmoscope or dermascope	Nail change of psoriasis may be subtle, and the only manifestation of psoriasis in children Dilated, tortuous nail bed capillaries suggests active inflammation in the context of connective tissue disease
Ear, nose, and throat examination	Cervical lymphadenopathy Oral mucosa, gums, and teeth Ears and nose (bridge and mucosa) Parotid swelling if sicca features or suspicion of connective tissue disease or sarcoidosis	Significant cervical lymphadenopathy may occur in malignancy or multisystem disease (such as Kawasaki's disease) Mouth ulcers—JSLE and Behçet's disease. Sjögren's syndrome is rare in childhood but may be a feature within mixed connective tissue disease Poor dental hygiene is a concern, particularly in the immunosuppressed child ENT abnormalities are common in ANCA +ve vasculitis, e.g. saddle nose (Wegener's granulomatosis) and sinusitis (Churg–Strauss syndrome)

(Continued)

Table 5.7 (*Continued*)

	Features	Context and comments
Cardiovascular	Blood pressure and pulses Presence of bruits Heart sounds	Hypertension in the context of rheumatic disease may signify renal involvement (e.g. vasculitic disease) Pericarditis is a feature of systemic-onset JIA and vasculitic disease in childhood Cardiac abnormalities are a feature of non-benign hypermobility syndromes (e.g. Marfan's and Ehlers–Danlos)
Respiratory	Lung fields Pulmonary function testing	Restrictive lung disease may be seen in connective tissue disease
Abdominal	Presence of guarding Hepatosplenomegaly	Abdominal pain may be a non-specific presenting feature of musculoskeletal disease and examination is often needed to exclude other pathology, e.g. limping child with psoas abscess or pyelonephritis. Similarly, a child with hip disease may localize this poorly to the lower abdomen
Neurological	Full neurological examination of the lower limbs is always indicated in children presenting with back pain Cranial nerve assessment in context of headache Peripheral nerve involvement Muscle power	Abnormal neurological examination (such as altered sensation or hyper-reflexia) in a child with back pain should lead to urgent imaging and expert assessment MRI ± angiography may be needed if cerebral vasculitis is suspected Reduced muscle strength is seen in JDMS and mixed connective tissue disease
Eye	Reduced visual acuity Fundoscopy Slit lamp examination	In JIA, uveitis may be asymptomatic and routine eye screening should be a mandatory part of management Multisystem disease (e.g. sarcoidosis, vasculitis) may manifest with ocular involvement
Renal	Blood pressure Urinalysis	Haematuria is a feature of renal disease associated with ANCA +ve vasculitis (i.e. Wegener's granulomatosis) JSLE-associated nephritis may present with hypertension and proteinuria Exclusion of UTI is important in a febrile child, particularly if immunosuppressed

ANCA, anti-neutrophil cytoplasmic antibodies; ENT, ear, nose, and throat; JDMS, juvenile dermatomyositis; JIA, juvenile idiopathic arthritis; JSLE, juvenile systemic lupus erythematosus; UTI, urinary tract infection.

(with the exception of ERA), and in isolation, other pathologies including orthopaedic conditions (dysplasia, slipped upper femoral epiphysis) and sepsis (including mycobacterial infection) need to be excluded. Referred pain such as from the hip or thigh as a cause of knee pain in the absence of physical signs (at the knee) must be considered.

Benign hypermobility is suggested within pGALS by symmetrical hyperextension at the fingers, wrists, elbows, knees, and flat pronated feet, with normal arches on tiptoe. It is important to consider 'non-benign' causes of hypermobility—checking body habitus, skin and sclerae may suggest marfanoid features or other syndromes associated with hypermobility. Conversely, lack of joint mobility, especially if asymmetrical, is always significant—for example, the loss of hyperextension at the knee, as an isolated finding is very suggestive of previous inflammatory arthritis at that joint and corroborates a diagnosis of previous JIA.

Documentation of pGALS

Documentation of pGALS within a standard medical clerking is important. A simple proforma is proposed in Table 5.8 using the example of a child with a short leg, calf wasting, and antalgic gait (Figure 5.5).

Table 5.8 Documentation of pGALS—example (see Figure 5.5)

The pGALS screening questions		
Pain	Right leg	
Dressing	No difficulty	
Walking	Some difficulty	
	Appearance	**Movement**
Gait		✗
Arms	✓	✓
Legs	✗	✗
Spine	✓	✓

Paediatric regional examination of the musculoskeletal system (pREMS)

Following pGALS as a basic assessment, the observer is directed to a more detailed examination of the relevant area(s). A consensus approach to paediatric regional examination of the musculoskeletal system (called pREMS) has been developed from observation

Fig. 5.5 Shortened right leg with resultant toe walking and muscle wasting.

of doctors and allied health professionals working in pMSK medicine.[27] pREMS is based on the 'look, feel, move, function' principle similar to that of adult REMS[28] (see Chapter 6) for each joint or anatomical region, with the same general principles, although it differs by anatomical region, reflecting different pathologies from those observed in adults. pREMS involves active movements performed first and then passively by the examiner and includes the addition of 'measure' for some joints and options pending the clinical scenario (Box 5.3). Details of the examination techniques for each joint are not included in this chapter and the reader is directed

---

Box 5.3 The paediatric regional examination of the musculoskeletal system (pREMS)

pREMS—general principles

Introduction

◆ Introduce yourself to child and parent/carer

◆ Explain what you want to examine, gain verbal consent to examine

◆ Be aware of normal variants in leg alignment, joint range, gait, developmental milestones

---

Box 5.3 (*Continued*)

Look for

◆ Swellings, rashes (e.g. psoriasis/vasculitis), muscle wasting, scars, leg length discrepancy

◆ Deformity, dysmorphism, 'disproportions', discomfort (non-verbal signals)

Feel for

◆ Temperature, swelling, tenderness (along bones and joint line)

Move

◆ Full range of movement—active and passive (note any asymmetry)

◆ Restriction—mild, moderate, or severe

Function and measure

◆ Functional assessment of joint/anatomic region to include power of muscles and stability

◆ Measurement of height/leg length

pREMS—Examination schedules by anatomical region[a]

Examination of the hand and wrist

◆ Inspect hands (palms and backs) for muscle wasting, skin and nail changes

◆ Feel for radial pulse, tendon thickening, and bulk of thenar and hypothenar eminences

◆ Feel for skin temperature

◆ Squeeze metacarpophalangeal joints

◆ Bimanually palpate swollen or painful joints, including wrists

◆ Look and feel along ulnar border

◆ Assess full finger extension and full finger tuck

◆ Assess wrist flexion and extension, abduction and adduction—active and passive

◆ Assess function: grip and pinch, picking up small object, writing/drawing

◆ Options[b]—assess for hypermobility syndromes, muscle power, capillaroscopy, peripheral neuropathy

Examination of the elbow

◆ Look for carrying angle, scars, swellings or rashes, deformity

◆ Feel for skin temperature

◆ Palpate over head of radius, joint line, medial and lateral epicondyles

◆ Assess full flexion and extension, pronation and supination—actively and passively

◆ Assess function—e.g. hand to nose or mouth, hands behind head

◆ Options[b]—assess for hypermobility syndromes, muscle power, instability tests, entheses

(*Continued*)

Box 5.3 (*Continued*)

Examination of the shoulder

With patient standing or sitting

- Inspect shoulders, clavicles, and sternoclavicular joints from the front, side, and behind, and assess shoulder height
- Inspect skin in axillae and palpate for lymphadenopathy
- Assess skin temperature
- Palpate bony landmarks and surrounding muscles
- Assess movement and function: hands behind head, hands behind back
- Assess (actively and passively) external rotation, flexion, extension and abduction
- Observe scapular movement
- Options[b]—assess for hypermobility syndromes, muscle power, instability

Examination of the hip

With patient lying supine on couch

- Look for flexion deformity and leg length disparity
- Check for scars, rashes
- Feel the greater trochanter for tenderness
- Assess full hip flexion, internal and external rotation, abduction and adduction
- Perform the Thomas test
- Hip abduction (lying on side)

With patient lying prone on couch

- Sacroiliac joint palpation
- Hip internal (and external) rotation

With patient standing

- Assess posture and leg alignment
- Look for gluteal muscle bulk
- Perform the Trendelenburg test
- Assess function (gait with turning and running, ancillary movements)
- Options[b]—assess for hypermobility, muscle power, enthesitis, thigh–foot angle (child with intoeing)

Examination of the knee

With patient standing

- Look for varus/valgus deformity, hyperextension, and popliteal swellings
- Inspect skin for pattern of bruising and rashes
- Assess gait (see hip)

With patient lying on couch

- Look from the end of the couch for varus/valgus deformity, muscle wasting, scars, and swellings

- Look from the side for fixed flexion deformity
- Check for passive hyperextension and leg length discrepancy
- Feel skin temperature
- With the knee slightly flexed, palpate the joint line and the borders of the patella
- Feel the popliteal fossa
- Perform a patellar tap and cross-fluctuation (bulge sign)
- Assess full flexion and extension (actively and passively)
- Options[b]—assess stability of knee ligaments—medial and lateral collateral—and perform anterior draw test
- Options[b]—tests for anterior knee pain/patellar maltracking/apprehension/patella glide
- Options[b]—assess for hypermobility, enthesitis, hamstring tightness, iliotibial band tightness/thigh–foot angle

Examination of the foot and ankle

With patient lying supine on couch

- Look at dorsal and plantar surfaces of the foot
- Feel the skin temperature
- Palpate for peripheral pulses
- Squeeze the metatarsophalangeal joints
- Palpate the midfoot, ankle joint line, and subtalar joint
- Assess movement (actively and passively) at the subtalar joint (inversion and eversion), the big toe (dorsi- and plantar flexion), the ankle joint (dorsi- and plantar flexion), and midtarsal joints (passive rotation)
- Look at the patient's footwear
- Options[b]—assess for hypermobility, thigh–foot angle, enthesitis, muscle power, capillaroscopy

With patient standing

- Look at the forefoot, midfoot (foot arch), and hindfoot
- Assess gait cycle (heel strike, stance, toe-off), running and turning, ancillary movement
- Assess muscle bulk (calves)

Examination of the spine

With patient standing

- Inspect from the side and from behind
- Inspect skin and natal cleft
- Inspect limb/trunk proportions
- Inspect facial and jaw profile
- Palpate the spinal processes and paraspinal muscles and temporomandibular joints (TMJs)
- Assess movement: lumbar flexion and extension and lateral flexion; cervical flexion, extension, rotation and lateral flexion, thoracic rotation

(*Continued*)

Box 5.3 (*Continued*)

◆ Assess TMJ opening

◆ Options[b]—Schober's test, stork test[c]

With patient sitting on couch (standing, for a younger child)

◆ Assess thoracic rotation

   With patient lying on couch

◆ Perform straight leg raising and dorsiflexion of the big toe

◆ Assess limb reflexes

◆ Options[b]—assess for leg length discrepancy, hypermobility, sacroiliac joint irritation on palpation

[a]Details of the examination techniques used are available (see Further Reading).

[b]The options refer to additional manoeuvres suggested pending common clinical scenarios.

[c]Stork test—standing on one leg and extension of spine causes pain (suggestive of spondylolysis).

---

to the Further Reading section. pREMS, in contrast to adult REMS, is primarily aimed at postgraduate medical training in paediatric rheumatology although clearly many of the components are relevant to paediatric orthopaedics as well as to allied health professionals working in pMSK medicine.

CHAPTER 6

Principles of clinical examination in adults

Lesley Kay

Introduction

There is a paradox at the heart of this chapter: clinical examination of the musculoskeletal system is upheld as being of fundamental importance, and yet it is generally poorly performed, and individual clinical examination tests have a scanty evidence base.

This chapter covers the importance of musculoskeletal examination skills, evidence that such skills have been poorly taught and performed, the efforts made to address and improve this situation and describes in particular two programmes of examination. These are the Gait, Arms, Legs and Spine (GALS)[1] screening examination, and the Regional Examination of the Musculoskeletal System (REMS)[2] core set of examination skills for medical students. Rheumatologists and others using this textbook will be in key positions to address the training and competence of doctors and other practitioners working with patients with musculoskeletal conditions in their normal working lives as well as in formal teaching situations.

The importance of musculoskeletal clinical examination skills

Clinical examination is one of the fundamental, core skills of the rheumatologist.[3,4] Evidence shows that the history can establish the correct diagnosis in 56% of cases, rising to 73% when patients have been examined[5,6] in general medicine. Arguably, for musculoskeletal conditions the figures are likely to be even higher. Careful examination limits the number of unnecessary investigations, leading to more rapid and accurate diagnoses,[7] and prompt treatment: advances in diagnostic investigations do not diminish the importance of clinical assessment.[8] In this context it is surprising that there has traditionally been little emphasis within rheumatology on the description of the required skills or the understanding of the validity of individual components of the examination itself. Although recommendations for undergraduate and other curricula emphasize the importance of clinical examination skills, they have not until recent years been specific in their recommendation of which examination tests are important for students and practitioners to learn.[9–14] Musculoskeletal examination skills are recognized as important not only for rheumatologists,[15] orthopaedic surgeons,[16] and other musculoskeletal practitioners,[17,18] but particularly for those working in primary care,[19–21] internal medicine,[22–24] and elderly medicine.[24]

Poor performance and confidence in musculoskeletal examination skills

The literature on the performance of musculoskeletal examination shows unfortunately consistent results. These studies are largely surveys and in some cases formal assessments, but each shows poor confidence in use of clinical skills, poorly rated training, and poor performance. This has been shown at different clinical levels including medical students in Germany,[25] foundation doctors in the UK,[26] and residents in Australia.[27] In general internal medicine (GIM) in the UK and Australia musculoskeletal examination is infrequently performed and recorded.[23,28,29] There is some evidence of use of GALS and other examinations but still low percentage recording and confidence as self-rated by doctors.[30] Despite the high incidence of musculoskeletal complaints presenting to primary care, the findings are no better in general practice in Germany,[31] the UK,[20,32] or the USA,[19,33] where family physicians are less confident in musculoskeletal examination than in other body systems.[34] Even those whose primary work is with patients with musculoskeletal conditions—orthopaedic surgeons[16,22] and rheumatologists[35] in training as well as osteopaths[17]—are found to have less good skills than one might expect. There is little work looking at the practice of trained orthopaedic surgeons or rheumatologists, but it is established that formal joint counts are not undertaken in the majority of consultations with patients with established rheumatoid arthritis,[36] which could suggest that examination is not performed to a high standard or completeness. A similar pattern is found in paediatric rheumatology practice, dealt with elsewhere (Chapter 5).

What are the barriers to performance of adequate musculoskeletal examination?

Irish hospital doctors think that examination of the musculoskeletal system is too difficult to be undertaken routinely,[37] and it is likely that they are not atypical. Performance and confidence in musculoskeletal examination are affected predominantly by undergraduate teaching. Both content and duration of rotations have been proposed as having an effect, but there is also the influential effect of role modelling by other specialists. If senior doctors do not themselves routinely conduct such examinations, or enquire into

the results on ward rounds, junior doctors will naturally concentrate on other matters. Low expectations, therefore, are important. At undergraduate level, teachers identify the main barriers to the delivery of effective clinical teaching as including the lack of agreement on what to teach, lack of confidence in teaching amongst non-musculoskeletal specialities, and poor communication between specialties. Students cite similar concerns.[38,39] Eponymous names for tests are thought to add to confusion.[40] The fact that musculoskeletal examination rarely appeared in important examinations may also have been a factor in its low status at medical school.[11]

Clinical examination tests have little demonstrated evidence base

In the past, examination was taught by tradition, relying on expert descriptions and respected textbooks. Available textbooks have, however, been shown to be generally inadequate for musculoskeletal examination in children[41] and adults.[42] Coverage is poor, and in general examination texts the musculoskeletal section is generally short, and positioned last, after the other body systems.[42] There has, however, been a sea change in the view taken of the role of clinical examination. Examination interventions are considered on the same basis as diagnostic tests. Examination should be understood as an evidence-based procedure whose sensitivity and specificity can be determined, to allow the clinician to understand the change in likelihood of a particular diagnosis depending on the results of the test.[43] This leads to the importance of studying examination tests for their performance[44] in terms of their validity, reliability, reproducibility, sensitivity and specificity, and likelihood ratio, as well as the normal range in a given population. Some normal ranges have been established, for example ranges of movement of the cervical and lumbar spine, for generalized hypermobility, and for differences with age and gender. Few examination tests have been well studied in this way, but good examples include systematic reviews of examination tests for meniscal tears[45] and of shoulder special examination tests.[46]

What has been done about it?

Curriculum and course design

The first and most important step has been the recognition of the need to agree and set standards for teaching, learning, and assessment. In one example, medical students at one university reported that even within the same course, delivered at different sites, the content of the course and their experience varied widely.[47] Agreement between specialties may be particularly important,[48] as conflicts are confusing and off-putting for learners, and should be resolved in course design. Recommendations for minimum length of course modules have been made, based on evidence that increasing the duration can improve knowledge outcomes,[49] but other evidence suggests that factors such as agreement about the content and delivery of rotation may be more important.[47] The emphasis has been on the development of courses which are appropriate for particular specialty groups or levels of training,[50] and it has been shown that teaching skills in defined modules improves confidence[33] and performance in musculoskeletal knowledge[49] and examination skills,[51] and in the skills and confidence of those used as tutors or models.[51]

Assessment drives learning

Students' learning, performance and confidence, at whatever level, is improved by clarity about the goals of the teaching, relevance of the material taught, and a clear link between the course content and its assessment. It is a truism in education that 'assessment drives learning' and therefore, rightly, much emphasis has been on the need to ensure that the musculoskeletal system is included in routine assessments of clinical skills, whether at medical school or in postgraduate settings.[48,51–54] There has been a clear increase in teaching and assessment of clinical skills in UK medical schools.[11]

Delivering improved skills training in real-life environments

In busy clinical practice, intensive courses designed to deliver high-quality musculoskeletal skills training can be labour-intensive and expensive.[47,55] Courses must be feasible in the settings in which they are taught,[56] so it is important to find ways of delivering good clinical skills teaching in the changing clinical environment even if it means taking teaching away from the bedside.[57,58] Some less resource-intensive ways of delivering teaching have been shown to be effective, such as using more senior students,[59,60] nurses,[55] or trained patient educators as tutors, and the use of assessment tools which reduce the need for expensive clinical examiners to assess confidence[61] and competence.[62] Curricula and assessments are traditionally derived separately for each institution, but it may be in future that work can be saved by sharing best practice to reduce workload.[63]

Streamlining, consistency, and standardization

The establishment of standardized examination regimes has been the biggest advance in musculoskeletal skills training in the last two decades.[12] The advantages of a standardized programme are: that learners and students are clear about what is to be learned; teaching and learning materials can be developed to support it; and assessment can be designed to test the agreed learning outcomes. It can additionally be tested for fitness-for-purpose, and revised in the light of further evidence. Systematized examination may help to make the best use of the limited time available in a consultation.[64]

GALS screening examination

The first, and most well-known, standardized examination regimen was the 'Gait, Arms, Legs, Spine' screening examination (GALS).[1] GALS is a rapid, simple, choreographed screening examination, which aims to distinguish between a patient with a normal musculoskeletal system and one with a musculoskeletal problem. It does not aim to describe or diagnose the problem, but is a tool that can guide subsequent examination and investigation.

Comparison of the musculoskeletal findings in patients admitted to general medical wards with the musculoskeletal problems and findings recorded in their case notes revealed a large deficiency.[28] Patients were further examined and a 'minimalist screening examination' was devised and validated.[65] This was subsequently published as GALS, as a scripted sequence, with short history questions and suggested notation, recommended for use in all patients by undergraduates, junior hospital doctors, and perhaps primary care (Box 6.1). Medical schools in the UK and Ireland now use GALS routinely in their teaching and it is incorporated into the

Box 6.1 Gait, Arms, Legs, Spine (GALS): a screening examination

Screening questions in the routine history

These should be incorporated into the routine systemic enquiry of every patient:

- 'Do you suffer from any pain or stiffness in your muscles, joints, or back?'
- 'Do you have any difficulty dressing yourself?'
- 'Do you have any difficulty walking up and down stairs?'

Gait

- Gait is observed for symmetry and smoothness as well as the ability to turn quickly.
- With the patient then standing in the anatomical position observe from behind, from the side, and in front of the patient for muscle bulk and symmetry, limb alignment, straight spine, level iliac crests, and the ability to fully extend elbows and knees.

Arms

- Asking the patient to put their hands behind their head, assess shoulder abduction and external rotation as well as elbow flexion.
- Joint swelling and deformity are then looked for, by observing the back of the patient's hands and wrists with the fingers outstretched.
- Ask the patient to turn their hands over. Look at the palms for muscle bulk.
- Assess power grip by asking the patient to make a fist
- Squeezing the examiner's fingers assesses grip strength.
- Assess fine precision pinch which is important functionally.
- Squeeze across the metacarpal-phalangeal joints for tenderness—be sure to watch the patient's face while doing this.

Legs

- With the patient lying on a couch or bed, assess full flexion and extension of both knees while feeling each knee for crepitus.
- Assess internal rotation of both hips by having the hip and knee flexed to 90, while gently guiding the patient's movement by holding their knee and ankle.
- Perform a patella tap checks for an effusion of the knee.
- Finally, inspect the feet for swelling and deformity as well as callosities on the soles, and squeeze across the metatarsal-phalangeal joints to detect inflammatory joint disease.

Spine

- With the patient standing, inspect the spine from behind for evidence of scoliosis and from the side for abnormal lordosis or kyphosis.
- Lateral flexion of the neck, is assessed by asking the patient to touch each ear to their shoulder in turn.
- Lumbar spine is assessed, by asking the patient to touch their toes. Normal movement of the spinal vertebrae is palpated for during this manoeuvre.

Recording the findings from the screening examination

It is important to record the positive and negative findings in the notes. A simple note of the presence or absence of any changes in the appearance or movement in the gait, arms, legs or spine should be recorded as follows:

	Appearance	Movement
Gait	✓	✓
Arms	✓	✓
Legs	✓	✓
Spine	✓	✓

The sequence is described and illustrated in *Clinical assessment of the musculoskeletal system*, a handbook[66] and DVD[67] available from Arthritis Research UK.

Arthritis Research UK handbook intended for medical students and others,[66] available as a DVD or online.[67]

Evaluation of GALS has been relatively limited,[68] but its widespread uptake shows its face validity and acceptability to teachers. Acceptability to students has not been formally assessed, but a jokey revision version has been recorded,[69] the makers of which describe GALS as 'the Big One' for musculoskeletal examination on their website. Students can learn it in a relatively short time.[70] Such learning improves examination of the musculoskeletal system by graduating medical students,[71] and in the detection of rheumatoid arthritis by physiotherapists.[72] The GALS screen is valid against measures of disability.[73] Its teaching improves confidence in junior doctors[23,30] and it is in limited use in clinical practice.[24,30]

REMS

The next step was to define the examination skills required to examine the patient where a problem had been identified via GALS, to localize and describe it further. The point of reference taken was that of the medical student at the point of qualification: skills should therefore be those relevant to all doctors in whichever specialty they go on to practise. The approach involved a literature review and focus groups with clinicians[40] and students[38] to identify potential examination manoeuvres. These were then listed for prioritization and assessment of relevance in a national survey of rheumatologists, orthopaedic surgeons, geriatricians, and general practitioners. The findings from both parts of the study were then moderated via a group nominative process. This derived 50 musculoskeletal examination skills considered essential for medical students at the point of qualification, and therefore, by implication, all doctors. (Box 6.2).[2] Following the model of GALS, these were then choreographed into a logical sequence of examination manoeuvres

---

Box 6.2 Core set of regional musculoskeletal examination skills appropriate for a medical student at the point of qualification, derived from the REMS project[2]

A student at the point of qualification should be able to:
1. Detect the difference between bony and soft tissue swelling.
2. Elicit tenderness around a joint.
3. Elicit temperature around a joint.
4. Detect synovitis.
5. Have an awareness of the difference between active and passive movements.
6. Perform passive and active movements at all relevant joints.
7. Detect a loss of full extension and a loss of full flexion.
8. Assess gait.
9. Correctly use the terms 'varus' and 'valgus'.
10. Assess limb reflexes routinely, when examining the spine and in other relevant circumstances.
11. Have an understanding of the term 'subluxation'.
12. Where appropriate, examine neurological and vascular systems when assessing a problematic joint (check for intact sensation and peripheral pulses).

13. Assess leg length with a tape measure when assessing for a real leg length discrepancy.
14. Make a qualitative assessment of movement (not joint end feel but features such as cog-wheeling).
15. Assess the median and ulnar nerves.
16. Be able to localize tenderness within the joints of the hand (palpate each small joint of the hand if necessary).
17. Assess power grip.
18. Assess pincer grip in the hand.
19. Make a functional assessment of the hand such as holding a cup.
20. Correctly use the term 'Heberden's nodes'.
21. Be able to perform Phalen's test.
22. Detect a painful arc and frozen shoulder.
23. Make a functional assessment of the shoulder (can the patient put their hands behind their head and their back?).
24. Perform external and internal rotation of the shoulder with the elbow flexed to 90° and held in against the patient's side.
25. Examine a patient's shoulder from behind for scapular movement.
26. Assess the acromioclavicular joint (by palpation alone).
27. Palpate for tenderness over the epicondyles of the elbow.
28. Palpate for tenderness over the greater trochanter of the hip.
29. Perform internal and external rotation of the hip with it flexed to 90°.
30. Perform Trendelenberg's test.
31. Perform Thomas' test.
32. Detect an effusion at the knee.
33. Perform a patellar tap.
34. Demonstrate cross-fluctuation or the bulge sign when looking for a knee effusion.
35. Test for collateral ligament stability in the knee.
36. Use the anterior draw test to assess anterior cruciate ligament stability in the knee.
37. Examine the sole of a patient's feet.
38. Recognize hallux valgus, claw and hammer toes.
39. Assess a patient's feet with them standing.
40. Assess for flat feet (including the patient standing on tip toes).
41. Recognize hindfoot/heel pathologies.
42. Assess plantar flexion and dorsiflexion of the ankle.
43. Assess movements of inversion and eversion of the foot.

(Continued)

Box 6.2 *(Continued)*
44. Assess the subtalar joint.
45. Perform a lateral squeeze across the metatarso-phalangeal joints.
46. Assess flexion/extension of the big toe.
47. Examine a patient's footwear.
48. Palpate the spinous processes.
49. Assess lateral and forward flexion of the lumbar spine (using fingers, not tape measure).
50. Assess thoracic rotation with the patient sitting.

using the Apley structure of 'look, feel, move' and adding 'function', to form a fluent examination series (Box 6.3). This is known as the Regional Examination of the Musculoskeletal System (REMS). REMS has been ratified by the British Orthopaedic Association education committee, the Education and Training committee of the British Society for Rheumatology, the Primary Care Rheumatology Society, and Arthritis Research UK, and incorporated into the Arthritis Research UK handbook and DVD, 'Clinical Assessment of the Musculoskeletal System'.[10,66] REMS has also undergone very limited evaluation. It was found to be acceptable to teachers and to learners, and to give a sustained increase in students' confidence over 6 months.[74] A similar approach has been taken for undergraduate core skills competencies in Canada.[75]

Examination skills required at postgraduate level

GALS and REMS are largely used in the training of medical students, in the hope that skills acquisition at that stage will provide a sound foundation for future practice. GALS and REMS are considered to contain the range of skills that is necessary for the generalist, or for a specialist in another field. Little work has been done to describe, codify, or standardize the range of skills, necessarily much larger, for those practising in specialist musculoskeletal fields, particularly rheumatology and orthopaedics. pREMS,[76] the equivalent of REMS for children, does identify some skills as needed in more specialist practice, and there has been an exercise describing the

Box 6.3 Regional examination of the musculoskeletal system (REMS)[2]
General principles
◆ It is important to introduce yourself, ensure that the patient is comfortable, explain what you are going to do, gain verbal consent, and ask the patient to let you know if you cause them any pain or discomfort at any time.
Look
◆ The examination should always start with visual inspection of the exposed area at rest, and a comparison of sides looking for symmetry.
◆ You should look specifically for skin changes, muscle bulk and swelling in and around the joint.
◆ Also look for deformity in terms of alignment and posture of the joint.
Feel
◆ Feel for skin temperature using the back of your hand, across the joint line, and at other relevant sites.
◆ Any swellings should be assessed for fluctuance and mobility. The hard, bony swellings of osteoarthritis should be distinguished from the soft, rubbery swelling of inflammatory joint disease.
◆ Tenderness is an important clinical sign to elicit, in and around the joint.
◆ As a general principle students should be able to elicit synovitis, which relies on detecting the triad of warmth, swelling, and tenderness.
Move
◆ The full range of movement of a joint should be assessed. Both sides should be compared.
◆ As a general rule both active (where the patient moves the joint themselves) and passive (where the examiner moves the joint) movements should be performed.
◆ You should be able to detect a loss of full flexion and a loss of full extension.
◆ A restriction in the range of movement should be recorded as mild, moderate or severe.
◆ The quality of movement should also be recorded, with reference to abnormalities such as the presence of crepitus or cog-wheeling (in Parkinson's disease).
◆ It is not considered necessary for medical students to perform resisted movements.

(Continued)

Box 6.3 (*Continued*)

Function

◆ It is important to make a functional assessment of the joint. For example, in the case of limited elbow flexion, does this limit them getting their hand to their mouth?

Examination of the hands and wrists

◆ This should normally take place with the patient's hands resting on a pillow.

Look

◆ With the patient's hands palm down observe for obvious swelling, deformity, posture, muscle wasting, and scars.

◆ Look at the skin for thinning, and bruising (signs of long-term steroid use) or rashes.

◆ Look for nail changes (for psoriasis) or evidence of nailfold vasculitis.

◆ Decide if changes are symmetrical or asymmetrical.

◆ Do changes mainly involve the distal small joints: PIP and DIPs or MCPs?

◆ Ask them to turn their hands over (do they have problems with this due to elbow and wrist involvement?)

◆ Look again for muscle wasting—is this both thenar and hypothenar eminences? (if thenar alone then perhaps they have carpal tunnel syndrome).

◆ Look at the wrist for a carpal tunnel release scar.

Feel

◆ Assess for the presence of a radial pulse.

◆ Assess for skin temperature using the back of your hand at the patient's forearm, wrist, and MCPs.

◆ Feel the bulk of the thenar and hypothenar eminences.

◆ Test median and ulnar nerve sensation (the thenar and hypothenar eminences).

◆ Assess radial nerve sensation—over the web space of the thumb and index finger.

◆ Gently squeeze across the row of MCP joints while watching the patient's face for signs of tenderness.

◆ Bimanually palpate any MCP joints and any PIP or DIP joints that appear swollen or painful.

◆ Is there evidence of active synovitis? (The joints are warm, swollen, and tender and may have a 'rubbery' feel, or you may even detect effusions).

◆ Bimanually palpate the patient's wrists.

◆ Finally run your hand up their arm to their elbow to look and feel for rheumatoid nodules or psoriatic plaques on the extensor surfaces

Move

◆ Ask the patient to straighten their fingers fully (against gravity).

◆ Ask the patient to make a fist—can they tuck their fingers into their palm?

◆ Assess wrist flexion/extension actively (e.g. by making the 'prayer' sign) then passively.

◆ Assess the median and ulnar nerves for power (abduction of the thumb and finger spread respectively).

◆ In patients where history and examination suggest a diagnosis of carpal tunnel syndrome, perform Phalen's test (forced flexion of the wrists for 30 seconds, looking for reproduction of pain, tingling, or numbness in the median nerve distribution).

Function

◆ Ask them to grip your two fingers. This assesses power grip—very important in function.

◆ Ask them to pinch your finger. This assesses pincer grip.

◆ Ask them to pick a small object such as a coin out of your hand.

Box 6.3 (*Continued*)

Examination of the elbow

Look

◆ Look for scars, muscle wasting, nodules, psoriasis, and swelling.

Feel

◆ Feel the temperature with the back of your hand.

◆ Hold their forearm with one hand and with the elbow flexed to 90° palpate the elbow, feeling head of the radius and joint line with your thumb. If there is swelling, is it fluctuant?

◆ Palpate the medial and lateral epicondyles (golfers' and tennis elbow) and olecranon process for tenderness and evidence of bursitis.

Move

◆ Does the elbow fully extend and fully flex (actively and passively)?

◆ Compare one side to another.

◆ Assess pronation and supination (actively and passively).

Function

◆ An important function of the elbow is to allow the patient's hand to reach their mouth. Other functions dependent on 'hands behind head', 'hands behind back' will have been assessed during the GALS screening examination.

Examination of the shoulder

Look

◆ With the shoulder fully exposed, inspect the patient from in front, the side, and then behind.

◆ Look for muscle wasting (compare sides) and look for scars.

◆ Is their posture normal? Are both shoulders symmetrical?

Feel

◆ Assess the temperature.

◆ Identify any tenderness. Palpate the muscle bulk of supraspinatus, infraspinatus, and deltoid.

◆ Palpate the bony landmarks starting at the sternoclavicular joint, the clavicle, acromioclavicular joint, acromion process, the joint line, and around the scapula.

Move

◆ Ask the patient to put their hands behind their head and then behind their back.

◆ With the elbow flexed at 90° and tucked into the patient's side assess external rotation of the shoulder—compare both sides.

◆ Assess flexion and extension.

◆ Ask the patient to abduct the arm to assess for a painful arc.

◆ Observe scapular movement.

Function

◆ Function of the shoulder includes reaching the hands behind the head and the back.

Examination of the hip

Look

◆ Observe the legs, comparing both sides: Is there an obvious flexion deformity of the hip with the patient lying flat?

◆ If there is a suggestion of a leg length disparity, assess true leg lengths using a tape measure.

◆ Check for scars overlying the hip.

◆ With the patient standing, assess for muscle wasting (gluteal muscle bulk in particular).

(*Continued*)

Box 6.3   (*Continued*)

Feel

◆ Palpate over the greater trochanter for tenderness.

Move

◆ Assess full hip flexion with the knee flexed at 90°—watch the patients face. Is full flexion painful? Compare both sides.

◆ Assess for a fixed flexion deformity of the hip by performing Thomas's test.

◆ Assess internal and external rotation of both hips with the hip and knee flexed at 90°. This is often limited in hip disease.

◆ A Trendelenburg test should also be performed.

Function

◆ Ask the patient to walk: Do they have an antalgic or Trendelenburg gait?

Examination of the knee

Look

◆ Observe the knee from the end of the bed, comparing both sides. Is the posture of the knee normal?

◆ Look for valgus and varus deformity.

◆ Is there muscle wasting or scars? Is the knee red (inflammation or infection) Is there obvious swelling? Is there a rash (e.g. psoriasis)?

Feel

◆ Feel the temperature using the back of your hand.

◆ Palpate for tenderness along the borders of the patella.

◆ With the knee flexed, palpate the joint line from both femoral condyles to the inferior pole of the patella, then down the inferior patellar tendon to the tibial tuberosity.

◆ Feel behind the knee for a popliteal (Baker's) cyst.

◆ Assess for an effusion by patellar tap

◆ Assess for a fluid bulge if there is no distinct patellar tap.

Move

◆ Do the knees fully extend? (making sure the patient is fully relaxed).

◆ Assess active and passive movement.

◆ Test the stability of the knee ligaments:

  · anterior draw test.

  · medial and lateral collateral ligament stability.

Function

◆ Ask the patient to stand to look again for varus/valgus deformity.

◆ Ask the patient to walk.

Examination of the foot and ankle

◆ With the patient sitting on a bed and their feet overhanging the end of it:

Look

◆ Observe the feet, comparing both sides for symmetry.

◆ Look specifically at the forefoot for nail changes or skin rashes.

◆ Look at alignment of the toes and evidence of hallux valgus of the great toe.

◆ Look for clawing of the toes, joint swelling and callus formation.

(*Continued*)

Box 6.3 (*Continued*)

◆ Look at the underside or plantar surface for callus formation.

◆ Finally, look at the patient's footwear.

Feel

◆ Assess the temperature over the foot and ankle and check for the presence of peripheral pulses.

◆ Gently squeeze across the MTP joints while watching the patient's face.

◆ Palpate the midfoot, the ankle and the subtalar joint for tenderness.

Move

◆ Movements of inversion and eversion at the subtalar joint, plus dorsiflexion and plantar flexion at the big toe and ankle should be assessed both actively and passively.

◆ Movement of the midtarsal joints are performed by fixing the heel with one hand, then passively inverting/everting the forefoot with the other hand.

◆ With the patient weightbearing:

  · Look again at the forefoot for toe alignment and the mid foot for foot arch position.

  · Look at the hind foot from behind the patient: Achilles tendon thickening or swelling may be seen. There should be normal alignment of the hindfoot.

Function

◆ Assessment of gait should be performed if not already done, observing for the normal cycle of heel strike and toe off.

Examination of the spine

Look

◆ Observe the patient standing. Look initially from behind the patient for any scars, muscle wasting, asymmetry, or scoliosis.

◆ Look from the side for the normal cervical lordosis, thoracic kyphosis, and lumbar lordosis.

Feel

◆ Feel down the spine starting at the occiput and palpating down the spinous processes to the sacrum and also down the paraspinal muscles for tenderness.

Move

◆ Assess lumbar flexion and extension and lateral flexion.

◆ Next, assess the cervical spine movements, which include lateral flexion, rotation, flexion, and extension.

◆ With the patient sitting on the edge of the couch, assess thoracic rotation is.

◆ With the patient lying as flat as possible, perform straight leg raise with the foot at right angles at the ankle.

◆ Finally, assess limb reflexes (upper and lower) and dorsiflexion of the big toe.

◆ If there has been any indication of an abnormality from the history, a full neurological and vascular assessment should be made.

* The sequence is described and illustrated in the 'Clinical Assessment of the Musculoskeletal System' handbook[66] and DVD[67] available from Arthritis Research UK.

examination skills appropriate for higher trainees in general hospital specialities[75] and in orthopaedics in Canada, derived in a similar way to REMS.[77] The European League against Rheumatism (EULAR) has a syllabus for specialist training in rheumatology,[78] and recommendations for continuing professional development:[79] neither mentions clinical examination skills, let alone defining which are needed. A survey of European centres[80] about the competencies needed for rheumatology again does not specifically mention musculoskeletal examination. The most recent UK curriculum for rheumatology higher training acknowledges that 'rheumatology has a very strong reliance on sound clinical skills'[81] and specifies that trainees should be able to perform GALS and REMS, as well as being able to identify, by examination:

◆ The normal musculoskeletal system and its variations, including at extremes of age

◆ The surface anatomical features of the shoulder girdle, elbow, hand/wrist, hip/pelvis, knee, ankle/foot, spine

◆ The normal range of movement (active and passive) of these joints

◆ The actions of major muscles/tendons acting on these joints

◆ The clinical signs associated with inflammation or structural damage of joints and periarticular structures (muscles, tendons, entheses, bursae, and bone)

◆ Non-articular, systemic, and other features of rheumatic disease

◆ General medical complications of rheumatological disease

◆ Diffuse or regional pain disorders or somatization disorders

It may be that many of the 'special tests' long associated with musculoskeletal examination are more within the domain of orthopaedics than rheumatology, but it is not clear from this curriculum whether they are expected to be part of the rheumatologist's repertoire. Each rheumatologist will have their own subset of such tests that they find useful but for each, it is important to remember that many are unvalidated, and of those that are, they are valid only providing the test is undertaken as originally described and in the situation in which it was evaluated. Original descriptions are not always easy to find in the literature.

A recent trend has been for clinical tests, originally intended for use as outcome measures in clinical trials, to be used in routine clinical practice. Examples include the DAS28 score in rheumatoid arthritis, the BASMI in ankylosing spondylitis, and the Rodnan skin score in scleroderma. As with special tests, it is important that the practitioner understands the validity of the test in the situation in which it is used and interprets the results with caution.

Relationship between clinical examination and imaging

The importance of detection of even quite subtle synovitis has led to a re-evaluation of the role of imaging to improve on examination findings. Ultrasound scanning may improve and augment clinical examination: for example, it can detect synovitis in patients clinically in remission and can detect more Heberden's nodes. MRI also detects more synovitis and can enhance clinical examination, but there are situations where dynamic imaging has advantages.[51] Clinical examination, particularly using the screening and regional approaches advocated in this chapter, is essential to target use of such imaging techniques appropriately, and in their interpretation.

Common clinical presentations of rheumatic disease

This page intentionally left blank

Monoarticular disease

Mark Lillicrap and Shazia Abdullah

Introduction

Monoarticular joint pain (joint pain affecting a single joint) is a common presentation both in primary care and in hospital emergency departments. The assessment and management of trauma-associated monoarticular joint pain is beyond the scope of this text. The remainder of this chapter will assume that trauma-associated causes of pain (fracture, avulsion injury, etc.) have been excluded (usually through history, examination, and radiographic imaging).

Atraumatic monoarticular joint pain can occur because of processes occurring in any of the component structures around the joint, as well as being referred from sources of pain at other sites. Inflammatory pain can be caused by microcrystals (gout and pseudogout), microorganisms (septic arthritis), and autoinflammatory diseases (rheumatoid arthritis (RA), reactive arthritis, spondyloarthritis). Mechanical pain can be caused by cartilage degeneration and associated bony reaction (osteoarthritis/osteoarthrosis) or by local effects on ligaments, tendons, and bursae. A more extensive list of the possible causes of monoarticular joint pain is shown in Table 7.1.

Epidemiology

Studies suggest that inflammatory monarthritis affects men more commonly than women[1] (largely because gout is more common in men) and the most commonly affected joints are the lower limb weight-bearing, joints (particularly the knee).[2] The underlying diagnosis of a transient self-resolving inflammatory monoarthritis may remain unknown, but crystal arthritis is the most common diagnosis; followed by reactive arthritis, RA, and then septic arthritis.[3] Undoubtedly the most important diagnosis to exclude is septic arthritis since, even with current antimicrobial management, it is associated with high levels of morbidity and mortality (approximately 10% case fatality rate).[4] Accurate information on the epidemiology of septic arthritis is lacking, for several reasons. First, the data is derived mainly from retrospective studies; secondly, there is a lack of clarity of case definition. The incidence of proven and probable septic arthritis in western Europe is 4–10 per 100 000 patient-years per year.[4] Various risk factors increase the likelihood of developing septic arthritis, including RA, osteoarthritis, prosthetic joints, low socioeconomic status, intravenous drug abuse, alcoholism, diabetes, previous intra-articular corticosteroid injection, and cutaneous ulcers.[5,6] The incidence of septic arthritis is also significantly higher in HIV infected patients than in the general population.[7] Across all age groups the most common aetiological organism of septic arthritis is *Staphylococcus aureus* followed by *Streptococcus pyogenes*.[5,8] In the young, sexually active population (particularly women) gonococcus remains an important cause, although its prevalence in developed countries is declining.[9] Immunocompromised patients may also develop septic arthritis from more unusual organisms.

Clinical features

General approach to history and examination

When approaching a patient presenting with monoarticular joint pain a number of key questions should be borne in mind:

- Is this inflammatory or non-inflammatory pain?
- Is this an acute or chronic problem?
- Is this a problem within the joint or arising from surrounding tissues?

Inflammatory versus non-inflammatory pain

From the perspective of patient management, the first key division is into those presentations caused by mechanical joint problems and those caused by inflammatory diseases. The patient's history is the key factor in addressing this question. In general, inflammatory joint diseases are associated with early morning stiffness of the affected joint, which will often last for several hours. Patients may spontaneously mention the joint feeling stiff as well as painful. In severe acute inflammatory arthritis this pain and stiffness may be so severe as to limit any movement and, when the lower limbs are involved, may restrict weight bearing. Mechanical joint problems tend to be associated with more short-lived stiffness (a few minutes in duration) and patients tend to identify activity-associated pain (rather than stiffness), which improves with rest, as their major concern.

A history of joint swelling can be an additional indicator of inflammatory joint disease, although this is less reliable when the affected joint is a knee (can occur in osteoarthritis) or an ankle (often due to oedema).

A symptomatic response to treatment with non-steroidal anti-inflammatory drugs (NSAIDs), particularly if the symptoms respond dramatically, can be supportive evidence of an inflammatory rather than a non-inflammatory process.

Table 7.1 Possible causes of monoarticular joint pain

	Inflammatory	Non-inflammatory

Common	Crystal arthritis:
	    monosodium urate
	    monophosphate
	    calcium pyrophosphate dihydrate
	    hydroxyapatite
	    calcium oxalate
	Reactive arthritis
	Spondyloarthritis:
	    psoriatic arthritis
	    enteropathic inflammatory arthritis
	Sarcoidosis/Lofgren's syndrome
	Lyme disease
	Juvenile idiopathic arthritis
	Septic arthritis:
	    bacteria (Staphylococcus aureus,
	    streptococcus, enterococcus,
	    E. coli, gonococcus)
	    fungi
	    mycobacteria
	Haemarthrosis
	    coagulopathy
	Monoarticular presentations
	of polyarticular synovitis:
	    rheumatoid arthritis
	    vasculitides
	    connective tissue diseases
	Idiopathic/self-resolving
		Osteoarthritis
		Trauma
		Avascular necrosis

Uncommon	Pigmented villonodular synovitis (PVNS)
	Foreign body synovitis
		Malignancy:
		    synovial metastasis
		    bone tumours
		Hypertrophic
		pulmonary
		osteoarthropathy
		Synovial chondromatosis
		Synovioma
		Charcot's arthropathy

A history of redness of the skin overlying the joint is highly suggestive of either crystal arthritis (gout or pseudogout) or septic arthritis. This is probably due to the acute neutrophil-driven inflammatory pathology in these diseases. Other causes of monoarthritis are not generally associated with overlying redness.

In patients with pre-existing inflammatory joint disease, such as RA, a clinical suspicion of additional septic arthritis should be considered if the symptoms in a single affected joint are significantly out of proportion to the disease activity reported in other joints.

Acute or chronic

Gout and pseudogout are characterized by a very acute onset of symptoms (usually over hours to days). Symptoms in septic arthritis are usually present for 1–2 weeks, but the onset can be slower, especially with low-virulence organisms, mycobacterial infection, and prosthesis infection. The other inflammatory arthritides all tend to be associated with a slower onset of symptoms (usually over several weeks).

A monoarthritis is generally considered acute if it has been present for less than 4 weeks,[10] although some have proposed a 2 week cut-off.[1] A joint problem which has persisted for more than 6 weeks is generally categorized as chronic. Although gout, pseudogout, and septic arthritis can occasionally be associated with a chronic monoarthritis, this is unusual. A chronic course would be more suggestive of conditions such as reactive arthritis, spondyloarthritis, chronic mycobacterial or fungal infection (if inflammatory), or osteoarthritis/osteoarthrosis (if non-inflammatory). A migratory monoarthritis, where several different joints are serially affected over time, can also be seen with a chronic autoinflammatory arthritis. However, this pattern is also recognized as a presentation of gonococcal septic arthritis.[9]

Localization of symptoms

It is important to ascertain whether the source of the pain is the joint or other surrounding structures. Joint pain is characteristically a deep-seated pain that may be localized to the joint or may be felt distal to the joint itself. The pain from surrounding structures is often a more superficial pain that the patient can clearly localize to one of the periarticular structures. It is important for the clinician to bear in mind that the common causes of monoarthritis can also affect other surrounding joint structures. Involvement of these areas can help guide diagnosis. Patients with reactive arthritis or other spondylarthritides may describe associated enthesitis, both of the affected joint and at other sites (e.g. plantar fasciitis, Achilles tendonitis)[11]; patients with gout may describe associated bursitis and inflammation of local tendon sheaths, as may patients with gonococcal septic arthritis.[9]

Additional information

Additional risk factors for septic arthritis should be sought in the history. Risk factors for septic arthritis include diabetes, prior RA, previous joint replacement, recent intra-articular corticosteroid injection, HIV infection, intravenous drug usage, or immunosuppression.[5,12] (Margaretten et al.[12] is a key reference here—a systematic review of the evidence base for diagnosis of non-gonococcal septic arthritis.) Other factors of relevance to alternative differential diagnoses that should be considered in the history are recent urethritis (reactive arthritis or gonococcal arthritis); conjunctivitis or diarrhoea (reactive arthritis); a history of cutaneous/nail psoriasis or inflammatory back pain (spondyloarthritis); history of tick bites (Lyme disease); dietary factors or features of the metabolic syndrome (gout); history of erythema nodosum (Lofgren's syndrome/acute sarcoid).

Examination

A screening examination of the musculoskeletal system (such as the GALS screen[13]) should be undertaken in any patient presenting with a monoarthritis.

Examination of the affected area, with an understanding of the relevant functional anatomy, is key to the localization of the problem. A discussion of the relevant regional examination routines can be found in other chapters, and detailed regional musculoskeletal examination routines have been published elsewhere.[6]

The key factors to consider when examining the affected joint of a patient with monoarthritis are:

- Is this a true joint problem or a peri-articular problem arising from the bursae or tendons?
- Is there evidence of inflammatory changes (a joint effusion, warmth, joint line tenderness)?
- Is there evidence of overlying erythema (suggestive of septic arthritis or crystal arthritis)?

General examination

Although the finding of an elevated temperature in conjunction with a hot, red, swollen joint should alert any clinician to a likely diagnosis of septic arthritis, the absence of any of these features does not exclude the diagnosis. In one prospective study of septic arthritis fever was only present in about one-half of the cases.[14] Furthermore crystal arthritis is not uncommonly associated with a low-grade elevation of the temperature[15] as well as swelling and frequently redness of the joint. It is therefore extremely difficult for a clinician to differentiate sepsis, as a cause of monoarthritis, from crystal arthritis, solely on the basis of examination findings.[16]

For other differential diagnoses, additional examination features may guide the diagnostic reasoning process. For example: evidence of relevant skin rashes (psoriasis or nail dystrophy (psoriatic monoarthritis), erythema nodosum (sarcoid/Lofgren's syndrome), keratoderma blenorrhagica (reactive arthritis), erythema chronicum migrans (Lyme disease); additional joint involvement (small joints of the hands (rheumatoid), sacroiliac joints (spondyloarthritis), distal interphalangeal joints (Heberden's nodes (both pseudogout and osteoarthritis)); conjunctivitis (reactive arthritis); anterior uveitis (spondyloarthritis) and cutaneous tophi (gout).

Management

An approach to investigations

The most common causes of an acute monoarthritis are crystal arthritis, reactive arthritis, rheumatoid arthritis, septic arthritis, and osteoarthritis.[3] The primary clinical concern, when assessing any patient with acute monoarthritis, is the exclusion of septic arthritis, because of its attendant morbidity and mortality.[4] For the purposes of diagnosis, all patients presenting with an acute non-traumatic inflammatory monoarthritis should therefore have a plain radiograph and arthrocentesis/synovial fluid analysis. These two investigations, combined with the history and examination, will result in a definitive diagnosis within 2–3 days in approximately three-quarters of cases.[1] Synovial fluid analysis is the most important investigation, facilitating immediate diagnosis in approximately one-third of cases.[1] In addition, synovial fluid analysis enables exclusion of most (but not all) cases of septic arthritis. In a systematic review of the clinical evaluation of septic arthritis, synovial fluid analysis was shown to be the most powerful laboratory test employed.[10]

An algorithm for the approach to a patient presenting with an acute monoarthritis (based in part on the British Society for Rheumatology guidelines 2006[17]) is shown in Figure 7.1. These guidelines, developed by a national working group reviewing the evidence base, give useful practical guidance for clinicians on how to assess and manage a patient presenting with an acute monoarthritis.

Other laboratory investigations can be contributory to diagnosis and management. In most patients a full blood count (to assess both the total white cell count and the neutrophil count), systemic inflammatory markers (C-reactive protein (CRP) or erythrocyte sedimentation rate (ESR)), electrolytes and liver function (important in management decisions) should be checked.[11] The total white cell count is not infrequently normal in patients with septic arthritis at initial presentation; the CRP is a more reliable predictor of septic arthritis in this context.[14] If they are raised, both the total white cell count and the CRP can be used to monitor response to treatment. In suspected septic arthritis blood should always be cultured before the initiation of antibiotic therapy, to increase the chances of identifying the causative organisms.[3–6,7] Sometimes blood cultures can be the only source of a positive microbiological diagnosis.[5] Although frequently checked, the serum uric acid levels are often non-contributory since these levels characteristically fall during an acute systemic inflammatory response. If the levels are found to be elevated the result can be helpful, but if the levels are normal during an acute attack it is not possible to exclude gout as the cause.[18]

If there are features in the history and examination that suggest other differential diagnoses, other appropriate laboratory studies should be undertaken. The relevant investigations for the assessment of other differential diagnoses are highlighted in the other relevant chapters of this book.

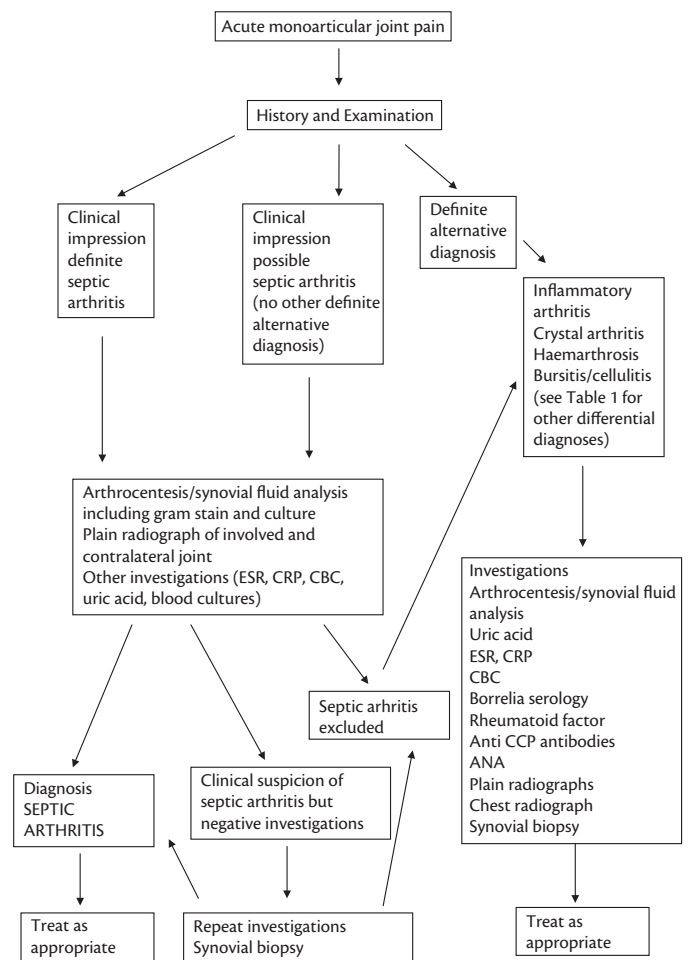

Fig. 7.1 Algorithm for the investigation of acute monoarticular joint pain.

Arthrocentesis

Arthrocentesis and prompt synovial fluid analysis (with Gram staining, culture, and assessment under compensated polarized light) are the key tools in making a diagnosis in patients presenting with acute monoarthritis. In patients with septic arthritis the Gram stain is positive in approximately 50% of cases, and cultures can be positive in approximately 90% of patients.[10,19,20] A negative synovial fluid culture does not exclude the diagnosis of septic arthritis, and the causative organism can sometimes be isolated from other sites (e.g. blood or urine). Where the clinical suspicion is high for septic arthritis, patients should be treated even in the absence of positive cultures.[14]

A structured approach to joint arthrocentesis is shown in Figure 7.2. It is a safe technique that is easily undertaken provided the clinician is aware of the relevant functional anatomy and has had appropriate training.

For skin preparation before aspiration, an aseptic no-touch technique using handwashing, non-sterile gloves, and alcohol swabbing prior to the procedure (also known as a clean technique) is as effective as a sterile technique (with sterile gloves/drapes and iodine swabs).[21]

The initial appearance of aspirated synovial fluid can itself guide the diagnosis. It is useful to document the gross appearance of synovial fluid, describing the colour, clarity, and viscosity. Clear, straw-coloured, viscous synovial fluid is usually indicative of normal or osteoarthrotic synovial fluid. Heavily blood-stained fluid may indicate an underlying traumatic cause or a haemarthrosis secondary to a coagulopathy. As the fluid becomes inflammatory it becomes less viscous and loses clarity due to the accumulation of white blood cells. Mildly cloudy synovial fluid (indicative of a mild or moderately elevated synovial fluid white cell count) is seen in autoinflammatory diseases such as RA and spondyloarthritis as well as crystal arthritis (and some septic arthritis). Turbid synovial fluid, indicative of a high synovial fluid white cell count (usually predominantly neutrophilic), is more commonly seen in septic arthritis.[22] Although synovial fluid white cell count can be measured, it is not a reliable measure to exclude or confirm a diagnosis of septic arthritis.[23]

Polarized light microscopy

In addition to microbiological assessment of aspirated synovial fluid, synovial fluid microscopy under compensated polarized light should also be undertaken. The demonstration of microcrystals within the synovial fluid remains the gold standard for the diagnosis of crystal arthritis. Synovial fluid analysis for monosodium urate monophosphate (uric acid) has a sensitivity of 69% and a specificity of 93%[24,25] (figures for calcium pyrophosphate dihydrate microcrystals are lower). Synovial microcrystals can occasionally coexist with septic arthritis, and the finding of crystals does not entirely exclude septic arthritis. Aspirated synovial fluid should therefore also be Gram stained and cultured if there is any clinical suspicion of sepsis.[25] (Zhang et al.[25] is a key reference—a report of a European task force which identifies 10 key recommendations for the diagnosis of gout.)

Radiology

A study of adult patients with acute non-traumatic monoarthritis[1] demonstrated the benefits of plain radiographs in the diagnostic approach. In their study, radiographs of the involved and the contralateral joint were undertaken and this is advantageous for the purposes of comparison. Radiographs can be diagnostically helpful if they demonstrate chondrocalcinosis (in patients with calcium pyrophosphate dihydrate (CPPD) arthritis/pseudogout). Characteristic radiographic changes can also be seen in other conditions (e.g. osteoarthritis, RA, psoriatic arthritis). Radiographs are rarely adequate to exclude septic arthritis, particularly when these other conditions present with monoarthritis—diseases like RA are a risk factor for the development of septic arthritis.[3] The radiographic changes of gout (e.g. gouty erosions) are occasionally demonstrable, although plain radiographs only have a sensitivity of about 30% for gout.[26] Plain radiographs can also be diagnostic of rarer conditions, e.g. Charcot joint, avascular osteonecrosis, and hypertrophic pulmonary osteoarthropathy.

Other imaging modalities can be helpful in the diagnostic work-up of monoarthritis. Ultrasound can be used both for guiding arthrocentesis and can also be helpful diagnostically. Ultrasound has a much greater sensitivity for gout (96%),[26] detecting stippled foci of uric acid deposition and hyperechoic soft tissue areas which are not seen on plain radiographs. However the specificity of ultrasound for gout is lower (73%).[26]

CT scanning and MRI can also be helpful in the identification of other causes of acute monoarthritis. For example, avascular

AN APPROACH TO ARTHROCENTESIS (JOINT ASPIRATION)
Introduce self; explain reason and nature of procedure. Gain verbal consent.
Prepare tray including: 10-20ml syringe, 21G (green) needle, some chlorhexidine swabs , gauze, sterile universal containers NB: If septic arthritis is suspected a wider bore 19G white needle may be used instead. If local anaesthetic is to be administered, draw up 2ml of 1% lignocaine, using a blue needle and then put a clean 25G (orange) needle on the syringe. (remember to check drug name, dose, route and expiry)
Roll up sleeves, remove watch, wash hands and put on gloves (non sterile).
Identify appropriate surface landmarks for joint to be aspirated
Check skin at the proposed aspiration site is lesion-free.
Clean skin with alcohol or chlorhexidine wipe in circular motion from injection point outwards then wait until cleaned area is dry.
Avoid touching the needle at entry point once cleaned.
If local anaesthetic is used, infiltrate 1-2ml 1% lidocaine subcutaneously and subsequently deeper along the aspiration track. Wait for at least 30 seconds for anaesthetic to take effect. Place sharps into sharps bin
Use appropriate volume syringe and appropriate gauge needle Insert needle through skin and advance until fluid is obtained.
Aspirate to dryness
Withdraw needle, place into sharps bin and apply pressure with gauze. Offer elastoplast or other appropriate dressing Ensure patient is comfortable
Place samples in universal container for laboratory analysis (microbiology for gram stain/culture; polarized light microscopy for crystals).
Leave clinical area clean and tidy, wash hands.

Fig. 7.2 An approach to joint aspiration (arthrocentesis).

necrosis, haemochromatosis, pigmented villonodular synovitis, and synovial chondromatosis all have characteristic appearances on MRI. MRI may also allow identification of a foreign body (e.g. a plant thorn) in foreign body synovitis.[27] Where the underlying diagnosis remains unclear despite initial investigations, such additional imaging should be considered to help guide further intervention.

Supplementary investigations

A proportion of patients with acute inflammatory monoarthritis cannot be diagnosed in the first few weeks. Some of these have a spontaneously resolving idiopathic inflammatory arthritis. If monoarthritic symptoms persist for several weeks, consideration should be given to arthroscopic biopsy of the synovium. Certain infections, such as mycobacterial and fungal infections, can present with a more chronic picture. A synovial biopsy can be subjected to prolonged culture and may also show characteristic histological changes such as granulomatous synovitis (suggestive of mycobacterial infection). PCR (of either synovial fluid or synovial tissue) is a further supplementary investigation that can be useful in the diagnosis of atypical infections.[28]

Characteristic histological changes are also seen in pigmented villonodular synovitis and other rarer synovial tumours that can again present with a more chronic indolent course.

Case history

A 75 year old woman, with a history of nodal osteoarthritis (OA) and a previous right total hip replacement, was admitted to hospital with a community-acquired pneumonia. Having been on appropriate intravenous antibiotic treatment for 48 hours she developed an acute monoarthritis of her left wrist. On general examination she had a pyrexia (temperature 37.8 °C) and changes on respiratory examination in keeping with pneumonia. On musculoskeletal examination she had nodal osteoarthritis changes of the distal interphalangeal joints and a scar from her previous total hip replacement. The left wrist itself was erythematous, warm, and tender with a markedly restricted range of movement. There was a palpable effusion with associated boggy synovial swelling.

What is the likely diagnosis and how should this be managed?

The first concern, in this clinical context, is septic arthritis and this diagnosis must be excluded. As highlighted in this chapter, pre-existing osteoarthritis is a recognized risk factor for septic arthritis and the presence of a coexisting infectious source would increase the likelihood of this. However, it is also possible that this is a crystal arthritis. In fact the most likely diagnosis, in this clinical setting, is pseudogout. As highlighted in the chapter on crystal arthritis (Chapter 151), pseudogout commonly occurs on a background of nodal osteoarthritis, can be triggered by intercurrent infection, and affects medium/large joints including, quite commonly, the wrist.

Reviewing the appropriate management in the algorithm illustrated in Figure 7.1, this patient would be described as having possible septic arthritis (although pseudogout/crystal arthritis is possible, it is not a definite diagnosis).

In this case the following investigations were initiated:

◆ joint aspiration/synovial fluid analysis (undertaken by the on-call rheumatologist)

◆ blood tests including CBC, CRP. and ESR and blood cultures

◆ plain radiograph of both wrists.

The following initial results were obtained:

◆ synovial fluid: turbid, inflammatory, blood-stained aspirate obtained

◆ Gram stain negative

◆ blood and synovial fluid cultures negative after 3 days

◆ weakly positively birefringent rhomboid crystals identified on polarized light microscopy

◆ chondrocalcinosis of triangular fibrocartilage complex on radiography.

Septic arthritis was therefore excluded and the patient was managed as having pseudogout. The pain was initially managed with NSAIDs but due to ongoing symptoms (when the culture results were known) the wrist joint itself was injected with hydrocortisone, resulting in a resolution of the patient's symptoms.

CHAPTER 8

Oligoarticular disease

Andrew Keat

Introduction

The definition of oligoarthritis as involving four or fewer joints over the first 6 months of the course of disease arises from childhood arthritis studies.[1] The term pauciarticular arthritis is also used with the same meaning and, in children, evolution of persistent arthritis to involve more than four joints is often referred to as 'extended oligoarthritis'. In adults the term is also sometimes used to apply to five or fewer joints.[2]

Involvement of a few joints is as characteristic a pattern of rheumatic disease as the monoarthritis of gout or sepsis and the symmetrical polyarthritis of rheumatoid arthritis. Typically, large joints such as the knee and ankle are primarily involved, though forefoot and toe joints may also be affected; upper limb joints are affected less commonly, unless psoriasis is present. In a few cases oligoarticular onset of disease in adulthood evolves into characteristic polyarticular or even monoarticular syndromes, but most cases either remain as undifferentiated oligoarthritis or differentiate into a more typical form of spondyloarthritis (SpA). The most common diagnoses to be made in patients presenting with oligoarticular arthritis are reactive arthritis and sarcoidosis,[2] but most patients defy convenient labelling. Most of these may be said to have undifferentiated peripheral SpA.

As the major diagnostic group of oligoarthritides, peripheral SpA requires some clarification before the diagnostic approach is considered. SpA currently defies tight diagnostic criteria. Initial criteria built on the description of 'seronegative polyarthritis' by Moll, Wright, and colleagues[3,4] were introduced by Amor and colleagues in 1990[5] and by the European Spondyloarthritis Study Group (ESSG) in 1991.[6] Both use a scoring system to identify SpA and the ESSG criteria specifically allow differentiation into principally spinal or peripheral disease. However, neither set of criteria works well as potential diagnostic criteria across a range of patients considered to have SpA. More recently the Assessment of Spondyloarthritis International Society (ASAS) has published further criteria for classification of spondyloarthritis[7] and these new criteria for classification of peripheral SpA are shown in Figure 8.1. Although the sensitivity of these criteria for diagnostic purposes remains modest at 77.8%, specificity exceeds that of the Amor and ESSG criteria;[7] these criteria are often used for diagnosis.

The classification of peripheral SpA overlaps with the diagnosis of the individual syndromes of psoriatic arthritis, enteropathic arthritis, and reactive arthritis and may accompany axial disease. The extent to which oligoarthritis associated with these

conditions actually represents a single condition is unresolved, so that at present both the individual syndromes and the over-arching 'peripheral SpA' concept are widely used.

The characteristic features of peripheral SpA and other conditions considered in this chapter are described elsewhere in this volume.

Epidemiology

Measuring or estimating the prevalence of oligoarthritis, including peripheral SpA, is fraught with difficulties. Epidemiologically it is pertinent and pragmatic to consider peripheral SpA as a surrogate for oligoarthritis, as this diagnosis accounts for the majority of patients. However, although data on prevalence of SpA as a group—including axial SpA—are available, it is strongly influenced by the prevalence of HLA B27 and the ethnic mix of the population under study. The prevalence of peripheral SpA may be assumed to be lower than the true figure for SpA overall. Moreover, it is clear that recognition of the various subtypes of peripheral SpA varies, so that psoriatic arthritis is generally under-recognized and many cases of reactive arthritis resolve. In the absence of clear diagnostic criteria or long-term outcome studies to establish which cases

evolve into another disease, designation of the patients is also difficult, especially in undifferentiated SpA.

Bearing in mind these difficulties, Haglund and colleagues[8] estimated the prevalence of SpA (not including chronic reactive arthritis) as 0.45% (95% CI 0.44%–0.47%) in Sweden; this included prevalences of psoriatic arthritis (0.25%), ankylosing spondylitis with peripheral involvement (0.12%), undifferentiated SpA (0.10%), and arthritis associated with inflammatory bowel disease (0.015%). The prevalence of SpA overall was similar in men and women. Reveille[9] estimated the prevalence of SpA in the United States at 0.2–0.5% for ankylosing spondylitis, 0.1% for psoriatic arthritis, 0.065% for enteropathic peripheral arthritis, and 0.05–0.25% for enteropathic axial arthritis. This review concluded that the overall prevalence of SpA was likely to be around 1%, a prevalence figure similar to that of rheumatoid arthritis.[10] Prevalence figures for individual SpA syndromes are given in the relevant chapters.

Aetiology

As oligoarthritis is a heterogeneous group of conditions there are no common aetiological factors, although in many cases a combination of genetic and environmental factors is implicated. Few oligoarticular diseases have clear pathognomonic features, so that diagnosis is based on the clinical pattern, associated comorbidities, and a few laboratory tests. Immunopathological and histopathological analyses are of limited value. Disorders that frequently or sometimes present in adult life with an oligoarticular pattern of disease are summarized in Table 8.1.

Presentation with oligoarthritis is relatively uncommon, but in one Norwegian study the outcomes of 146 patients with this presentation were recorded.[2] Of these, 46 patients were found to have reactive arthritis, 15 had sarcoidosis, 15 had non-inflammatory joint disease, and 62 were recorded as 'undifferentiated arthritis' with 8 having a spread of other conditions. Oligoarticular presentations of disseminated gonococcal and meningococcal infection are unusual but well recognized,[11,12] and this pattern is characteristic of Lyme disease.[13] Septic arthritis is usually monoarticular though multifocal joint sepsis may occur, especially in the case of tuberculosis. Oligoarticular involvement is typical of Behçet's syndrome,[14] and evolution of oligoarthritis to rheumatoid arthritis or Sjögren's syndrome is not rare. In Kvien et al.'s study[2] the diagnosis of oligoarthritis was made in some patients with osteoarthritis; in older patients an inflammatory element with joint swelling is often present with osteoarthritis, so that the diagnosis may not be straightforward.

The features of sarcoidosis and spondyloarthritis are considered elsewhere. However, the term 'peripheral SpA' covers a large spectrum of rheumatology without absolute clarity of meaning. Under the terms of the ASAS classification criteria[7] this term covers peripheral forms of psoriatic arthritis, reactive arthritis, enteropathic arthritis, and the arthritis associated with axial SpA. In many patients, however, the disease does not meet the strict criteria and yet the arthritis has characteristic features of asymmetrical lower limb oligoarthritis and the HLA B27 gene may be present. Clinical studies have generally focused on the 'polar' forms of disease such as psoriatic arthritis, for which clear criteria exist (CASPAR),[15] and reactive arthritis; relatively little work provides evidence of the assumed homogeneity of peripheral SpA. Based on the likely role of initiating infections in reactive arthritis[16,17] and the high frequency of HLA B27 throughout the SpA,[18,19] it remains likely that there is a range of initiating triggers with some commonality of pathogenetic mechanisms. Potential initiating events are discussed in appropriate chapters (see Chapter 123, Psoriatic arthritis; Chapter 124, Reactive arthritis and enteropathic arthropathy).

Exploration of potential synovial characteristics which might allow differentiation of peripheral SpA from other inflammatory joint diseases and of individual SpA syndromes have not led to identification of any reliable histological differentiators.[20] Nonetheless, evidence of increased synovial mast cell numbers and of increased expression of IL-17 by mast cell in SpA synovium may offer both mechanistic clues and a degree of differentiation from other forms of arthritis including RA.[21] Increased IL-17 production has also been noted in specific CD4 T-cell lines from patients with SpA.[22] The known link between spondyloarthritis and IL-23 receptor polymorphisms[23] may underpin increased IL-17 production and this might be both an important element of pathogenesis and a potential target for treatment.

In the absence of hard diagnostic criteria, it is unclear whether oligoarticular psoriatic arthritis really represents the same condition as polyarticular disease or whether some cases of the latter are more closely allied to rheumatoid arthritis.[24,25]

The approach to diagnosis

It is not uncommon for symptoms suggestive of oligoarthritis to reflect non-inflammatory lesions, so care should be taken to discriminate between true synovitis and arthralgia, regional pain syndromes, and other painful lesions. Similarly, presentation may be with a single symptomatic joint but with additional inflamed joints being identified by thorough examination. An early element of the diagnostic approach is, therefore, the objective demonstration of the presence and extent of inflammatory synovitis by clinical joint assessment, ultrasound, or MRI. As in other aspects of rheumatic

Table 8.1 Disorders that frequently or sometimes present in adult life with oligoarticular arthritis

Spondyloarthritis	Infective	Miscellaneous	Atypical rheumatic
Reactive arthritis	Gonococcal arthritis	Sarcoidosis	Rheumatoid arthritis
Psoriatic arthritis	Meningococcal arthritis	Paraneoplastic arthritis	Sjögren's syndrome
Enteropathic arthritis	Lyme disease	Behçet's syndrome	Crystal arthritis

Axial SpA with peripheral arthritis	Whipple's disease		Polymyalgia rheumatica
Undifferentiated SpA	Septic arthritis		

SpA, spondyloarthritis.

Table 8.2 Three layers of diagnostic information in oligoarthritis

Layer	Elements	Examples
1	Age, gender, ethnicity	Reactive arthritis, sickle cell disease in young adults
		Polymyalgic or paraneoplastic arthritis in elderly people
2	Personal and family history	Previous monoarthritis at knee or hip suggests SpA
		Family history of comorbidities suggests SpA or atypical RA
3	SpA-associated features	Eye, skin, bowel, enthesis spine lesions suggest SpA

RA, rheumatoid arthritis; SpA, spondyloarthritis.

disease, diagnosis is heavily dependent on three 'layers' of diagnostic information (Table 8.2).

The first layer consists of age, gender, and ethnicity. Infection-related arthritides and episodic arthritis associated with haemoglobinopathies[26] particularly affect the young; atypical connective tissue diseases and sarcoidosis may be suggested by oriental or Afro-Caribbean origins while, in elderly people, joint disease associated with polymyalgia rheumatica,[27] paraneoplastic syndromes,[28] and atypical crystal synovitis may be suspected.

The second layer includes personal and family history. Occurrence of an idiopathic monoarthritis at the knee or hip in childhood or teenage is a frequent precursor or early feature of SpA; a family history of ankylosing spondylitis, psoriasis, iritis, inflammatory bowel disease, or multiple joint replacements in early adult life suggests peripheral SpA.

The third layer pertains to comorbidities present in the patient, including a personal history of inflammatory eye disease, possible inflammatory bowel disease, spinal pain, genitourinary or gut infection, and psoriasis. The use of comorbidities as signposts to the diagnosis of oligoarthritis is illustrated in Figure 8.2 and the case histories.

A methodical approach to reaching a diagnosis in the case of an adult patient presenting with oligoarthritis based on comorbidities is suggested in Figure 8.2A and developed in Figure 8.2B–F.

The diagnostic approach is exemplified by the following illustrative case histories.

Consideration of diagnoses according to confirmed or potential comorbidities is a sensitive part of the diagnostic process. The

Case history 1

A 32-year-old white woman presents with a 3-week history of pain and swelling at the right knee. She has been previously well, but over the preceding few days had noticed discomfort at the right forefoot and ankle. She felt systemically well.

She worked as a bank cashier and had last travelled abroad some 7 months ago.

The family history was notable but non-specific. She was single, but both parents were alive and she had four siblings. Her

father suffered from some back pain attributed to his work as a builder; one sister had an undiagnosed skin rash, and another was said to suffer from 'colitis'. The maternal grandmother was said to have rheumatoid arthritis but this was unconfirmed.

Enquiry into the past history did not disclose any significant illnesses apart from intermittent abdominal discomfort with alternating diarrhoea and constipation ascribed to irritable bowel syndrome.

The patient's general health was reportedly good with steady weight (BMI 27.3), bowel symptoms as above but without passage of blood per rectum. Specific enquiry revealed some 'scalp dryness' but no eye symptoms, skin rashes, dysuria, vaginal discharge, or breathlessness.

Physical examination confirmed the presence of synovitis with effusion at the right knee and soft tissue swelling and tenderness at the right second and third metatarsophalangeal (MTP) joints. The remainder of the physical examination was normal.

In this instance the age of the woman raises several diagnostic possibilities, as indicated in Table 8.1. As is often the case, the personal and family history raise issues that may well be non-contributory but raise suspicions about possible links with inflammatory bowel disease, psoriasis, and ankylosing spondylitis.

diagnostic pathways are summarized in Figure 8.2B and C. In the first instance establishment of a comorbid lesion or symptom leads on to further analysis of the possibilities. In the case cited, intestinal inflammation and skin lesions are indicated as possible comorbid lesions although the history would be consistent with unrelated irritable bowel syndrome and non-specific skin dryness. Figure 8.2B sets out possible gut-associated disorders and suggests a pathway for investigation; similarly, Figure 8.2c sets out the various skin lesions which should be sought and their potential diagnostic implications.

Enquiry about genital tract symptoms and possibility of recent genital tract infection should be made in all patients with

Case history 2

A 37-year-old Afro-Caribbean man presents with a 3-week history of painful ankles. He works in an office and runs regularly; he initially ascribed the ankle pain to a possible running injury. Over the previous 2 months he has felt tired but attributed this to working long hours. There is no history of skin rash, back pain, recent infections, cough, fever, diarrhoeanor eye symptoms. There was no weight loss. In the past he has been well and the family history was non-contributory.

He appeared unwell. Examination revealed soft tissue swelling with some induration of the skin over both ankles but no other clinical features. In particular, there was no lymphadenopathy and the chest was clinically clear.

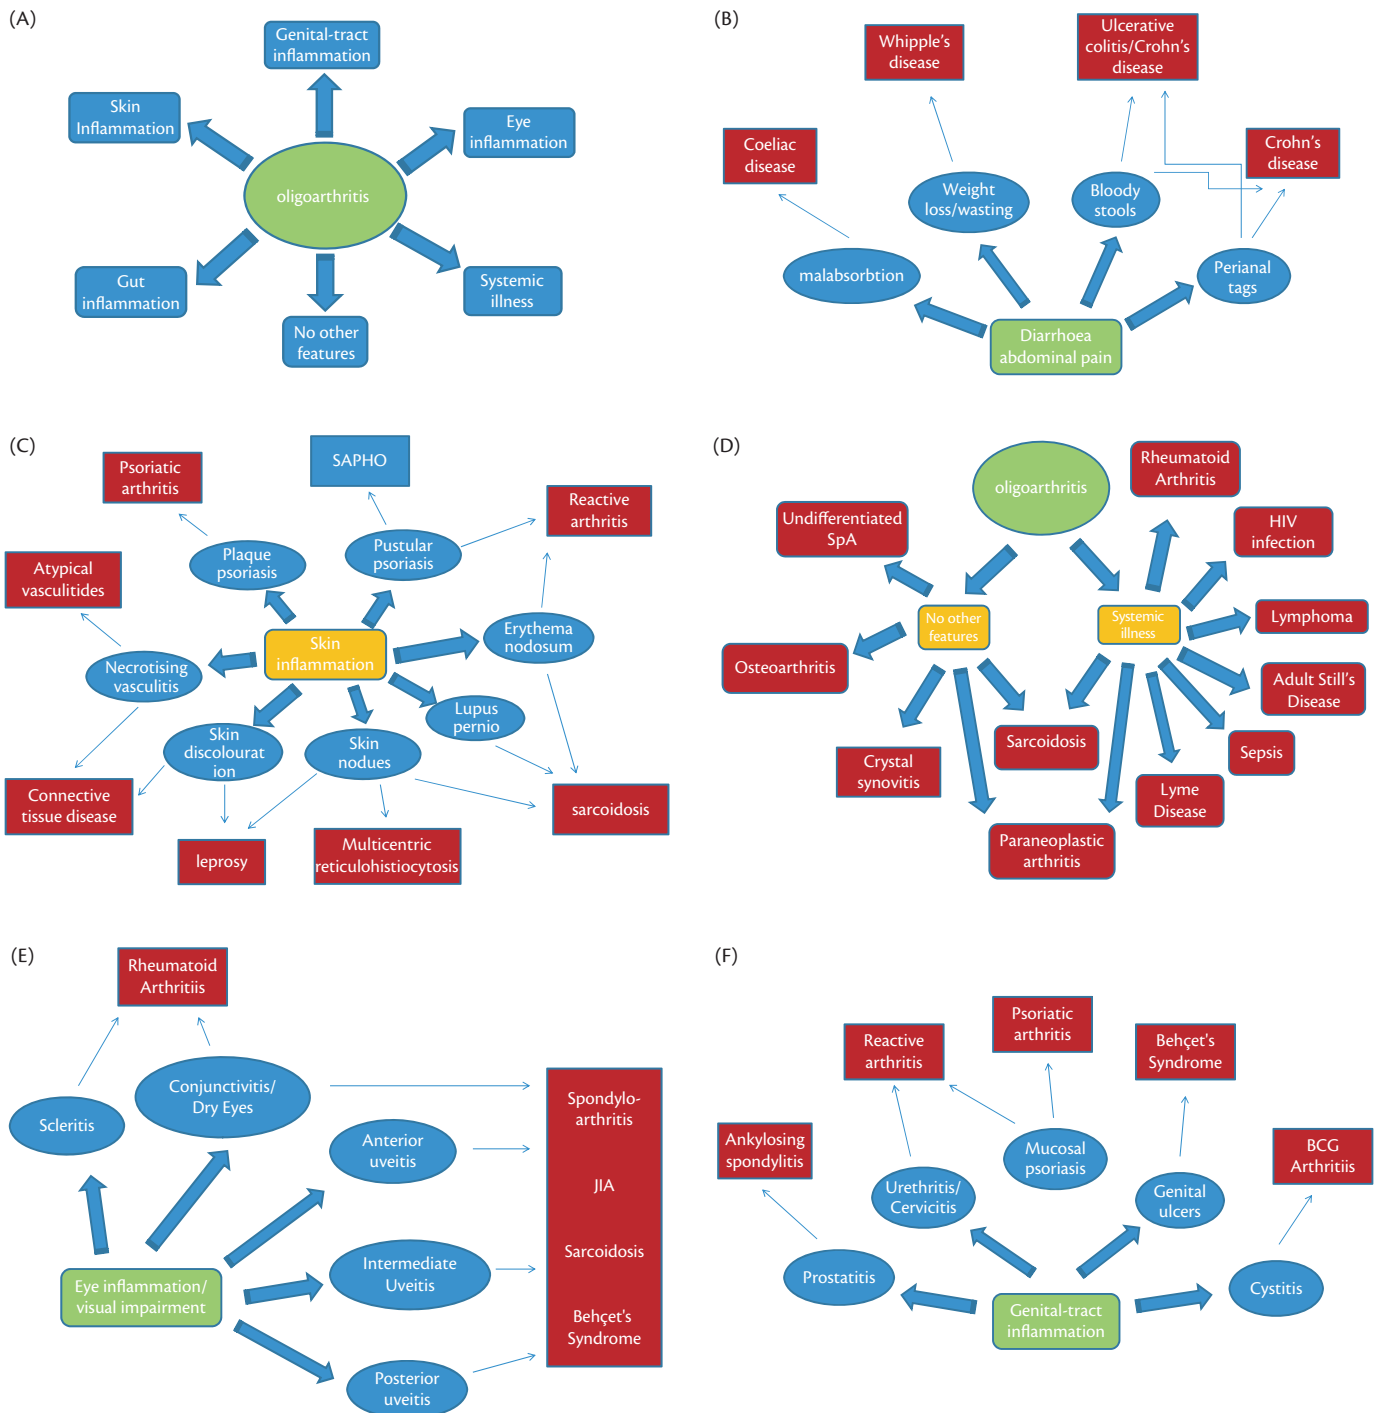
The diagnostic algorithm in this case of a systemically unwell patient with no apparent comorbidities is described in Figure 8.2D. In a man of this age the most likely diagnosis is sarcoidosis.


Fig. 8.2 Approach to investigation of a patient with oligoarthritis: (A) key diagnostic comorbidities; (B) oligoarthritis with diarrhoea and/or abdominal pain; (C) oligoarthritis with skin lesions; (D) oligoarthritis in a systemically unwell patient with no apparent comorbidities; (E) oligoarthritis with eye lesions; (F) oligoarthritis with genital tract lesions.

oligoarthritis, especially in young adults. The personal history may also have disclosed previous infections or high-risk behaviour, though urethritis and genital lesions may occur in their absence and ongoing infection, especially in women and passive homosexual men, may be asymptomatic or unrecognized by the patient. Key genital tract lesions of diagnostic significance are indicated in Figure 8.2F.

Case history 3

A 23-year-old man presents with pain at the right foot. Symptoms have been present for 7 weeks in spite of taking ibuprofen prescribed by his primary care physician. In other respects he is well, though walking is now difficult because of pain and work is interrupted. There is no family history of note and he feels generally well. On questioning he described an episode of a painful red eye at the age of 18 years for which he consulted an ophthalmologist and which settled over 2–3 weeks with topical treatment. There was no other history offered. Enquiry about possible diarrhoea or genital tract symptoms revealed no symptoms, but he acknowledged several recent new sexual contacts.

Examination revealed a well man with marked synovitis at the second, third, and fourth MTP joints of the right foot. There was also tenderness but not swelling at the attachment of the right Achilles tendon and a small right knee effusion. The combination of oligoarthritis and previous probable inflammatory eye disease prompted referral to a genitourinary physician who identified non-gonococcal urethritis. History obtained subsequently from the general practitioner confirmed the diagnosis of acute anterior uveitis in the past.

A history of an episode (or episodes) of painful red eye is always important. Acute anterior uveitis is seldom synchronous with episodes of arthritis, though may occur episodically during persistent arthritis and, because of its intensity in adults, the diagnosis may be known. It is usually impossible for non-ophthalmologists to distinguish the various causes of 'painful red eye', so every opportunity should be taken to arrange ophthalmological assessment when symptoms or signs are present. Visual disturbance may also be associated with all forms of uveitis, so careful expert assessment of both the anterior and posterior elements of the eyes is important in establishing the diagnosis. Key diagnostic possibilities are outlined in Figure 8.2e.

CHAPTER 9

Polyarticular disease

Ade Adebajo and Lisa Dunkley

Introduction

When presented with a patient who has joint disease, it is important to have a clinical strategy for making a diagnosis and effecting an appropriate management plan. The first question that the clinician should ask is 'Is this a joint problem?', as one needs to make sure the patient does not have bony pain, muscle pain/weakness, or a tendon or other soft tissue problem (Table 9.1). If it is a joint problem, one should ask, 'Does this affect one joint (monoarthritis), a few joints (oligoarthritis), or multiple joints (polyarthritis)'? With these basic first steps, the clinician is already beginning to formulate a differential diagnosis.

The presentation of monoarthritides is considered elsewhere (Chapter 7). Here we consider a clinical approach to polyarticular disease.

General information from clinical history and examination

All clinical assessment begins with a clinical history and examination. Specific information relating to individual diagnoses will be considered in later sections, but the following are useful generic points to consider when assessing a patient with polyarticular disease.

Age

Inflammatory joint disease may occur at any age from childhood to very old age, but degenerative disease is much more common as we get older. Gout is uncommon before the fifth decade and calcium pyrophosphate disease typically develops from the seventh decade.

Gender

Gout is more common in men, but the autoimmune diseases are more common in women with female: male ratios of 3–5:1 (rheumatoid arthritis, RA) and 9:1 (systemic lupus erythematosus, SLE).

Table 9.1 Examples of mimics of joint disease

Symptom	Possible causes
Bone pain	Osteomalacia, Paget's, bony metastases, hypertrophic pulmonary osteoarthropathy (HPOA)
Muscle pain/weakness	Polymyalgia rheumatica, vitamin D deficiency, polymyositis

Lifestyle factors

Smoking is associated with RA, which is three times more common in smokers than in non-smokers. Alcohol is associated with gout and psoriasis. Obesity is associated with osteoarthritis (OA) of the knees and feet, but equally, patients with a history of high-level sports activity are also at risk of early OA (e.g. in the knees of footballers or the shoulders of cricketers or racquet sports players). Occupational history is also important; physical jobs can similarly lead to early OA, e.g. of the knee in plumbers, and classically of the hip in farmers. High-risk behaviour for contraction of blood-borne diseases raises the possibility of arthritis related to chronic infections, such as hepatitis B and C.

Family history/personal medical history

Patients with one autoimmune disease often develop another, or have family members with autoimmunity. Ask about thyroid disorders, vitiligo, and pernicious anaemia. Also ask about underlying conditions that might be directly associated with joint disease—Crohn's disease. ulcerative colitis, skin psoriasis, uveitis. Patients with the 'metabolic syndrome' (central obesity, type 2 diabetes, hypertriglyceridaemia, and hypertension) are at high risk of developing gout (or vice versa) and there is often a positive family history. Patients with renal impairment are also at risk of gout. Metabolic conditions can be associated with calcium pyrophosphate disease (CPPD), most commonly primary hyperparathyroidism, but rarer associations include hypomagnesaemia, Wilson's disease, and acromegaly.

Honing the diagnosis: inflammatory versus non-inflammatory disease

There are many approaches to formulating a differential diagnosis. Considering whether a patient presents with inflammatory or non-inflammatory symptoms is often helpful (see Table 9.2).

Inflammatory joint pain

Patients typically describe pain and *stiffness* within the affected joints, that is often worst first thing in the morning (after the inactivity of being asleep all night) and again after a period of rest (often later in the evening as they relax before bed). Moderate movement typically eases this stiffness and pain—'Once I get going again I'm fine'. Generally early morning stiffness is considered significant and indicative of inflammatory pathology, if it lasts at least

Table 9.2 Comparison of inflammatory and degenerative joint symptoms

Symptoms	Inflammatory	Degenerative
Pain	Eases with use	Increases with use
		Often clicks/clunks heard
Stiffness	Significant (>60 min)	Not prolonged (<30 min)
	Early morning/at rest (evening)	Morning/evening
Swelling	Synovial ± bony	None or bony
Inflammation	Hot and red?	Not clinically inflamed
Patient demographics	E.g. young, psoriasis, family history	E.g. older, prior occupation/sport
Joint distribution	E.g. hands and feet	E.g. 1st CMCJ, DIPJ, knees
Responds to NSAIDs	Positive response	Less convincing response

CMCJ, carpometacarpophalangeal joint; DIPJ, distal interphalangeal joint; NSAIDs, non-steroidal anti-inflammatory drugs.

30–60 minutes. Non-steroidal anti-inflammatory drugs (NSAIDs) may be of significant benefit, more so than paracetamol or codeine-based simple analgesia, but this is not ubiquitously true. If steroids have been administered, usually either orally or intramuscularly, these would be expected to bring about a substantial but temporary relief of symptoms.

Non-inflammatory joint pain

Patients also describe pain and stiffness, but the stiffness is usually less persistent than in inflammatory disease. Both of these symptoms are at their worst in the evenings, and typically movement of a joint makes the pain worse. Early morning stiffness may be present, especially in osteoarthritis of the hands, but the duration and intensity of stiffness is not as marked as in inflammatory disease.

NSAIDs are often of no additional benefit to simple codeine/paracetamol-based analgesia.

Joint distribution

The distribution of affected joints can help differentiate not only between inflammatory and non-inflammatory disease, but also between specific types of inflammatory disease (Figure 9.1).

Involvement of the first carpometacarpal (CMC) joint is almost always due to osteoarthritis; RA rarely involves the distal interphalangeal (DIP) joints of the hands, and never in isolation. The commonest joints to be affected by gout are the first metatarsophalangeal (MTP) joints (classical podagra), ankles, and knees.

Appearance of the joints

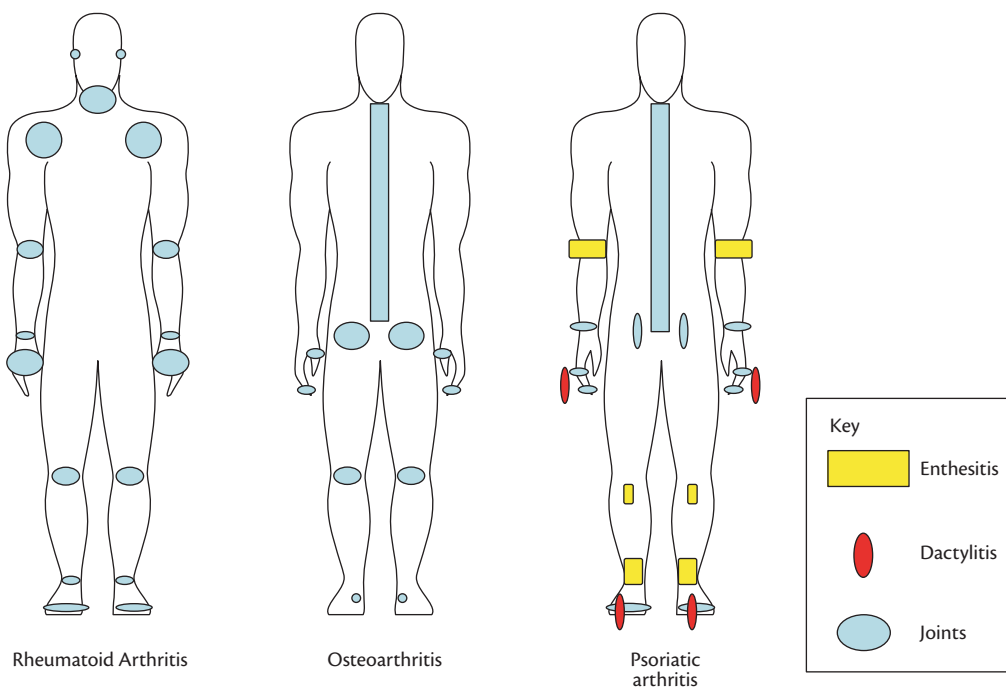
A red, hot, swollen joint classically occurs with the very acute history of gout/pseuogout. A septic joint can also present in this way. Both may present with systemic fever. The chronic inflammatory arthritides of RA and psoriatic arthritis typically present with a more subacute picture of swelling and warmth, but not classically markedly erythematous joints.

Chronicity of symptoms

Typical timelines of various polyarticular conditions are illustrated in Figure 9.2. Crystal disease and infection are usually acute conditions; RA and psoriatic arthritis may evolve slowly over many months, waxing and waning in that time frame, but for a small proportion of patients, these too can be 'explosive' and rapidly progressive.

Inflammatory versus non-inflammatory disease

The clinician has now established whether the patient has inflammatory or non-inflammatory joint symptoms. Considering the joint pain paradigm as shown in Figure 9.3, it is now possible to explore the non-inflammatory versus the inflammatory arms and begin to work towards a specific diagnosis.



Rheumatoid Arthritis   Osteoarthritis   Psoriatic arthritis

Key

Enthesitis

Dactylitis

Joints

Chronicity of joint symptoms

Fig. 9.2 Typical chronicity of symptoms in common arthritides.

Fig. 9.3 A paradigm for diagnosis of polyarticular joint pain. CWPS = chronic widespread musculoskeletal pain syndrome.

Non-inflammatory polyarticular diseases

Degenerative disease: osteoarthritis

OA is a condition of degradation within the joint, usually involving cartilage loss and damage to subchondral bone. It may also involve an exaggerated repair response to the initial degradative stimulus.[1] It is the commonest form of arthritis worldwide.

Different patterns of OA exist. It may affect the spine, the large joints, isolated small joints (e.g. the first MTP joint) or multiple small joints (typically 'nodal OA' of the hands). This latter subset of OA can mimic inflammatory arthritis in terms of the inflammatory nature of the joint pain, but the presence of Heberden's and Bouchard's nodes and involvement of the first CMC joint are usually enough to confirm the diagnosis.

There are also further polyarticular subsets of OA, often referred to as 'inflammatory OA' or 'erosive OA'. These patients have inflammatory symptoms, typically involving the small joints of the hands as described above. The key difference is that their radiographs show erosive change.

Fig. 9.4 Erosive osteoarthritis involving proximal and distal interphalangeal joints.

In one subset, patients have erosive disease of the proximal and distal interphalangeal joints of the fingers, and symptoms are often poorly responsive to conventional treatments. Typical radiographs are shown in Figure 9.4.

The second subset of patients are those who have arthritis associated with CPPD. This is also often referred to as 'inflammatory OA' but has a propensity to involve the second and third MCP joints in isolation. Secondary causes of CPPD, such as haemochromatosis, diabetes, hypomagnesaemia, and hyperparathyroidism show this same pattern of joint involvement (see also section 'Pseudogout: calcium pyrophosphate disease').

Non-degenerative disorders

Benign joint hypermobility syndrome

Approximately 10% of the adult population are hypermobile.[2] Joint hypermobility in itself is not pathological, but may be considered so if associated with persistent pain and joint dysfunction. Diagnosis of benign joint hypermobility syndrome (BJHS) is made using the Brighton criteria[3] which identify the combination of joint hypermobility *and* patient symptoms. Joint hypermobility may be associated with chronic non-inflammatory joint pain. The pain might be restricted to one or two (often weight-bearing) joints, but can present as a symmetrical polyarticular condition. The clue to diagnosis is often the initial examination.

Chronic widespread musculoskeletal pain

Chronic widespread musculoskeletal pain syndrome (CWPS) is also referred to by many as 'fibromyalgia'. These overarching terms encompass a syndrome of widespread joint and muscle pain that is accompanied by multiple associated symptoms, including fatigue, poor sleep, and mood disturbance. Taking a careful history to elicit these associated symptoms, and establishing the presence of widespread but non-inflammatory pain, helps confirm the diagnosis.

Inflammatory polyarticular diseases

Autoimmune conditions

Rheumatoid arthritis

RA is a symmetrical, erosive polyarthritis that typically affects the small joints of the hands and feet. The key features of the history are inflammatory pain and stiffness, usually progressive over several months, and a description of joint swelling. Patients may also describe fatigue or general malaise. As described above, there may often be a family history of RA or other autoimmune disease. Symptoms and signs can be quite subtle, but some patients present with rapidly progressive synovitis and grossly swollen 'boxing glove' hands.

Examination typically demonstrates swelling and/or tenderness in the wrists, MCP and PIP joints of the hands and MTP joints of the feet. Look for callus on the soles of the feet, and rheumatoid nodules which typically occur on the extensor surfaces of the elbow, hands, and the Achilles tendon. Some patients, however, have large joint predominant disease, so it is important to examine these joints too.

Spondyloarthropathy

The 'spondyloarthropathies' encompass a broad range of related arthritides that are variously associated with the tissue type HLA B27 (see Table 9.3). The clinical presentation varies widely between and within them. As well as inflammatory arthritis, the hallmark of these conditions is the presence of an enthesopathy. The arthritis itself may be a symmetrical small joint polyarthropathy (typically psoriatic arthritis) but may be restricted to the spine only (ankylosing spondylitis), or present as a peripheral large joint oligoarthritis (psoriatic arthritis, reactive arthritis, enteropathic arthritis). There is much overlap between the individual spondyloarthropathies, and a patient may evolve between diagnoses over time.

Spinal involvement is indicated by inflammatory back pain—stiffness after a period of rest, pain directly over the sacroiliac joints (i.e. mid-buttock), thoracic and anterior chest wall pain, and significant early morning stiffness in the spine. A patient may not know that he/she has psoriasis. It is worth asking for a history of itchy, scaly skin patches, remembering the 'hidden' sites for psoriasis—the scalp, behind the ears, umbilicus, natal cleft, palms and soles, nails. Dystrophic toenails may be psoriatic rather than fungal, and nail clippings are worth sending if in doubt. The patient may not have psoriasis (yet) but there may be a family history.

Enquire about bowel symptoms and uveitis—both current and historical. Take a sexual history, but be sure to make the relevance of this clear 'some arthritis conditions can be triggered by sexually transmitted infections'. This may require a second visit, a telephone call, or a discreet question in a separate examination room if the patient is accompanied by a partner. Even if the history is 'negative', if reactive arthritis is a possibility, invite the patient to self-refer to the genitourinary medicine clinic.

Examine for peripheral arthritis, enthesitis (commonly Achilles tendon with associated plantar fasciitis, and/or epicondylitis at the

Table 9.3 The HLA association of spondyloarthropathies[4]

Diagnosis	HLA B27 positivity (% of patients)
Ankylosing spondylitis	90–95%
Psoriatic arthritis	50% overall (10–20% peripheral disease; 60–70% if spinal involvement)
Reactive arthritis	70–85%
Enteropathic arthritis	50%
Isolated anterior uveitis	50%

Table 9.4 ILAR classification of juvenile idiopathic arthritis (JIA)[5]

JIA subtype	Key features
Systemic onset (SOJIA)	10–20% patients; usually polyarticular, quotidian (daily) fever, evanescent rash, lymphadenopathy. Differential diagnosis includes infection/malignancy
Oligoarthritis	Most common form of JIA. 1–4 joints in 1st 6 months; age usually <6 yrs.
	May 'extend' to >4 joints—'extended oligoarticular'—after 1st 6 months; **worst prognosis and often missed at onset**
Polyarticular RF (−)	Typically young children, girls > boys, ANA(+) = high risk of anterior uveitis
Polyarticular RF (+)	Typically teenage girls; much like adult RA
Psoriatic arthritis	Dactylitis common
Enthesitis-related	Often boys >6 yrs. Resembles adult AS, but peripheral involvement greater
Undifferentiated	Does not fit into any of the categories above

For all the above, arthritis of unknown aetiology occurring before the 16th birthday and persisting for >6 weeks. All other known conditions excluded.

elbow), chest wall involvement (sternoclavicular joint, costochondral joints) and spinal restriction.

Juvenile idiopathic arthritis

The above sections address inflammatory joint disease in adults. Children and young people may also develop inflammatory arthritides, but the clinical presentation, natural disease history, and management can be very different. A separate classification of diseases is used (Table 9.4) and it is critical that these patients are managed by multidisciplinary, multiagency teams that have specific expertise in managing all aspects of their care. 30–50% continue with their arthritis into adulthood so it is important that clinical pathways exist to manage this transition properly.

All patients with juvenile idiopathic arthritis (JIA), particularly those under the age of 11 and those with positive anti-nuclear antibodies, must have ophthalmic screening. Anterior uveitis is common; it is an important reversible cause of childhood blindness in the UK, and is often asymptomatic in children.

Connective tissue disease/vasculitis

Connective tissue diseases and vasculitides originally became the domain of the rheumatologist as they can present with arthritis (and latterly because they are also immunologically driven). These conditions can be associated with life-threatening organ involvement, so remember that what might appear to be a 'simple (unclassified) inflammatory arthritis' may herald a more severe systemic disease.

Remember too that connective tissue diseases may occur as overlap syndromes: a patient with limited cutaneous systemic sclerosis may have true erosive RA alongside the scleroderma.

A selection of diagnoses is considered in Table 9.5.

Crystal arthritis

Both gout and pseudogout show acute and chronic forms. In general, the acute disease is a mono- or oligoarthritis, whilst the chronic disease is polyarticular.

Gout

Gout is painful. Patients often describe waking in the early hours with joint pain, and by the morning being unable to put their foot to the floor. The affected joint is typically hot, red, and swollen. The patient may be systemically unwell. Joint distribution has been described earlier (first MTP joint, knees, ankles). Diffuse involvement of the midfoot is also common. It can also present as a truly polyarticular disease, especially if there is a more chronic history of joint pain. In this latter scenario, when you explore the patient's history you will usually elicit the typical acute monoarthritis history of gout from several years or even decades earlier. In this situation, examine for gouty tophi—if present, these will help confirm the diagnosis.

Serum uric acid may be elevated, but can be normal or low during an acute attack. The gold standard for diagnosis is polarized microscopy of synovial fluid from an acutely affected joint, demonstrating the classical negatively birefringent needle-shaped crystals of uric acid. Radiographs may show 'punched out' periarticular erosions.

Table 9.5 Clinical presentations of common connective tissue diseases/vasculitides

Diagnosis	Associated arthritis	Non-articular features
SLE	'Jaccoud's arthritis'—symmetrical, correctible polyarthritis—phenotypically like RA but typically non-erosive	Photosensitivity, malar rash, mouth ulcers, hair fall, fatigue, abnormal nailfold capillaries
MCTD	Arthralgia/symmetrical erosive arthritis—75% of patients have true RA overlap	Raynaud's, sclerodactyly, myositis, pulmonary hypertension, pleuritis/pericarditis
PSS	Non-erosive inflammatory arthralgia/arthritis	Sicca complex (dry eyes/dry mouth and mucous membranes), fatigue, peripheral and central nervous system involvement. Risk of lymphoma (NHL)
Large-vessel vasculitis	Myalgia and stiffness (polymyalgia rheumatica); not typically true arthralgia	Temporal arteritis/vascular bruits/systemic malaise/jaw, tongue, calf claudication
ANCA-associated vasculitis	Inflammatory, erosive (true RA?) or non-erosive	Respiratory/renal/cardiac/ENT/neurological involvement of vasculitis + systemic malaise

ANCA, anti-neutrophil cytoplasmic antibodies; MCTD, mixed connective tissue disease; NHL, non-Hodgkin's lymphoma; PSS, primary Sjögren's syndrome; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus.

Pseudogout: calcium pyrophosphate disease

Pseudogout or calcium pyrophosphate disease is common in elderly people. It often occurs during or following an intercurrent illness and presents, like gout, with a hot, swollen, red joint. Wrists and knees are classically affected in acute disease. Synovial fluid examination reveals positively birefringent rhomboid crystals of calcium pyrophosphate. Radiographs may show chondrocalcinosis (linear calcification of the cartilage), typically in the menisci of the knees or the triangular ligament of the wrist. If looked for, chondrocalcinosis may also be present in the symphysis pubis.

The more chronic polyarticular form of calcium pyrophosphate disease can affect any joint, but often the second and third MCP joints, wrists, elbows, shoulders, and knees. This clinical picture is often described synonymously with 'inflammatory OA' and is alluded to in the earlier section on OA. Radiographs may show hook osteophytes, usually at the second and third MCP joints (Figure 9.5).

Other crystal deposition diseases

Calcium hydroxyapatite and calcium oxalate crystals may also cause crystal-associated arthritis. As with gout and pseudogout, presentation may be acute/mono- or oligoarticular, or chronic/polyarticular. Patients may have associated renal stone disease.

Infection

The classical history of joint sepsis is that of a single hot, red swollen joint in a patient who may be systemically unwell. Joint sepsis can, however, be polyarticular in up to 20% of cases[6,7] and may involve the spine/intervertebral discs/sacroiliac joints as well as peripheral joints. Mortality is much higher, at 30% compared with 4–8% for monarticular sepsis. Risk factors for polyarticular disease include RA, diabetes, SLE, malignancy, alcoholism, and immunosuppression, but it can occur in patients with none of these. The clinician must maintain a high index of suspicion for sepsis in polyarticular presentations. Diagnosis is confirmed by joint aspiration, and if necessary radiologically guided aspiration should be undertaken.

Fig. 9.5 Typical hook osteophytes and narrowing at MCPJ 2&3 in CPPD—in this case associated with haemochromatosis.

- Coeliac disease
- Whipple's disease
- Lymphocytic colitis
- Primary biliary cirrhosis/chronic active hepatitis
- Infectious hepatitis/HIV
- Sarcoidosis
- SAPHO (synovitis, acne, pustolosis, hyperostosis, osteitis)
- Infections—post strep/post viral/parvovirus/Lyme disease/tropical arthritis
- Inflammatory—Behçet's, familial Mediterranean fever

Rarities

This chapter has deliberately concentrated on common clinical presentations. There are, however, rarer causes of polyarticular joint disease. Most of these are systemic conditions associated with inflammatory joint pain but, with the exception of sarcoidosis and SAPHO syndrome, usually cause a non-erosive arthritis. Some examples are listed in Box 9.1.

Generic management of polyarticular disease

Confirming the diagnosis

The first step, after clinical assessment of the patient, is to confirm the diagnosis. For some conditions this will rely on the clinical assessment alone, but often we can supplement this with additional investigations.

Blood tests may confirm inflammation (or sepsis) with raised white cell count, thrombocytosis, elevated inflammatory markers (ESR and CRP) and often elevated alkaline phosphatase too. Specific autoimmune diagnoses may be supported by the presence of antibodies such as rheumatoid factor, anti-CCP, ANA, and ENA. Elevated uric acid may be present in gout. Synovial fluid examination for crystals or infection may be important. Imaging with plain films, ultrasound, and MRI is often useful. Isotope bone scanning is used less these days.

Response to a one-off dose of intramuscular steroid (usually depomedrone or triamcinolone) is often used to confirm the presence of inflammatory vs non-inflammatory pathology. Relief of symptoms is indicative of underlying inflammatory disease.

Managing the 'non-inflammatory' patient

Management of non-inflammatory joint pain is often supportive; to reduce pain and optimize function whilst attempting to minimize future joint damage. This requires the input of a multidisciplinary team.

Medical management includes simple analgesia and anti-inflammatories (NSAIDs) if required,[8] with all the usual precautions about prescription of the latter. For selected patients with OA, intra-articular injection of steroids may be appropriate.

Patients with 'inflammatory OA' associated with calcium pyrophosphate deposition may benefit from NSAIDs, low-dose colchicine, low-dose oral steroid or even methotrexate and hydroxychloroquine.[9]

Input from other members of the multidisciplinary team should include physiotherapy, occupational therapy, podiatry, and often pain management specialists. Principles of therapy include maintenance of appropriate muscle strength and flexibility, maximizing function despite joint disease/pain, joint protection, pacing of activities, and consideration of the impact of occupational and recreational activities on joints and vice versa.

Surgical management is reserved for patients where medical and conservative therapy has failed. The usual indication for joint surgery is intractable pain and/or instability.

Managing the 'inflammatory' patient

The generic multidisciplinary management described for 'non-inflammatory' joint pain applies equally to patients with inflammatory disease. In addition, these patients require specific therapy to treat the underlying inflammatory process.

Management of individual conditions will be addressed in detail in later chapters of this book. What follows is an overview of the principles of treatment.

Erosive/organ-threatening disease

In most cases, where joint disease is driven by inflammation, the earlier we treat, the better the outcome. Modern management of erosive/organ-threatening disease takes a zero tolerance approach to inflammation. Treat early and treat hard, using combinations of drugs where appropriate to induce disease remission. Maintenance of disease remission may be achieved at a later date with less aggressive therapy.

Non-erosive disease

In the case of non-erosive disease, we still want to control inflammation but can use the patient's symptoms as an indicator of severity, rather than worrying about underlying joint/organ damage. In certain conditions, treatment of the underlying disease, e.g. a gluten-free diet in coeliac disease or viral eradication therapy in hepatitis B/C, will be the most helpful strategy in controlling joint symptoms.

Managing the chronic disease

Most of our patients with inflammatory disease have chronic disease. We need to manage not only their acute presentations/relapses but their ongoing disease, even when it is well controlled. We use drugs that require monitoring as they can cause toxicity and complications. We now know that patients with chronic inflammatory disease are at higher risk of cardiovascular events and osteoporosis.

Box 9.2 describes the components required for chronic disease management, and gives a generic checklist of topics to cover in a routine patient review.

The future

With the advent of biological drugs, the last decade has seen a period of immense change in the management of rheumatological disease. In future we may well see more targeted therapy, hopefully guided by individual patient biomarkers/genetic predictors, so that the most aggressive therapy is appropriately targeted to the patients that really need it. Regardless, we believe that the need for a comprehensive history, thorough clinical examination, and appropriate investigations will continue to be precursors to an accurate diagnosis and an effective management of polyarticular disease.

Box 9.2 Management principles for chronic inflammatory joint disease

Management of chronic polyarticular disease[10–12]

◆ Assessment of disease activity (DAS, PsARC, BASDAI, SLEDAI, etc.)

◆ Drug toxicity? (bloods, CXR/PFTs, blood pressure)

◆ Multidisciplinary team accessible to patient

◆ Helpline/counselling/rapid access for flares

◆ Shared care with GP

◆ Patient information and education/modification lifestyle factors/acceptance of chronic disease

Checklist for routine review

◆ Disease activity

◆ Drug monitoring

◆ Extra-articular features disease/new symptoms

◆ Osteoporosis assessment/DEXA

◆ Cardiovascular risk factors

◆ Vaccinations (in patients on immunosuppressive drugs)

◆ Special considerations, e.g. pregnancy

The systemically ill patient

Joanna Robson, Anna Mistry, Kuljeet Bhamra, Stefan Kluzek, and Raashid Luqmani

Introduction

Diagnosis of the systemically unwell patient is a very common rheumatological problem. The patient may present with seemingly disparate problems in different organ systems; the challenge is to identify whether there is a unifying underlying disease process, such as infection, malignancy, an autoimmune inflammatory condition, or an autoinflammatory disease, or if different disease processes are coincidentally occurring within the same patient. Table 10.1 lists the differential diagnoses of the systemically unwell patient. A systematic approach requires a thorough history, examination, and appropriate baseline investigations, before the use of potentially more invasive and specialist tests—because common things are common. With practice, the diagnostic process should also be one of pattern recognition; examining each feature and asking: does this fit—or is there something we are missing? This caution to ensure the correct diagnosis before starting treatment is appropriate; for example, gaining biopsy evidence of systemic vasculitis before starting therapy with steroids or immunosuppressants is important, to avoid inappropriate treatment which may mask or worsen an underlying condition such as tuberculosis or lymphoma. In individual cases, though, delays brought about through waiting for further investigations to conclusively prove the diagnosis, will be less acceptable in the case of a patient with rapidly worsening organ or life-threatening disease. In this chapter we propose a stepwise approach to the systemically unwell patient; the outline of this is shown in Figure 10.1.

First line assessments—history, examination, and baseline investigations

Constitutional features

Of patients presenting with unintentional weight loss, a quarter have malignant disease; a third a non-malignant gastrointestinal tract disorder; and only 2–3% have an underlying rheumatological disorder.[1] Sixteen to 30% of patients with a fever of unknown origin (FUO) have an underlying infection; 7–10% a malignancy; 22–33% a non-infectious inflammatory condition; and no cause is found in 20–51% of cases.[2] The pattern of constitutional features may be informative; for example, patients with adult-onset Still's disease present with spiking fevers and evanescent rashes occurring in a quotidian pattern. The significance of night sweats is not well defined because they are reported in up to 40% of adult in-patients within 3 months prior to admission.[3] Night sweats are a presenting feature in 40% of cases of lymphoma[4] and 50% of cases of tuberculosis.[5] It is usual to perform three sets of blood cultures in patients with FUO; without a clinical suspicion of endocarditis, however, continuing to culture beyond this is unlikely to be diagnostic.[2]

Initial investigations

Inflammation, infection, and malignancy can all result in similar abnormalities on the full blood count, namely anaemia of chronic disease, thrombocythaemia, lymphocytosis, and neutrophilia.[6] Eosinophilia is seen in lymphomatous diseases,[4] parasitic infestations,[7] cholesterol emboli, or eosinophilic granulomatosis with polyangiitis (formerly termed Churg–Strauss syndrome).[8] Pancytopenia may be secondary to bone marrow infiltration from malignancy or infection[9] or marrow suppression due to medications such as methotrexate or azathioprine.[10] Systemic lupus erythematosus (SLE) can present with immune-mediated haemolytic anaemia, thrombocytopenia, lymphopenia, or neutropenia.[10] Baseline investigations should include parvovirus serology, a peripheral blood film, serum and urine electrophoresis, haematinics, direct Coomb's test, and lactate dehydrogenase (LDH).[10]

Respiratory system

A focused respiratory history, including symptoms of breathlessness, hoarseness, wheeze, cough, and haemoptysis may help to delineate between infection,[11] malignancy,[12] and inflammatory conditions.[13] Haemoptysis, for example, is caused by infection in 60–70% of cases, especially tuberculosis in people from developing countries[14]; and is rarely caused by pulmonary embolic disease or a small-vessel vasculitis such as granulomatosis with polyangiitis (Wegener's), which account for only 1.4% of cases.[15] In patients with FUO, a baseline chest radiograph has a high specificity of 87% but a lower sensitivity of 60%, so may need to be supplemented with further investigations.[2]

Cardiovascular system

Patients with systemic inflammatory diseases may develop a spectrum of cardiovascular manifestations; for example, pericarditis in SLE; cardiac amyloid or sarcoidosis causing conduction defects; pulmonary hypertension in systemic sclerosis or SLE; valvular

Table 10.1 Differential diagnosis of the systemically unwell adult patient

Infection	Drugs and environment	Systemic connective tissue diseases	Paraneoplastic

Infective endocarditis
 	
Viral infections:
    Hepatitis B and C virus
    HIV
    Human T cell lymphotropic virus type 1
    Parvovirus B19
    Herpes simplex and varicella zoster virus
    Cytomegalovirus and Epstein–Barr virus
    Alpha-viruses
 	
Bacterial infections:
    Mycobacterium tuberculosis
    Neisseria meningitidis
    Streptococcus pneumonia
    Salmonella
    Chlamydia pneumonia
    Treponema pallidum
 	
Parasitic infections
    Plasmodium spp.
    Giardia
    Toxoplasma gondii
    Shistosoma
 	
Fungal infections
    Aspergillus spp.
    Cryptococcus neoformans
    Histoplasma capsulatum
    Pneumocystis jirovecii
 	
Systemic inflammatory disease secondary to infection:
    Borrelia burgdorferi—Lyme disease
    Tropheryma whippelii—Whipple's
    Group A streptococcus—rheumatic fever
	Acute poisoning:
	    Paracetamol
	    EtOH
	    Ethylene glycol and methanol
	    Cyanide
	    Organophosphates
	    Heavy metals and solvents
	    Lead
	
	Drug-induced SLE:
	    Procainamide
	    Hydralazine
	    Quinidine
	    Isoniazid
	    Methyldopa
	    Chlorpromazine
	    Minocycline
	
	Drugs associated with ANCA-positive vasculitis:
	    Hydralazine
	    Propylthiouracil
	    Leukotriene inhibitors
	    Sulfasalazine
	    Minocycline
	    D-Penicillamine
	    Ciprofloxacin
	    Phenytoin
	    Clozapine
	    Allopurinol
	
	Drug-induced vasospasm:
	    Methysergide
	    Ergot derivatives
		Rheumatoid arthritis
		SLE
		Primary Sjögren's syndrome
		Systemic sclerosis
		Mixed connective tissue disease
		Dermatomyositis/polymyositis
		Adult-onset Still's disease
		Anti-phospholipid syndrome
		Eosinophilic fasciitis
		IgG4 related systemic disease
		Macrophage activation syndrome
			Myelodysplastic syndrome
			Lymphoid malignancies:
			    Non-Hodgkin's lymphoma
			    Hodgkin's disease
			    Chronic lymphocytic leukaemia
			    Multiple myeloma
			
			Solid tumours:
			    Lung cancers
			    Gynaecological and genitourinary cancers
			    Breast cancers
			    Mesothelioma

Systemic vasculitides	Other

Small-vessel vasculitis (ANCA-associated):
    Granulomatosis with polyangiitis (Wegener's)
    Microscopic polyangiitis
    Eosinophilic granulomatosis with polyangiitis (Churg Strauss)
Medium vessel vasculitis:
    Polyarteritis nodosa
Large-vessel vasculitis:
    Giant cell arteritis
    Takayasu's arteritis
Other:
    IgA Vasculitis
    Cryoglobulinaemic vasculitis
    Behçet's disease
    Relapsing polychondritis
    Cogan's and Berger's disease
	Autoinflammatory syndromes e.g.:
	    Familial Mediterranean fever (FMF)
	    Pyogenic arthritis, pyoderma gangrenosum, and acne (PAPA) syndrome
	    TNF receptor associated periodic syndrome
	    Deficiency of IL-1 receptor antagonist
	    Cryopyrin-associated periodic fever syndromes
	    Hyper IgD syndrome
	
	Hypersensitivity syndromes
	Atherosclerosis/embolic disease
	
	Venous thromboembolic disease
	
	Haematological:
	    Thrombotic thrombocytopenic purpura
	    Haemolytic uraemic syndrome
	    Sickle cell disease

disease secondary to inflammatory aortitis; and peripheral arterial disease through primary or secondary vasculitis.[16] Absent pulses, asymmetrical blood pressure readings, and peripheral bruits are important clues. Peripheral stigmata of infective endocarditis include splinter haemorrhages. Inflammation is a risk factor for accelerated atherosclerosis in patients with rheumatological diseases;[16] an assessment of their classical risk factors, such as smoking, hypertension, and hypercholesterolaemia, is therefore important.

Gastrointestinal system

Intra-abdominal infection should always be considered in patients with a FUO, particularly patients who are immunosuppressed, have had previous surgery, or have a reduced mental state or spinal cord injury.[17] Diarrhoea may be secondary to small bowel inflammation and malabsorption; cancer or inflammation of the colon; pancreatic insufficiency; motility problems; or functional disorders.[18] Common causes of acute liver failure include drug-induced, viral hepatitis, autoimmune liver disease, and shock or hypoperfusion;

in 20% of cases there is no discernible cause.[19] Medications that are associated with acute liver abnormalities are listed in Table 10.2. Seventy-five per cent of patients who present with ascites will have cirrhosis; other causes include malignancy in 10%, heart failure in 3%, tuberculosis in 2%, and pancreatitis in 1%.[20]

Renal system

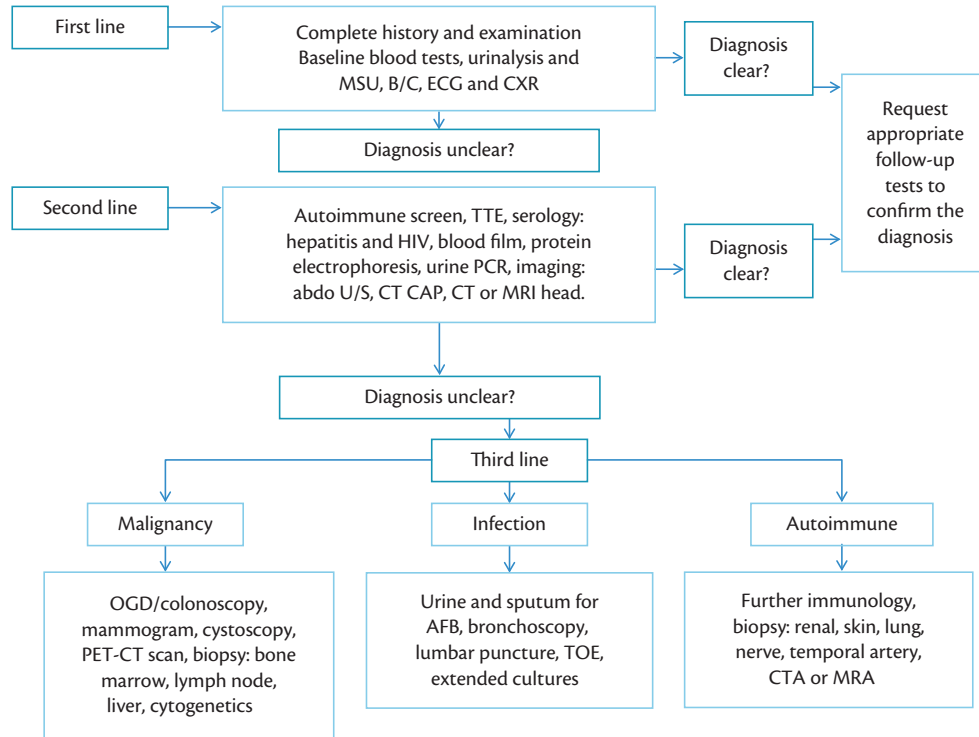
Acute renal failure is characterized by a rise in the serum creatinine and urea, often associated with oliguria or anuria.[21] Acute tubular necrosis secondary to multiple nephrotoxic insults such as sepsis, hypotension, and nephrotoxic drugs (e.g. NSAIDs, antibiotics, diuretics, or contrast agents used for radiological imaging) is the most common cause of in-hospital acute renal failure, especially in elderly people and patients with pre-existing comorbidities.[21] On urine dipstick testing, the presence of haematuria should prompt a search for red cell casts which are seen in glomerulonephritis (can be postinfective or related to medications, or secondary to an underlying systemic vasculitis or connective tissue disease); any proteinuria should be quantified by sending a sample for a


Fig. 10.1 Approach to the investigating the systemically unwell patient. AFB, acid-fast bacilli; B/C, blood culture; CT CAP, CT of chest, abdomen, and pelvis; CTA, CT angiography; CXR, chest radiograph; ECG, electrocardiography; MRA, magnetic resonance angiography; MSU, mid-stream urine; OGD, oesophagogastroduodenoscopy; PET-CT, positron emission tomography–CT; TOE, transoesophageal echocardiography; TTE, transthoracic echocardiography; U/S, ultrasound; urine PCR, urine protein:creatinine ratio.

Table 10.2 Drugs capable of causing clinical syndromes similar to SLE and vasculitis, and drugs that can induce hepatitis

Drug-induced vasculitis	Drug-induced lupus	Drug-induced hepatitis
Propylthiouracil	Hydralazine	Diclofenac
Allopurinol	Procainamide	Antibiotics, e.g. sulphonamides, isoniazid, dapsone
Hydralazine	Isoniazid	
Colony stimulating factors	Minocycline	Antihypertensives, e.g. lisinopril, methyldopa
Ceflacor	Pyrazinamide	Antiepileptics, e.g. phenytoin, sodium valproate
Minocycline	Quinidine	
D-penicillamine	D-penicillamine	Antiarrhythmics, e.g. amiodarone
Phenytoin	Carbamazepine	Statins
Isoretinoin	Phenytoin	Propylthiouracil
Methotrexate	Propefone	Halothane
Sulfasalazine		Amphetamines/ecstasy
Quinolones		Herbals medications
Carbimazole		Antivirals, e.g. efavirenz
Cocaine		Antifungals, e.g. ketoconazole
Levamisole		Allopurinol
		Diabetic medications, e.g. metformin, tioglitazone

protein:creatinine ratio and a sample should also be sent for culture.[21] In those without red cell casts, other causes of haematuria such as bladder cancer or infections such as schistosomiasis should be considered, especially in those with a travel history or risk factors such as smoking, exposure to aniline dyes, or cyclophosphamide treatment. However, it is important to remember that unless urine is carefully examined soon after the sample is provided, red cell casts may not be seen.

Nervous system

Chronic non-pathological headache affects up to 70% of all adults, but atypical presentations should raise concern.[22] The presence of photophobia, neck stiffness, or altered mental state suggest meningoencephalitis;[23] a thunderclap headache confers an increased likelihood of a subarachnoid haemorrhage (SAH); a sudden severe unilateral headache radiating into the neck with a Horner's syndrome may be due to arterial dissection.[22] There is an increased rate of intracranial haemorrhage in younger (40–50%) rather than older patients (15–20%) presenting with stroke, although cerebral infarction is still the most common cause.[24] In younger patients, the following conditions should be considered: anti-phospholipid syndrome; connective tissue disease such as SLE or Sjögren's; cardiac embolization secondary to rheumatic heart disease or infective endocarditis; Behçet's syndrome (specifically venous sinus thrombosis); primary cerebral vasculitis; HIV; sarcoidosis or one of the systemic vasculitides (from small to large vessel).[24] Neuropsychiatric symptoms associated with systemic inflammatory diseases also include diffuse symptoms, such as depression and cognitive impairment, through to distinct entities such as transverse myelitis or peripheral neuropathy.

Ophthalmic features

Infectious causes of uveitis include toxoplasmosis, herpes, tuberculosis, , syphilis, and, in those with a travel history, West Nile virus, Rift Valley fever, dengue, and chikungunya.[25] Forty per cent of patients with uveitis will have an underlying autoimmune disease

including sarcoidosis, Behçet's syndrome, spondyloarthropathies, juvenile inflammatory arthritis, or a systemic vasculitis.[26] Orbital pain and swelling are present with infectious orbital cellulitis, tumour with acute inflammatory signs, thyroid eye disease or the multisystem granulomatous conditions: sarcoidosis and granulomatosis with polyangiitis (Wegener's).[27] A quarter of patients with giant cell arteritis present with visual symptoms: blurring, colour fading, or complete visual loss; important associated features in this subgroup are jaw claudication and low inflammatory markers.[28]

ENT features

Patients with chronic rhinosinusitis, cocaine use, fungal sinusitis, lymphoma, sarcoidosis, tuberculosis, and granulomatosis with polyangiitis (Wegener's) may describe nasal crusting and recurrent sinusitis; in a proportion there may also be a depression of the overlying skin secondary to underlying necrosis of the septum or adjacent structures.[8] A history of nasal polyposis is reported in 50% of patients with eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome).[8] Sinus radiographs are unhelpful in a patient with systemic disease and sinus involvement;[2] CT scanning of the sinuses can identify any destruction of the sinuses and nasendoscopy will aid visualization and biopsy in those with intranasal lesions.[8]

Musculoskeletal system

Septic arthritis is the most serious type of monoarthritis, with a mortality rate of 11%; other causes of monoarthritis include crystal arthropathies, reactive arthritis, or a limited form of a polyarthritis: all should be investigated with urgent joint aspiration if there are no contraindications.[29] Inflammatory polyarthritis secondary to viruses such as parvovirus B19, rubella, mumps, and acute hepatitis B usually resolve within 6 weeks; beyond this time point inflammatory arthropathies such as rheumatoid arthritis become more likely, particularly in the presence of rheumatoid factor or anti-citrullinated peptide antibodies. Inflammatory arthritis is discussed extensively elsewhere in this book.

Dermatological features

Drug reactions can cause many skin manifestations; ranging from mild transient erythema through to toxic epidermal necrolysis, which has a mortality of 25%.[30] Common culprits include antibiotics and antiepileptics.[30] Rashes in the systemically unwell patient may be secondary to an underlying condition: for example, infections such as herpes simplex or mycoplasma cause erythema multiforme;[31] inflammatory conditions such as sarcoidosis or Behçet's syndrome are associated with erythema nodosum[32] or small-vessel vasculitis (leucocytoclastic vasculitis).[33] The presence of finger clubbing, splinter haemorrhages, and abnormal capillary loops can indicate cancer, endocarditis, or connective tissue disease respectively.[34]

Drug history

All medication and recreational drugs taken by the patient should be recorded, with careful attention to the time frame between drug and onset of illness. Drugs that can mimic or precipitate vasculitis,[35] SLE,[36] or hepatitis[19] are shown in Table 10.2.

Family history

A family history of autoimmune disease is important to elicit; for example, up to 10% of patients with SLE have another family member with the disease and there is a greater than 20% concordance rate between monozygotic twins.[37] For patients without a personal history of cancer, the likelihood ratio (LR) in a first-degree relative is 34 for ovarian cancer, 23 for colon cancer, 14 for ovarian cancer, 12.3 for prostate cancer, and 8.9 for breast cancer.[38] Autoinflammatory syndromes are rare monogenic disorders with defective innate immunity.

Social history

Living in low-cost crowded housing communities is associated with an increase in infectious diseases such as tuberculosis.[39] Smoking is also associated with low socio-economic status and increases the risk of cardiovascular disease, cancer, and autoimmune diseases such as rheumatoid arthritis. Higher risk behaviours such as intravenous drug use, tattoos, unprotected sexual activity, alcohol abuse, and prostitution predispose to bacterial infections, such as endocarditis and staphylococcal abscesses, and viruses such as HIV and hepatitis, which can be associated with the development of hepatic malignancy and systemic vasculitides such as polyarteritis nodosa (PAN).[40]

Occupation

The risk of exposure to specific infectious diseases differs between occupations. Hepatitis, tuberculosis, and MRSA occur in healthcare workers; *Brucella* spp., *Borrelia* spp., *Clostridium tetani*, *Strongyloides sercoralis*, and *Toxoplasma gondii* are seen in farmers and veterinarians; and *Brucella spp.*, hepatitis, and *Toxoplasma gondii* occur in refuse collectors.[41] Baking, farming, and occupational exposure to silica may predispose to granulomatosis with polyangiitis (Wegener's)[42]; farming and insecticide exposure may increase the risk of developing SLE or rheumatoid arthritis (RA)[43]; and asbestos, silica, and coal mining all predispose to lung cancer.[44]

Travel history

A detailed history is important, documenting geographical location, urban vs rural dwelling, exposure to bites, daily activities, sexual contacts. and prior vaccination and chemoprophylaxis.[7] Arboviruses are the most common viral infections in the returning traveller; chikungunya, West Nile virus, and Japanese encephalitis present with fever, myalgia and headache, and a maculopapular rash.[7] Intermittent or periodic fever, headache, myalgia, and abdominal pain suggest malaria, while a slow, grumbling, increasing fever with abdominal pain is characteristic of *Salmonella typhi*.[7] HIV seroconversion should be considered in a patient with fever, pharyngitis, lymphadenopathy, rash, myalgia, oral ulceration, headache, and general malaise. A viral serology screen is helpful but the results need expert interpretation in distinguishing a current from a past infection.[7]

Second line investigations

Further haematological tests

Bone marrow aspirate and biopsy can be useful; in patients with prolonged fever, it has been shown to result in a definitive diagnosis in one-fifth of patients, specifically detecting haematological malignancy, infection, systemic mastocytosis, or granulomatous disease.[45] Lymph node biopsies may be considered; a core needle or excisional node biopsy is preferable to a fine needle aspiration

because of increased diagnostic yield.[46,47] Granulomas are present in lymph node biopsies in tuberculosis, sarcoidosis, or granulomatosis with polyangiitis (Wegener's).[46]

Autoimmune screen

Autoantibodies are common in the normal population, particularly with increasing age; the pre-test likelihood of a positive autoantibody in normal females aged 60 and above is 20%.[9] Serological testing should only be considered when the clinical features suggest an autoimmune process is present and results should be carefully interpreted, bearing in mind that a generally unwell patient with overwhelming infection or malignancy can have non-specifically positive serology.[9] The range of autoantibodies and their potential associations with infectious diseases, malignancies, and rheumatological conditions are outlined in Table 10.3; a practical approach to the stepwise use of autoantibodies is summarized by Stinton and Fritzler (2007).[9]

Further imaging

In patients with FUO, abdominal ultrasound has a sensitivity of 86% and a specificity of 65%, CT scanning of the chest has a sensitivity of 82% and a specificity of 77%, and CT scanning of the abdomen has a sensitivity of 92% and a specificity of 63% for correctly identifying the underlying diagnosis.[2] FDG-PET scans have a sensitivity of 92% and a specificity of 78% in patients with FUO[2]; they can be diagnostic for large-vessel vasculitis, and identify the site of infection or malignancy to allow further targeted investigation and biopsy.[2]

Biopsy

Histology is key to establishing the diagnosis in a patient presenting with multisystem disease; the use of a focused history, examination, and investigations increases the diagnostic yield by identifying a specific target organ to biopsy,[2] for example the lung, gut, kidney, skin, or nerve. Temporal artery biopsy is the current but imperfect gold standard for diagnosis of giant cell arteritis; the presence of skip lesions can lead to false-negative results.[48] Due to the risk of blindness in giant cell arteritis, steroid treatment should be initiated on clinical suspicion before a biopsy; these will in any case remain positive for up to 1–2 weeks following steroid therapy.[48]

Cardiovascular investigations

Angiography of the arterial tree is still the gold standard test for the presence of arterial stenosis or aneurysm in patients with suspected medium- or large-vessel vasculitis (such as polyarteritis nodosa or Takayasu's arteritis); however, non-invasive techniques such as CT or MR angiography (MRA) and cardiac MRI are now more widely available.[16] The negative predictive value of a normal transthoracic echocardiogram in a patient with normal heart valves is 90% or more;[49] it therefore sensitive enough to be a screening test for native valve infective endocarditis, although complex cases may be aided by a transoesophageal echocardiogram. Ultrasonography of the temporal artery is currently undergoing validation for use in the diagnosis of giant cell arteritis.[48]

Neurological investigations

Infection, inflammation, tumours, haemorrhage, or ischaemia can all result in neurological symptoms; a stepwise approach to investigation, starting with CT or MRI head, then lumbar puncture for

Table 10.3 An overview of autoantibodies and potential associated medical conditions

Test	Association
ANA	SLE, MCTD, SSc, PM, DM, SjS, RA, older age
ACPA	RA, PsA, TB
dsDNA, Sm	SLE
Centromere	lcSSc, PBC
Scl 70/topo-I, fibrillarin	dcSSc
Jo-1	PM, DM
C1q antibodies	HUV
C-ANCA (PR3 positive)	GPA, MPA, EGPA
aCL, β2GI and LA	APS
RF	RA, SLE, SSc, MCTD, SjS, PM, sarcoid, chronic hepatic and pulmonary diseases, chronic infections (subacute bacterial endocarditis, tuberculosis, parasitic infections, HIV, parasitic infections), cryoglobulinaemia, and malignancies
PL-7	PM/DM with ILD
Ro(SS-A) and La (SS-B)	SjS, SLE
U1-RNP	Mixed connective tissue disease
Low C3, C4	SLE, urticarial vasculitis, cryoglobulinaemia, RA, infectious diseases (subacute bacterial endocarditis, pneumococcal or Gram-negative sepsis, hepatitis B, parasitaemias), glomerulonephritis (membranoproliferative or post-streptococcal)
PM/Scl	PM-SSc overlap
Cryoglobulins	Cryoglobulinaemia (types I,II and III)
P-ANCA (MPO positive)	MPA, EGPA, GPA, drug-induced syndromes
P-ANCA (MPO negative)	UC, autoimmune liver disease, RA, SLE, HIV infection, other chronic infections or malignancies

aCL, anti-cardiolipin antibodies; ACPA, anti-citrullinated protein antibody; ANA, anti-nuclear antibodies; APS, anti-phospholipid antibodies; β2GI, β2-glycoprotein I; C-ANCA, anti-neutrophil cytoplasm antibodies; dcSSC, diffuse systemic sclerosis; DM, dermatomyositis; dsDNA, double-stranded DNA; EGPA, eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome); HIV, human immunodeficiency virus; HUV, hypocomplementaemic urticarial vasculitis; ILD, interstitial lung disease; Jo-1, histidyl tRNA synthetase; LA, lupus anticoagulant; lcSSc, limited systemic sclerosis; MCTD, mixed connective tissue disease; MPA, microscopic polyangiitis; MPO, myeloperoxidase; P-ANCA, anti-neutrophil cytoplasm antibodies; PL7, threonyl-tRNA;PM, polymyositis; PR3, proteinase 3; PsA, psoriatic arthritis; RA, rheumatoid arthritis; SjS, Sjögren's syndrome; SLE, systemic lupus erthematosus; TB, tuberculosis.

Gram stain and culture of cerebrospinal fluid for bacteria, fungi, and viruses is indicated as first line;[6] MRA and MR venography are second line investigations to look for abnormalities in the blood vessels of the brain as seen in cerebral vasculitis or venous sinus thrombosis in Behçet's syndrome.

Respiratory investigation

Sputum cultures, specifically for acid-fast bacilli (AFB), and early morning urine specimens should be sent in patients with

risk factors for tuberculosis and serological tests such as the Elispot or interferon-gamma release assays should be performed. Bronchoscopy in patients with FUO can allow direct visualization, bronchial washings, and biopsies of suspicious lesions for histology and microbiology.[2]

CHAPTER 11

Spinal pain

Karl Gaffney and Louise Hamilton

Introduction

Spinal pain is so common that it could be considered, like the common cold, a normal part of life. Yet it is also the second commonest cause of both long-term disability and chronic work-related absence in the UK, costing at least £10 billion annually.[1] It has a similar impact in other developed countries, with the yearly cost to the US economy exceeding $100 billion.[2]

Around a third of the UK adult population annually complains of low back pain.[3] For most people episodes are short-lived and self-limiting. Only a fifth of those with pain will consult their GP,[4] and by 3 months 90% of patients will have stopped consulting.[5] However, it is a mistake to assume that they are therefore symptom-free. At 12 months a majority still have pain, with 60% reporting relapsing symptoms.[6]

Despite huge advances in musculoskeletal medicine and a reduction in heavy manual labour in the last half-century, the prevalence of musculoskeletal pain in general has increased since the 1950s, with a doubling of low back pain prevalence in one UK study.[7] However, it is the exponential rise in chronic disability that has led to claims of an epidemic of back pain, and this is as much a social and cultural problem as a medical one. The point prevalence of back pain is similar throughout the world, but associated disability seems to be a phenomenon of the developed world.

For the rheumatologist, the art in assessing patients with spinal pain is to identify those with a serious underlying cause for their symptoms without over-medicalizing the vast majority with non-specific pain.

Some definitions

Terminology relating to spinal pain is varied. We define pain as acute when the duration is less than 6 weeks, subacute if 6–12 weeks and chronic if more than 12 weeks, while recognizing that symptoms are often recurrent. Non-specific back pain is diagnosed in the absence of a clear pathological cause.

Sciatica means different things to different people and is therefore a term best avoided. Instead we use 'leg pain' if the pain radiates and 'nerve root pain' for neuropathic pain caused by nerve root impingement.

Overview of anatomy

The spine is an articulated column supporting the body and protecting the spinal cord (Figure 11.1). The two areas of natural curvature (or lordosis) in the cervical and lumbar regions develop after birth, once a child starts to mobilize. Vertebrae articulate anteriorly through the intervertebral discs and posteriorly through the facet joints. These are synovial joints, innervated by medial branches of the dorsal rami, which protect the intervertebral discs from axial shear forces. The intervertebral disc comprises a gel-like collagen and proteoglycan core (nucleus pulposus) surrounded by concentric sheets of collagen fibres (annulus fibrosus). It acts as a shock absorber and allows some movement in the sagittal plane. Disc degeneration is common with age and often asymptomatic. The nucleus pulposus can also herniate through the annulus fibrosus, narrowing the spinal canal and impinging on the cauda equina or traversing nerve roots.

The spinal cord is housed in the spinal canal and terminates at the conus medullaris between the T12 and L2 vertebrae. Distal to this the lumbar and spinal nerve roots form the cauda equina, exiting the spinal canal through their respective foramina.

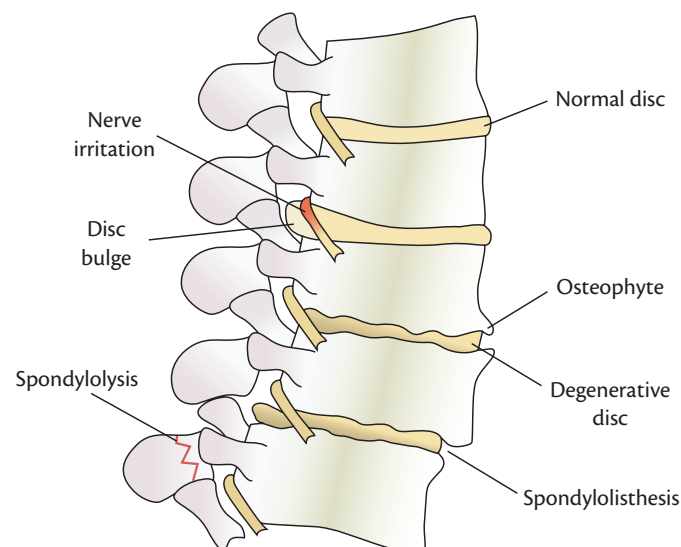
Pain can arise from any of the structures in the spine, which are manifold. There are 24 articulating vertebrae; 9 fused sacral and


Fig. 11.1 Schematic diagram of the spine showing a normal vertebral unit with examples of structural abnormalities.

coccygeal vertebrae; 24 intervertebral discs; 139 joints; ligaments, bursae, and muscles, together with the spinal cord and nerve roots. However, correlation between symptoms and imaging findings is weak and in as many as 85% of patients with low back pain a specific diagnosis cannot be made.

Most patients describe some referred pain in the legs, and this too can arise from any structure in the back. Referred pain tends to be a diffuse dull ache which does not extend below the knee. Nerve root pain, on the other hand, has a neuropathic quality (burning, associated with paraesthesia), conforms to a dermatomal distribution, and usually radiates to the foot. It is also uncommon, with a lifetime prevalence around 5%.[8]

Approaching the patient with spinal pain

History

A thorough history is key when evaluating spinal pain, enabling decisions to be made about imaging and further management. The aim should be to answer three questions:[9]

- Is there serious underlying pathology?
- Is there an indication for surgery?
- Are there psychosocial factors which may impede recovery?

Age does not affect the overall prevalence of back pain,[10] but does change the likely underlying cause of new-onset pain. Think about axial spondyloarthropathy (SpA) in young adults, disc disease in the middle-aged, and osteoporosis and malignancy in the elderly. Reassess symptoms each time a patient presents with an exacerbation; having a blinkered approach to a patient with a label of chronic back pain risks missing their vertebral fracture or malignancy.

The pain

Ask about onset, radiation, and duration. Remember that osteoporotic fractures may occur in the absence of trauma. Radiation of pain into the leg is common and not specific for nerve root compression; radiculopathy is more likely if the leg pain is worse than the back pain. Are there features of inflammatory back pain (Box 11.1)? Is pain provoked by straining (disc herniation) or lumbar spine extension? (facet joint osteoarthritis). Patients with spinal stenosis can present with claudication symptoms. Mechanical pain will tend to improve with rest, so night pain is a red flag symptom (see Box 11.2). Do not be caught out by referred pain; conditions as diverse as pancreatic cancer, aortic aneurysm, and Guillain–Barré syndrome can present with back pain.

Box 11.1 Features of inflammatory back pain

- Age of onset <40 years
- Insidious onset
- >30 minutes morning stiffness
- Improvement with exercise
- No improvement with rest
- Awakening with pain in the 2nd half of the night
- Alternating buttock pain
- Improvement with NSAIDs

Box 11.2 Red flags—features suggestive of serious spinal pathology

- Age of onset <20 or >55 years
- Thoracic pain
- Nocturnal pain disturbing sleep
- Fever and unexplained weight loss
- Bladder or bowel dysfunction
- History of malignancy
- History of osteoporosis (or prolonged steroid use)
- Progressive neurological deficit
- Saddle anaesthesia

Other symptoms

Ask specifically about paraesthesiae and weakness in the limbs, saddle anaesthesia, and loss of sphincter control (cauda equina syndrome). Fevers, weight loss, and malaise suggest infection or malignancy and would be a definite indication for imaging.

Past medical history

Prior history of malignancy (especially breast, lung, and prostate) raises the possibility of spinal metastases. Spinal tuberculosis (TB) is rare in the developed world but should be considered in those with risk factors such as HIV infection. Ask about conditions associated with axial SpA: psoriasis, inflammatory bowel disease, iritis, and peripheral arthritis.

Social history

There may be diagnostic clues; intravenous drug abuse is a risk factor for discitis. Psychosocial factors are also an important determinant of outcome in non-specific low back pain. The development of chronic pain is associated with so-called 'yellow flags' (see Box 11.3) and early identification allows these risk factors to be modified.

Examination

The general physical examination may be expanded to include breast and prostate examination if malignancy is a concern. Examine the

---

Box 11.3 Yellow flags—psychosocial factors leading to chronic back pain

- Attitudes—believing that pain and activity are harmful, catastrophizing, passive attitude towards treatment.
- Behaviours—extended rest, increased alcohol use, avoiding normal activities
- Compensation issues—previous claims
- Diagnostic and treatment issues—lack of satisfaction with treatment, inappropriate expectations, conflicting diagnoses
- Emotions—depression, anxiety, stress, fear of making pain worse
- Family—either overprotective or lack of support
- Work—manual work, unhappy at work, shift work, job dissatisfaction, no opportunity for gradual return to work

spine for deformity: kyphosis (convex-posterior curvature), scoliosis (lateral curvature), and spondylolisthesis (a step may be palpable). An apparent scoliosis due to muscle spasm will generally correct when the patient lies prone. Localized vertebral tenderness suggests infection or a fracture. Examine the hips—buttock pain is frequently due to hip osteoarthritis.

Perform a straight leg raise in patients with leg symptoms. Passively raise the leg with the knee fully extended until the patient complains of pain. The test is positive if leg pain is elicited at an angle of 30–70°. Pain on straight leg raise can be due to hamstring tightness or ischial bursitis; only increased pain on dorsiflexing the foot confirms L5/S1 nerve root irritation. Pain provoked by raising the contralateral leg implies the presence of a central disc prolapse. Pain on femoral stretch (extending the affected leg while the patient is prone) is pathognomonic of an L4/5 disc protrusion. Focus the neurological examination on the L5 and S1 nerve roots by checking extensor hallucis longus power and ankle jerks, though bilateral loss of ankle reflexes can occur with age.

Range of motion testing is not helpful in differential diagnosis, though a reduced Schober's test does at least indicate organic pathology. Signs of a behavioural component to a patient's pain include non-dermatomal weakness and sensory disturbance, pain on axial loading, and a discrepancy in the degree of straight leg raise when the patient is supine and sitting.[11]

Investigations

For the great majority of patients a diagnosis of uncomplicated low back pain can be made at this stage without the need for any further investigation.

If further tests are indicated, avoid a scatter-gun approach. The low pre-test probability of serious spinal pathology means that untargeted investigations risk a high false-positive rate.

A number of blood tests have been suggested in evaluating red flag patients (Box 11.4), but in only a handful is the predictive value known.[12]

Radiography is readily available and useful when osteoporotic vertebral fractures are suspected. Otherwise it is of limited benefit in assessing acute low back pain. Lateral lumbar spine radiographs will only reveal bony destruction once 50% of a vertebra is destroyed, so abnormalities may take weeks to develop. The bottom line is that a normal radiograph does not exclude serious pathology.

Box 11.4 Blood tests in spinal pain

- ESR and CRP—↑ in malignancy, infection, (axial SpA)
- White cell count—↑ in infection
- Haemoglobin—normocytic anaemia with chronic inflammation/ infection/myeloma
- Serum protein electrophoresis—paraprotein in multiple myeloma
- Serum calcium—↑ in myeloma, bony metastases
- Alkaline phosphatase—↑ in metastatic disease, Paget's (and also as acute-phase protein)
- HLA B27—only useful if axial SpA suspected clinically

An MRI scan should be performed immediately if cauda equina syndrome is suspected, and urgently if malignancy or spinal infection is likely. Although patients with non-specific pain report higher levels of satisfaction if they are offered immediate lumbar spine imaging (radiography or MRI) there is no clinical benefit in terms of pain and disability.[13] Radiological investigations should therefore be avoided at the outset unless serious underlying pathology is suspected. Patients' expectations about investigations may need to be managed, but education can be helpful in this respect.[14]

MRI can be considered after 4–6 weeks in patients with ongoing nerve root pain severe enough to warrant surgery, or features of spinal stenosis where surgery is considered an option. For non-specific low back pain MRI should only be offered if a referral is being made for spinal fusion.[3] Clinicians must be alert to the high prevalence of abnormal radiological findings in asymptomatic patients, and resist the urge to pronounce an incidental finding the source of pain. The majority of people aged over 40 have facet joint osteoarthritis on CT scanning; this does not correlate with symptoms.[15] Over half of asymptomatic adults have bulging discs on MRI and 28% have disc herniation.[16] Spondylolysis (a stress fracture of the pars interarticularis) causes no pain in 50% of cases.[17] The most clinically significant findings on MRI scanning are disc extrusions, nerve root compression, and at least moderate spinal stenosis.[18]

An isotope bone scan can be useful in the detection of spinal metastases and occult infection, but has a lower sensitivity and specificity than MRI.

Specific disease processes

'Red flag' pain

Cauda equina syndrome

Compression of the caudal nerve roots is a true surgical emergency necessitating immediate investigation and treatment. The usual cause is a massive disc prolapse into the spinal canal, but any space-occupying lesion (e.g. tumour, abscess, haematoma) can have a similar effect. The syndrome presents with severe back and bilateral leg pain, perineal numbness, and eventually an inability to void (due to involvement of the sacral nerve roots). A rectal examination will reveal reduced tone. It often manifests on a background of less severe back and leg pain, so patients presenting with nerve root signs should be instructed to report the development of perineal numbness and sphincter disturbance immediately.

Osteoporotic fracture

Most vertebral fractures are asymptomatic and diagnosed incidentally on a chest radiograph, or once a patient has developed a kyphotic deformity. When symptomatic, the pain can be severe, and may last for up to 6 months. The pain will start acutely, often after minimal or no trauma (coughing or twisting is sufficient), and may radiate in a dermatomal pattern bilaterally. Most fractures occur in the mid-thoracic or thoracolumbar vertebrae. Have a high index of suspicion in patients with risk factors (chronic steroid use, early menopause, family history, alcohol abuse). The pain may be severe enough to need opiates initially and some patients, particularly elderly people, may need hospital admission. Intravenous pamidronate and calcitonin can help intractable acute pain, but vertebroplasty is not usually recommended in the acute setting. Patients will need to start appropriate treatment for osteoporosis, usually with a bisphosphonate and calcium and vitamin D supplement.

Malignancy

Spinal tumours typically present with unremitting back pain, though neurological involvement including spinal cord compression may be the first indication of pathology. Almost three-quarters are due to metastatic spread, with prostate, breast, and lung cancers having a particular predilection for the spine. Spinal metastases should be suspected in anyone with a prior history of malignancy, or features of systemic disease (weight loss, night sweats, etc.). An erythrocyte sedimentation rate (ESR) over 20 is 78% sensitive and 67% specific in identifying occult malignancy presenting as back pain.[12] Most primary spinal tumours are benign, though even benign tumours can have aggressive features and therefore management usually involves surgical excision.

Infection

The terms vertebral osteomyelitis and discitis are used interchangeably to describe localized spinal infection. Spread is usually haematogenous but can be a complication of injection or instrumentation. Think about underlying infective endocarditis, particularly in patients with valvular heart disease. *Staphylococcus aureus* is the causative organism in over half of cases, but pseudomonas and candida are seen in IV drug users and brucella is important in the Middle East. Pain starts insidiously and early on there may be no suspicious features. Well-localized spinal tenderness is a reliable sign but only half of patients have a fever. Positive blood cultures are seen in 70% of patients[19] and elevated inflammatory markers in 80%.[20] Most patients respond to intravenous antibiotics, though vertebral instability or abscess formation may necessitate surgery.

Spinal involvement is seen in 1–2% of cases of TB. In the developed world it is a late manifestation associated with reactivation, but in endemic areas it is a disease of the young. Diagnostic delay is common, as is neurological compromise at presentation.[21] Constitutional symptoms and an abnormal chest radiograph are seen in fewer than half of cases, so a high index of suspicion is needed. Over 90% of patients with spinal tuberculosis have a positive tuberculin test,[22] but the diagnosis should be confirmed by biopsy. A 6 month course of therapy including rifampicin should be sufficient, but as with pyogenic osteomyelitis surgical stabilization or debridement may be required.

Axial spondyloarthropathy

Ankylosing spondylitis is the prototypical spondyloarthropathy. It usually presents in early adulthood with inflammatory back pain. Radiographic changes occur late, so MRI scanning of the whole spine and sacroiliac joints is the radiological investigation of choice to avoid the diagnostic delay sadly typical of this condition (see Chapter 122).

Diffuse idiopathic skeletal hyperostosis

Diffuse idiopathic skeletal hyperostosis (DISH) is a non-inflammatory disease characterized by widespread ossification of the spinal ligaments and entheses, and can be confused with ankylosing spondylitis. Patients present with back pain, often with associated morning stiffness, but may also complain of dysphagia (due to oesophageal compression by large anterior osteophytes), recurrent Achilles tendonitis, and palpable bony spurs. Radiographs show flowing calcification, typically in the thoracic region, likened to wax dripping down a candle. Treatment is symptomatic with analgesia, and rarely surgery (when osteophytes are large enough to cause dysphagia or myelopathy).

Crystal arthritis

Both gout and pseudogout can involve the spine. The usual presentation is with pain, fever and raised inflammatory markers, but large tophi can cause nerve root symptoms or spontaneous fractures. Atlanto-axial disease is typical of pseudogout. Because of the associated systemic upset crystal arthritis is frequently mistaken for infection or malignancy, and only diagnosed at the time of surgery.

Lumbar radiculopathy

Acute nerve root irritation is usually due to a herniated disc. Although the pain may be severe enough to warrant bed rest (which is usually discouraged) at the start, most episodes resolve without surgery. MRI scanning is only indicated in those whose symptoms have not improved after 6 weeks or those with progressive neurological signs. Only 10% of patients ultimately require surgery. Epidural steroid injections can improve pain in the short term, but do not reduce the rate of subsequent surgery.[23]

Spinal stenosis

Narrowing of the central canal by a number of pathologies can cause compression or ischaemia of the nerve roots. Degenerative arthritis is the commonest cause, but disc herniation, space-occupying lesions, and bony hypertrophy (e.g. in DISH, Paget's, ankylosing spondylitis) may also play a role. Patients typically present with bilateral leg pain, worse on walking or standing (neurogenic claudication) and relieved by sitting or bending forward. Neurological examination is usually normal, with a negative straight leg raise test. MRI is the investigation of choice although, as always, results should be interpreted with caution; at least a fifth of asymptomatic adults over 60 have radiological spinal stenosis.[24] In most patients the course is benign, and conservative treatment options (physiotherapy, analgesia) should be exhausted before surgery is contemplated.

Degenerative disease

The classical medical model of low back pain would dictate further sections here on facet joint arthritis, degenerative disc disease, and spondylolisthesis. We have deliberately avoided this approach as the 20th century's focus on a structural cause for back pain has not helped to reduce its prevalence and has not improved treatment. There is no good evidence to support the use of facet joint injections[25] or intradiscal therapy[26] in managing low back pain, and many 'abnormalities' are normal features of ageing not correlated with symptoms.[27] That said, it would be equally wrong to lump all patients with degenerative changes into the 'non-specific low back pain' group. There are undoubtedly individual patients who benefit from facet joint blocks, and the following management guidelines are just that—evidence-based guidelines, not dogma.

Managing non-specific low back pain

This is an overview of management. For more details, including comprehensive literature reviews, see the current UK[3,28] and European[10,29] guidelines.

Acute pain

Education

Reassure the patient that there is unlikely to be a serious underlying cause for their pain, that they do not need radiographs or scans, and that they will get better rapidly. Warn them that recurrence is possible, but is not a sign of ongoing damage. Use neutral terms like 'sprain' or 'strain' when explaining the pain, and avoid at all costs 'crumbling discs'. Encourage them to take responsibility for their recovery. Written information for patients such as *The Back Book*[30] can be helpful.

Activity

Encourage normal activity and warn against bed rest. There is no evidence that a back-specific exercise programme is helpful in acute pain—general aerobic exercise to avoid deconditioning is adequate. Try hard to keep the patient at work—a patient off work for a month has a 20% chance of still being off at a year, and by 2 years they are unlikely to work again.[31] A return to full duties may be slower if a patient has a very physically demanding job, but there is no good evidence that occupational factors cause back pain or delay recovery.[32]

Medication

Start with regular paracetamol and add a non-steroidal anti-inflammatory drug (NSAID) and/or a weak opioid if necessary. Strong opioids may be needed in the short term for patients with severe pain, but benzodiazepines are best avoided. Tricyclic antidepressants can be helpful for patients who remain symptomatic at this stage, especially if there is nerve root pain, but selective serotonin reuptake inhibitors should not be used for this purpose.

Physical methods

Spinal manipulation is safe in acute back pain without radiculopathy.

Most patients will have recovered by 6 weeks. For those with ongoing symptoms consider:

- *Physical therapies:* Depending on patient preference offer a structured exercise programme (group or one-on-one), a course of acupuncture, or spinal manipulation. Injections are not indicated for non-specific pain.
- *Rehabilitation programme*: A combined physical and psychological treatment programme should be offered to patients who have tried at least one of the physical therapies and have ongoing pain with either high disability levels or psychological distress.

Surgery

A referral for spinal fusion can be considered when patients have completed a rehabilitation programme but still have severe pain. Surgery before this point is inappropriate as neither spinal fusion[33] nor disc replacement surgery[34] is clinically more effective than intensive rehabilitation. Non-surgical interventions such as radiofrequency facet joint denervation[35] and intradiscal therapy[35] are not indicated for those with non-specific chronic low back pain.

Is prevention better than cure?

The identification of risk factors for non-specific low back pain has not translated easily into evidence-based interventions. Primary prevention studies are difficult because of the high lifetime prevalence of back pain, and only exercise has been shown to be protective. Obesity[36] and smoking[37] are associated with low back pain but the effect is modest and there is no evidence that interventions are beneficial in primary prevention. Manual handling is seen as an important preventive measure but there is no evidence that training workers to lift 'correctly' or use mechanical aids prevents back pain.[38]

In patients who have already had pain, physical activity is beneficial in preventing relapses and work absence[39] and weight loss programmes can improve disability[40] and pain.[41] However, encouraging patients to engage with lifestyle changes may be difficult. One Australian study showed that while 68% of respondents to an online survey were overweight or obese, only 8% were actively trying to lose weight and only 19% of all patients were trying to exercise.[42]

Perhaps the most important goal is preventing long-term disability and unemployment in patients with back pain. Interventions should be timely, as the prognosis is determined by levels of pain and disability in the first 3 months of symptoms.[43] Temporary job modifications can help with an early return to work,[39] and cognitive behavioural therapy can reduce absenteeism at 1 year.[44] At the societal level successful return to work is more likely in countries in which there is an emphasis on reintegration without loss of partial benefits, rather than a need for patients to adopt a sick role and demonstrate their disability to doctors in order to qualify for compensation.[45] Ultimately the cure for disabling back pain is social, not medical.

Pain and fatigue

Candy McCabe, Richard Haigh,
Helen Cohen, and Sarah Hewlett

Introduction

Pain and fatigue are cardinal symptoms of the rheumatic diseases. The majority of patients will experience them over the course of their disease, though the intensity and quality of them may vary over the time course. This chapter focuses on the identification and management of pain and fatigue in the clinical setting and provides a broad overview of the mechanisms that drive these symptoms and their incidence. In each section pain is discussed first, followed by fatigue.

Epidemiology

Pain

In both developed and developing countries, 25–30% of the total adult population, and approximately 8% of children, may be affected by musculoskeletal pain.[1,2] As the mean age of the global population rises, it is likely that these percentages will increase. Joint pain is estimated to affect 12.9–57.0% of those over 85 years of age, with the lower limb most commonly involved.

The financial burden of musculoskeletal pain is also high. UK data for chronic low back pain alone has estimated direct healthcare costs of £1632 million per year with indirect costs of £10 668 million.[3] In the US, common pain conditions account for a loss of 13% of the total workforce at any one time and 6.2% of this group report some form of arthritis or musculoskeletal pain.[4]

Fatigue

Fatigue is experienced by over 90% of people with a rheumatic condition, who often rate their fatigue as more severe than their pain,[5] with severity levels as severe as those seen in chronic fatigue syndrome.[6] People without a long-term condition report mean fatigue scores of 20.5 on a visual analogue scale of 0–100, while in rheumatic conditions fatigue ranges from 40.8 (psoriatic arthritis) to 74.4 (primary Sjögren's syndrome), with fatigue scores for people with rheumatoid arthritis (RA), osteoarthritis (OA), lupus, ankylosing spondylitis, and fibromyalgia lying between those two extremes.[7] The financial burden of fatigue in rheumatic disease is not readily identifiable, but people with inflammatory arthritis consider fatigue the primary cause of days lost from paid work.[8]

Definitions of pain and fatigue

Pain

Pain is defined by the International Association for the Study of Pain (IASP) as:

> An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.

For those with a rheumatic disease pain is usually chronic (≥12 weeks duration) and most commonly falls within one or more of the following classifications: musculoskeletal, inflammatory, neuropathic, or a dysfunctional state.

Musculoskeletal pain

Musculoskeletal pain is pain that arises from any structures within the musculoskeletal system such as bone, muscles, tendons, and/or ligaments. Pain may arise from mechanical dysfunction within a joint, as in advanced OA, or from the bone, as in Paget's disease or malignancy. Pain that arises from the muscles alone is commonly referred to as 'myofascial pain'.

Inflammatory pain

Inflammatory pain arises from tissue-damaged associated inflammation that is usually accompanied by oedema, redness, heat, and a possible reduction in function. When present in the joints it is commonly associated with a perception of stiffness.

Neuropathic pain

Neuropathic pain may be central or peripheral in origin and is defined as 'pain caused by a lesion or disease of the (central/peripheral) somatosensory system'.[9] Clinical signs of neuropathic pain may include evidence of **allodynia** (pain to a stimulus that is not normally painful) and **hyperalagesia** (increased pain to a stimulus that normally evokes pain) (see IASP Taxonomy[10]).

Dysfunctional state

This is the term given to conditions where there is a lack of structural cause for the persistent pain experienced, such as fibromyalgia and complex regional pain syndrome.[11] People with these conditions may present with the clinical signs and symptoms of other pain states, such as neuropathic and myofascial pain, but there is no evidence of an underlying pathology.

Fatigue

Fatigue has been defined and classified in a number of ways, yet there is no overall consensus. In terms of the fatigue that is related to musculoskeletal conditions, a broad conceptual definition appears the most appropriate:

> Fatigue is a subjective, unpleasant symptom which incorporates total body feelings ranging from tiredness to exhaustion, creating an unrelenting overall condition which interferes with individuals' ability to function in their normal capacity.[12]

Here, the term 'function' should be assumed to include physical and/or cognitive function. The term 'tiredness' might be disputed, as people with RA consider tiredness to be the phenomenon experienced by healthy people, and believe the terms 'fatigue' or 'exhaustion' are necessary to encapsulate the intensity of the symptoms experienced within chronic illness.[13,14]

Aetiopathogenesis

Pain mechanisms

The pain pathway describes the anatomical route that a peripheral stimulus takes to the brain, via peripheral nerves, dorsal horn, and spinal cord, to register as a painful perception. Central projections of the pain pathway from the thalamic nuclei include somatosensory cortex and the limbic system. Although the pain pathway is a credible neuroanatomical concept, multiple brain areas are activated during a pain experience in addition to the classic lateral sensory–discriminative and medial emotional–affective areas involved in pain processing. Melzack and others have proposed that this extensive network of brain regions activated during pain perception, represents a specific cerebral signature, a pain neuromatrix.[15] A pain experience can be modified by dysfunction at multiple levels along this pathway, ranging from changes in the molecular constituents of the peripheral inflammatory milieu to alterations in the complex circuitry of cortical representation. Disease states, psychosocial factors, and medical interventions can influence the activity of the pathway.

Despite the elaborate multifaceted system of pain perception, broad types can be identified which correlate with known pain mechanisms (see 'Pain'). It should be noted that much of the research that underpins our knowledge of the neurobiology of pain is undertaken in animal models.

Nociceptive pain is caused by stimulation of peripheral nerve fibres (Aδ and C fibres) via tissue pathology such as inflammation, ischaemia, and mechanical stimuli such as pressure and heat. C fibres can release local peptides to induce neurogenic inflammation via neuropeptides such as substance P and calcitonin gene-related peptide (CGRP), which induce vasodilatation, plasma extravasation, and interaction with immune cells.

Neuropathic pain (see 'Pain') arises via nerve signalling from ectopic discharges of damaged neurons or those induced by adjacent healthy nerves, including sympathetic system fibres. Both nociceptive and neuropathic signals can be modified along the pain pathway, so that a given stimulus is amplified—this is sensitization. At the site of tissue damage and inflammation, a large number of mediators can cause the reduction in excitation thresholds of peripheral nociceptors, thereby increasing signalling to the spinal cord dorsal horn. These alterations to the properties of ion channels can be short lived, as in the case of prostaglandins or bradykinins, or much longer lasting such as the effects of cytokines, including tumour necrosis factor alpha (TNFα) and nerve growth factor. There are also important inhibitory mechanisms present in peripheral tissues, and the balance between proinflammatory/excitatory mechanisms and the inhibitory cytokines, cannabinoid, and opioid systems play an important role. The peripheral nerve message can be amplified on a molecular level by complex intracellular mechanisms which modulate gene transcription via second messenger systems.

Central sensitization is considered the main pathophysiological mechanism responsible for neuropathic pain and contributes significantly to nociceptive pain. Peripheral nociceptor hyperactivity causes major secondary changes in the spinal cord dorsal horn, such as enhanced AMP acid (AMPA) N-methyl-D-aspartate (NMDA) receptor activation in the dorsal horn, mediated by protein kinases, and upregulation of the signalling cascade that modulates gene transcription (e.g. c-*fos*, c-*jun*). In addition, changes in the descending modulatory systems and functional changes in spinal cord microglial cells and astrocytes contribute to the enhanced signal transmission of central sensitization.

Specific joint and musculoskeletal pain mechanisms

Features that reflect local joint pathology and characteristics such as mood, social circumstances, and central pain processing mechanisms determine pain report in arthritis. Both peripheral and central mechanisms contribute to chronic arthritis pain.[16] Peripheral mechanisms such as inflammation, oxidative stress, and ischaemia may be more important in the early disease, with central mechanisms having a greater influence on pain report and disability in later stages. Patients with arthritis often describe a 'neuropathic pain' pattern, but whether this reflects true neuropathic pathology or the complex pain experience derived from multiple dysfunctional systems is unclear.

Joints are well innervated by sensory, sympathetic, and nociceptive fibres, though large proportions of them are usually insensitive to normal stimuli. These normally quiescent nerve fibres, the 'silent nociceptors', can be sensitized by peripheral joint pathology and respond to mechanical stress such as (normal) movement. Joint effusion, especially in chronic arthritis where the synovium and capsule are less compliant, causes significant increases in intra-articular pressure that can activate joint nociceptors.

Rheumatoid arthritis

Despite modern treatment approaches, a majority of patients with RA still describe chronic pain. Some of the abnormal pain processing can revert to normal after prolonged periods, as evidenced by restoration of pain threshold and descending pain analgesic pathways, following joint replacement. There may be differences in chronic pain due to OA and RA; for example, RA patients have lower pain thresholds than controls.[17] This may reflect subtle differences in joint innervation in chronic synovitis, combined with altered pain processing, endogenous opioid systems, and descending control.

Osteoarthritis

Why an osteoarthritic joint is painful is not clear. Multiple joint structures are abnormal in established OA. It is likely that combinations of peripheral inflammation, synovitis, bone marrow lesions (seen with MRI scanning), and mechanical stress on periarticular structures, along with peripheral and central sensitization, are responsible. Whether clinical examination and readily available imaging can

predict which of these is the dominant pathway and therefore guide treatment is debatable. Poor outcome from joint replacement may be related to preoperative pain experience, such as rest pain, night pain, and low pain threshold which may be construed as neuropathic.

Fibromyalgia

The chronic widespread pain of fibromyalgia is a common presentation to rheumatologists. Extensive clinical observation, quantitative sensory testing, and functional neuroimaging studies all point towards significant abnormalities in pain perception; widespread multisystem pain report, diffusely lower pressure pain thresholds, temporal summation, deficiencies in descending pain modulation, and cognitive disturbance. This evidence suggests a global amplification of central pain processing. The relative contributions of aberrant descending analgesic serotonergic–noradrenergic system activity, and peripheral and central sensitization is unclear. Further imaging studies have suggested that spontaneous pain is related to enhanced activity in multiple brain networks—additional evidence of a disseminated pain processing problem.[18]

Fatigue mechanisms

The causal mechanism for fatigue in musculoskeletal disorders remains an issue of debate fuelled by poor study design and conflicting results from studies that are largely cross-sectional using small or biased samples (e.g. patients in flare). Although some studies show that fatigue may be causally linked to inflammatory processes, mood, disability, sleep, pain behaviours, and beliefs, the evidence is inconsistent[19] and associations vary across musculoskeletal conditions.[20] In inflammatory musculoskeletal conditions, it has been suggested that interleukins IL-1 and IL-6 might provide a partial explanatory mechanism.[21]

It is proposed there are three main elements driving fatigue in musculoskeletal conditions (Figure 12.1).[22] Disease processes including inflammation and pain may affect fatigue directly, or indirectly through poor sleep, disability, and deconditioning. Cognitions, feelings, and behaviours may interact to produce over- or under-exertion in physical activities, such as 'boom and bust' behaviours. These three elements interact to form a multicausal pathway, where for each patient, different factors are present in different strengths and interact to produce fatigue, with different combinations on each occasion.[22] Such an aetiology would account for a symptom that occurs across the whole spectrum of musculoskeletal conditions, disease durations, and levels of inflammation, and also allows for fatigue as both cause and effect (e.g. sometimes fatigue may be driven by low mood, and at other times low mood may be driven by fatigue).

Clinical features

Pain

Pain may be intermittent or continuous and vary in nature depending on the cause and course of the disease.

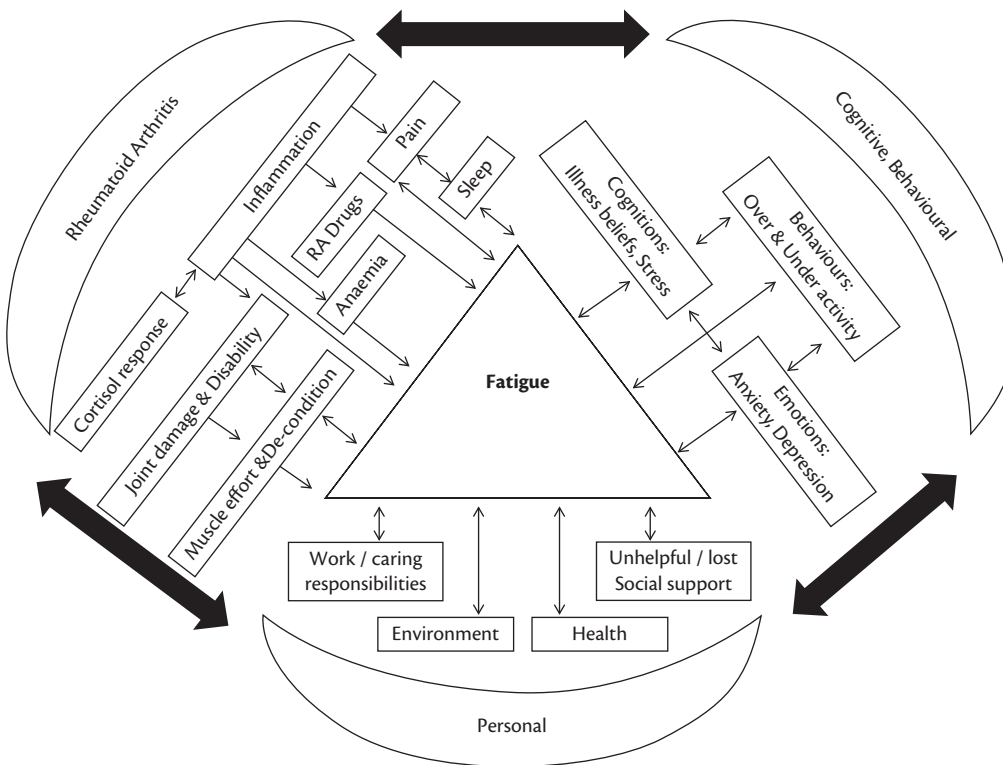
Pain arising from inflammation, such as in RA, will be accompanied by the other classical signs (see 'Inflammatory pain') and is commonly described as throbbing in nature, at rest and on movement, and exacerbated by use of the affected part. The descriptions that patients with RA use to describe their pain may alter depending on the time of day, the duration of their disease, the joints that are involved, and whether those joints are moving or at rest.[23] Diurnal variation of pain and stiffness is common, with patients describing an increase in intensity of these symptoms at the start and end of the day.


Fig. 12.1 Conceptual model of RA fatigue (by kind permission of Rheumatology).

Myofascial pain may be diffuse and poorly localized with reports of a cramp-like, dull aching pain either at rest or in motion.[24] Other musculoskeletal pains, such as osteoarthritic joint pain, is typified by the sufferer describing stiffness on initial movement, increasing pain with prolonged movement and disturbed sleep due to pain.[25] There is a reduction in the range of movement in the affected joint and associated muscle weakness.

Neuropathic pain is typically burning in quality and commonly associated with allodynia (see 'Neuropathic pain'). Decreased (hypoaesthesia) and increased (hyperaesthesia) sensitivity to stimulation may coexist in the affected region, and itchiness may also be present. The patient may avoid touch to the affected part by themselves and others. They may prefer to keep allodynic areas free from clothing during the day and from the bedclothes at night.

People with fibromyalgia report more widespread chronic pain that is commonly associated with fatigue and psychological distress.[26] Although hyperalgesia and allodynia are commonly reported at specific trigger points these sensations often spread far beyond these areas, with sufferers describing generalized sensitivity.[27]

Fatigue

Fatigue has a very similar picture across RA, lupus, OA, and fibromyalgia, with numerous qualitative research studies evidencing common perceptions of the nature, consequences and attitudes toward fatigue (e.g.[13,28,29]). Fatigue is the physical feeling of a heavy body that seems hard to move ('paralysed') and has run out of energy. Fatigue also has a cognitive element, with descriptions of 'foggy-headedness', with difficulty concentrating or focusing, a feeling of an 'absent presence'. The extremes of this physical and mental fatigue are akin to being 'wiped out' with exhaustion or 'overwhelmed'. Fatigue occurs on most days for many people and varies in intensity, with duration ranging from hours to weeks.

Fatigue threatens people's normal roles. It reduces or even stops their ability to perform everyday activities and chores, social and leisure activities, voluntary and paid work, because of either physical or cognitive exhaustion. It has emotional consequences from frustration, leading to anger and depression, and may cause difficulties with relationships when social arrangements are cancelled. This is compounded by a reluctance to discuss fatigue as it is invisible, therefore people feel disbelieved or fraudulent, and struggle with the society's general perception that everybody gets tired. People with musculoskeletal conditions differentiate fatigue from the tiredness experienced by healthy people by its unpredictability, lack of causality ('unearned'), intensity (tired vs fatigue or exhaustion), constancy, and the fact that rest does not lead to recovery.

Management of pain and fatigue

Pain

To manage pain effectively, it is necessary to recognize the differing components that contribute to the subjective and personal experience termed 'pain'. Therefore the approach to the management of chronic musculoskeletal pain should be multidisciplinary.[30–38]

Pharmacological approach

The use of oral analgesics should balance the beneficial effects on pain against the risk profile of the medication in that specific patient.[39] Many patients with chronic musculoskeletal pain will not achieve a pain-free state. Referral to a pain clinician should be considered when; a patient is gaining medications on increasing doses for little further impact on pain but accruing short and long-term adverse effects, or is on high dose strong opioids. Patients with concurrent chronic pain states or neuropathic pain may also need neuromodulatory agents and specialist pain advice. The pharmacological approach to management of patients with chronic musculoskeletal pain is summarized in Figure 12.2.

Non-pharmacological treatment—multidisciplinary approach in chronic pain

Exercise should be a core treatment irrespective of age, comorbidity, pain severity, and disability, and should include local muscle strengthening and general aerobic fitness.[30] Physiotherapy will play a key role in initiating and advising how a patient can safely exercise. Weight reduction is beneficial, and patients may need encouragement and advice. Many patients may have significant psychosocial comorbidity including depression and anxiety, which if left untreated will hamper pain management. Psychological support such as counselling and cognitive behavioural approaches should be considered.[30,31] Orthotics, podiatry, physiotherapy, and occupational therapy can provide advice on appropriate braces, splints, assistive devices, and walking aids. Assessment of footwear and provision of insoles may relieve pain, improve gait and posture, and help to reduce falls.

Pain management approach

Patients with chronic musculoskeletal pain who have exhausted medical and surgical management options and continue to struggle in coping with their symptoms should be considered for a multidisciplinary pain management approach.[40,41] Pain management programmes can be outpatient or in-patient based, and are usually accessed through the pain clinic.[41]

Fatigue

Guidelines by the British Society for Rheumatology and the National Institute for Health and Clinical Excellence (NICE) on the management of RA recommend that fatigue is addressed, but do not provide guidance on management. Assessment could be by visual analogue scale or numerical rating scale, or by multidimensional questionnaires, which yield a more complete picture of different dimensions of fatigue. Such patient-reported outcome measures (PROMs) need to be well validated, and can be selected from a comprehensive review of fatigue PROMs in musculoskeletal conditions.[7]

Pharmacological approach

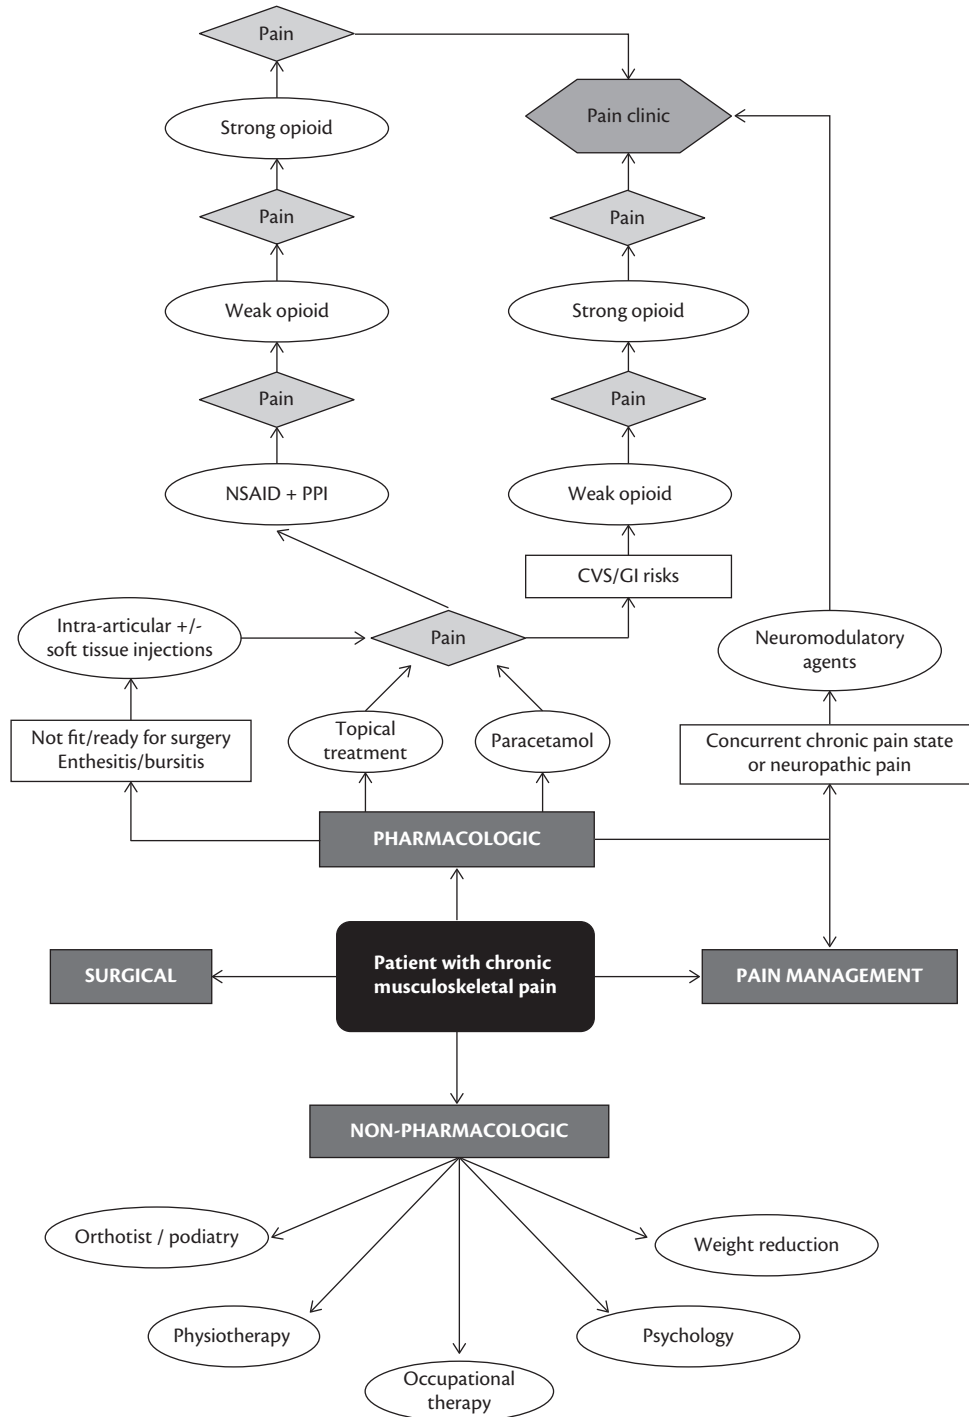
In RA, Cochrane reviews of the effectiveness of biological and non-biological pharmacological (disease-modifying) therapies on fatigue are under way (2011). A systematic review of biological therapies suggests small effects on RA fatigue, as does an overview of disease-modifying therapies.[42,43] This small effect maybe because inflammation is not always the main driver for fatigue. The presence of fatigue in the absence of inflammation is currently not an indication for changing or starting biological or disease-modifying therapies. In fibromyalgia, meta-analyses show no effect for gabapentin or pregabalin on fatigue, but there is evidence that antidepressants may reduce fatigue in the short term.[44] No reviews of pharmacological interventions could be found for fatigue in other musculoskeletal conditions.


Fig. 12.2 An approach to the management to the patient with chronic musculoskeletal pain. The flow diagram is based on the references cited in the text. Each step is additive.

◆ When considering use of an oral NSAID, the potential adverse cardiovascular risks (any NSAID, especially COX II), adverse effect upon the cardioprotective action of low-dose aspirin, adverse renal effects, and gastrointestinal ulceration risks (especially COX I) need to be assessed for the individual patient.

◆ Intra-articular injections: both corticosteroid and hyaluronic acid injections are used, although the evidence base for efficacy is difficult to interpret.[3]

◆ Surgical options may include arthroplasty or spinal surgery such as discectomy. Pain clinics may offer additional interventional procedures such as nerve root blocks or epidurals for chronic back pain.

CVS, cardiovascular; GI, gastrointestinal; NSAID, non-steroidal anti-inflammatory drug; PPI, proton pump inhibitor.

Multidisciplinary team interventions to support self-management of fatigue

Given the presumed multicausal pathway for fatigue, and the consequent limited evidence for pharmacological interventions, the multidisciplinary team should aim to support the patient in their self-management of fatigue. A Cochrane review of non-pharmacological fatigue interventions in RA is under way and meta-analysis currently shows small effects from psychological interventions.[45] However, none of the interventions had fatigue reduction as the main aim: fatigue was a secondary outcome and thus patients were not recruited with fatigue, and the studies were not powered for fatigue. A review of arthritis self-management programmes shows courses that aim to enhance self-efficacy (confidence in personal ability to undertake a task) result in better overall outcomes.[46] Self-efficacy can be enhanced by approaches such as cognitive behavioural therapy (CBT)—linking thoughts, feelings, and behaviours—or social cognition (groups and peer role models), and include teaching patients skills such as problem-solving and goal-setting. Subsequently, a single randomized controlled trial (RCT) of group CBT that specifically aimed to reduce the impact of fatigue in RA has shown benefit, and this utilized high/low energy activity monitoring, pacing, sleep, and stress management and assertiveness skills, using a goal-setting approach over 6 weeks.[47] However, the intervention was facilitated by a clinical psychologist—a resource most rheumatology departments do not have—therefore clinical teams need to find ways of developing skills to deliver interventions using these approaches. In fibromyalgia, reviews showed no effects on fatigue from either CBT or acupuncture, but a short-term effect was seen with educational/psychological interventions that included exercise.[48]

For exercise interventions alone, a meta-analysis in fibromyalgia showed a small effect on fatigue.[49] A Cochrane review of fibromyalgia exercise interventions in which fatigue was reported concluded that effects on fatigue were unknown. Meta-analysis of exercise interventions in RA showed small effects on fatigue, but none of the interventions had fatigue as their main aim.[45] Few exercise interventions have been performed in other musculoskeletal conditions that either specifically target or report fatigue, but single studies suggest exercise may be useful (e.g. in lupus).[50]

Conclusion

Pain and fatigue are significant and common symptoms in the rheumatic diseases and commonly coexist. The clinician should be aware of these problems and regularly provide an opportunity for the patient to discuss these at routine appointments. Treatment strategies should be informed by clinical presentation and knowledge of mechanistic pathways. A multidisciplinary approach to care is important for optimum outcome. Regular review of pain and fatigue throughout the disease trajectory is required to accommodate changes driven by disease activity and patient lifestyle.

CHAPTER 13

The limping child

Yukiko Kimura and Taunton R. Southwood

Introduction

Musculoskeletal pain with or without dysfunction is a very common complaints in children and adolescents which frequently requires medical evaluation. Being able to effectively triage such patients and formulate a differential diagnosis is therefore an important skill for generalists and specialists alike.[1] Some diagnoses may require more rapid treatment than others (e.g. sepsis, non-accidental injury, leukaemia, localized neoplasia, vasculitis, Kawasaki's disease) or may require referral to different subspecialists. Being able to identify specific abnormalities in gait and recognizing symptom patterns in children who are limping will enable clinicians to triage effectively and make more accurate diagnoses. The evaluation should start with a thorough history and physical examination, supplemented by laboratory studies and imaging studies if necessary.[2]

History

Although a multitude of conditions can cause limping in children, a thorough and systematic history and physical examination will enable the practitioner to narrow the differential diagnoses and prioritize conditions based on likelihood. There are many factors that must be considered in this process, but the three key initial differentiating factors are (1) the presence or absence of fever, (2) the location of the pain (whether it affects one joint or one location or is more generalized), and (3) the age of the patient. These factors dictate the urgency of the investigation, and also greatly assist in prioritizing the differential diagnoses. This process is highlighted in the following sections 'Fever and the child with a limp,' and 'Differential diagnosis based on age'. In addition to these key factors, essential elements for taking the history in any child with a limp or musculoskeletal pain are outlined in Table 13.1.

Fever and the child with a limp

When a child presents with limping or joint pain along with fever, and especially when the pain is localized to one area, an immediate concern should be whether there could be a bacterial infection of the bone or joint (septic arthritis or osteomyelitis).[3] This likelihood is greater if the pain and limitation are severe, and if it is accompanied by warmth, redness, and inability to bear weight completely. If bacterial infection seems likely, an urgent evaluation consisting of blood tests (complete blood count, ESR with or without C-reactive protein, blood culture) and arthrocentesis or aspiration of the possible affected bone or joint for culture should be done before any treatment with antibiotics in order to identify the suspected organism. If a bacterial infection is ruled out or seems extremely unlikely, then a work-up for a suspected inflammatory or other cause should begin.

If more than one joint or location are involved, the likelihood of an inflammatory disorder increases.[4] However, red flags such as inability to bear weight with or without an ill appearance are suggestive of malignancy, especially if accompanied by lymphadenopathy, or hepatosplenomegaly and abnormal laboratory tests (such as abnormal blood cell counts or a highly elevated lactate dehydrogenase), even in the absence of lymphoblasts on the blood film.[5–7] A complete review of systems and a thorough physical examination are both essential to localize the pain and to assess for other signs and symptoms which can be clues to the diagnosis.

Figures 13.1 and 13.2 present an algorithmic approach to the diagnosis of the child with a limp, based on the presence or absence of fever in the child as the primary differentiating point. It is also important to take the child's age into account in considering the range of differential diagnoses that may account for a limping gait (Table 13.1).

Physical examination of the limping child

The astute clinician begins the physical evaluation of any child or young person as soon as they lay eyes on them, even from a distance. Relatively 'covert' surveillance may be the only opportunity for the clinician to assess unguarded musculoskeletal movement, and this should continue during the history taking, to provide important diagnostic clues (Table 13.2). The posture of the child may reveal subtle favouring of a limb which the child may compensate for, or even disguise, with more formal examination. This is particularly true for the limping child, as the child may self-consciously alter their gait patterns during clinical gait analysis.

The general appearance and behaviour of the child may highlight disturbed conscious states such as drowsiness, listlessness, or irritability suggesting fever, infection, pain, inanition or exhaustion (Table 13.3). The interaction between the carer and the patient may also be informative, ranging from parental hypervigilance of an apparently well child, to parental indifference to an apparently sick child. The opinion of an experienced and observant clinic nurse is often helpful, particularly if they have assessed the child's general

Table 13.1 Age-based differential diagnosis of the limping child

	Infants and toddlers	School-age children	Adolescents

appearance of health and their cooperation with measuring vital signs and anthropometry.

General physical examination

Every limping child requires a thorough general physical examination and a detailed musculoskeletal assessment. The most common misdiagnoses in a limping child are made because the clinician limits their physical examination to the feet and legs only. Examples of diseases outside the musculoskeletal system that can cause limping can include testicular torsion, inguinal hernia, and intra-abdominal pathology (such as appendicitis, intussusception, or psoas infection). In addition, even if the primary complaint is knee pain and arthritis is discovered, it can be present in other locations as well, which would impact the diagnosis and treatment. Lastly, it is important to examine extra-articular systems, as musculoskeletal dysfunction is common in many multisystemic diseases (see 'Vital signs and examination of extra-articular systems').

Growth

Anthropometric measures are of relevance to the diagnosis of a limping child. The patient's current height and weight should be recorded on appropriate percentile charts, as well as growth records for the previous few years. The combination of short stature and abnormal gait may be found in skeletal dysplasias (achondroplasia, multiple epiphyseal dysplasia, spondyloepiphyseal dysplasia) and chromosomal abnormalities (Turner's and Down's syndromes). Any indication of growth failure or a decline from the child's normal growth trajectory could signal a systemic illness, such as inflammatory bowel disease, malignancy, severe juvenile idiopathic arthritis (JIA), or systemic lupus erythematosus (SLE), among others. Abnormally rapid growth (e.g. Marfan's syndrome, Marshall–Weaver syndrome, hyperthyroidism) may also be associated with musculoskeletal pain and limping in a child.

Vital signs and examination of extra-articular systems

Every child should have temperature, pulse and respiratory rate, and blood pressure documented by the clinic nurse before review by the doctor. In a child or young person who is limping, abnormal findings in these parameters are always relevant. A systematic general examination is also mandatory, as a wide range of primarily extra-articular diseases may present with gait disturbance or musculoskeletal pain (Table 13.4). A general physical examination may also highlight many systemic manifestations of diseases in which musculoskeletal involvement is well recognized. Thorough skin

**A CHILD WITH FEVER AND
MUSCULOSKELETAL PAIN OR LIMPING ***

Number of involved joints

| One joint | None | More than one joint: *Likely an inflammatory disorder, but need to go through algorithm* |

Strongly consider arthrocentesis:
Purulent joint fluid, positive Gram stain and/or culture?

No →

Appears ill, refuses to bear weight or has bony point tenderness?
If none of the above but fever & pain continue: Go to "Diagnosis still unknown" below

Yes

Possible osteomyelitis, discitis or malignancy?

Yes, could be osteomyelitis   No   Yes, could be malignancy

Yes ↓

INFECTION
Treat for septic arthritis or aspirate bone and treat for osteomyelitis

Discuss further imaging studies with radiologist
Treat according to diagnosis

MALIGNANCY
Bone marrow aspiration/biopsy or other diagnostic testing as appropriate

DIAGNOSIS STILL UNKNOWN: Consider infection syndromes associated with infection. If not consistent, go to next step

Child continues to have musculoskeletal pain and fever
Check or repeat CBC, ESR, CRP, chemistry panel, urinalysis
Blood, urine cultures (Obtain Ferritin and D-dimer if Systemic JIA strongly suspected)

Negative cultures and normal acute phase reactants (APR)   Negative cultures but elevated APR   Positive culture(s)

CONSIDER PSYCHOGENIC CAUSES OR IDIOPATHIC
Factitious fever and/or other psychogenic illness;
Continue to monitor and consider other conditions if symptoms continue

LOOK FOR ADDITIONAL CLUES (Look for symptom and fever patterns, rash, other organ system involvement) Remember Kawasaki Disease, Autoinflammatory Disorders (Periodic Fever Syndromes) If diagnosis still unknown & symptoms still present, continue algorithm

CONSIDER EXTRA-ARTICULAR INFECTION
such as endocarditis, pyomyositis, perinephric, psoas, renal or other intra-abdominal abscess, etc.

Fig. 13.1 Algorithm: the child with fever and musculoskeletal pain.

*IMPORTANT NOTES:

Children with significant continued fever and musculoskeletal pain should have the following during the work-up:

- ◆ Complete blood count with differential
- ◆ Acute phase reactants (ESR, C-reactive protein)
- ◆ Routine serum chemistries (including creatinine, muscle and liver enzymes)
- ◆ Urinalysis
- ◆ ASO titre
- ◆ Cultures as appropriate (blood, urine, throat); if considering endocarditis, obtain at least 2 blood cultures from separate sites (remember that endocarditis can present with polyarthritis and fever)
- ◆ Testing for mycobacterial infection
- ◆ Imaging studies of involved area (plain X-rays, other tests as indicated in algorithm)
- ◆ Immunoglobulins and other immunodeficiency studies as appropriate

Fig. 13.1 (Continued)

examination skin is of particular relevance: a wide variety of rashes (e.g. scaling, purpuric, erythematous, nodular, infected) are part of the typical patterns of rheumatic disease (e.g. JIA, systemic arthritis, psoriatic arthritis, enthesitis-related arthritis, rheumatic fever, Henoch–Schonlein purpura, Kawasaki's disease and other forms of vasculitis, SLE, dermatomyositis).

The musculoskeletal examination

pGALS screening musculoskeletal examination

The paediatric Gait, Arms, Legs, Spine (pGALS) is a simple and systematic method to screen for musculoskeletal problems in children that allows busy practitioners to quickly assess the musculoskeletal system[8]. The pGALS assessment is covered in more detail in Chapter 5.

Gait

Gait is the first part of the pGALS, and an important element of the musculoskeletal examination that is often overlooked. It is easier to observe a child's gait when they are wearing shorts, barefoot, and walking repeatedly up and down a long hallway. Further clues may be gained by asking the child to walk on tiptoes (away from the examiner, to facilitate comparison of heel height off the ground), and on heels (towards the examiner, to facilitate comparison of toe height off the ground).

Abnormal gaits
Antalgic gait

The most commonly seen abnormal gait is the antalgic gait, which displays a shortened stance (weight bearing) on the affected leg because of pain in the hip, knee, and/or ankle and foot.

Hypermobile gait

Hypermobility is commonly seen and can present with multiple musculoskeletal complaints. Key features to note are pes planus, foot overpronation at the subtalar joint (subtalar valgus), and knee valgus and recurvatum on standing. There may also be increased lumbar lordosis. If the child is asked to walk on their toes, the foot arch will be restored unless there is a neuropathy or a structural disorder such as tarsal coalition.

Trendelenburg gait

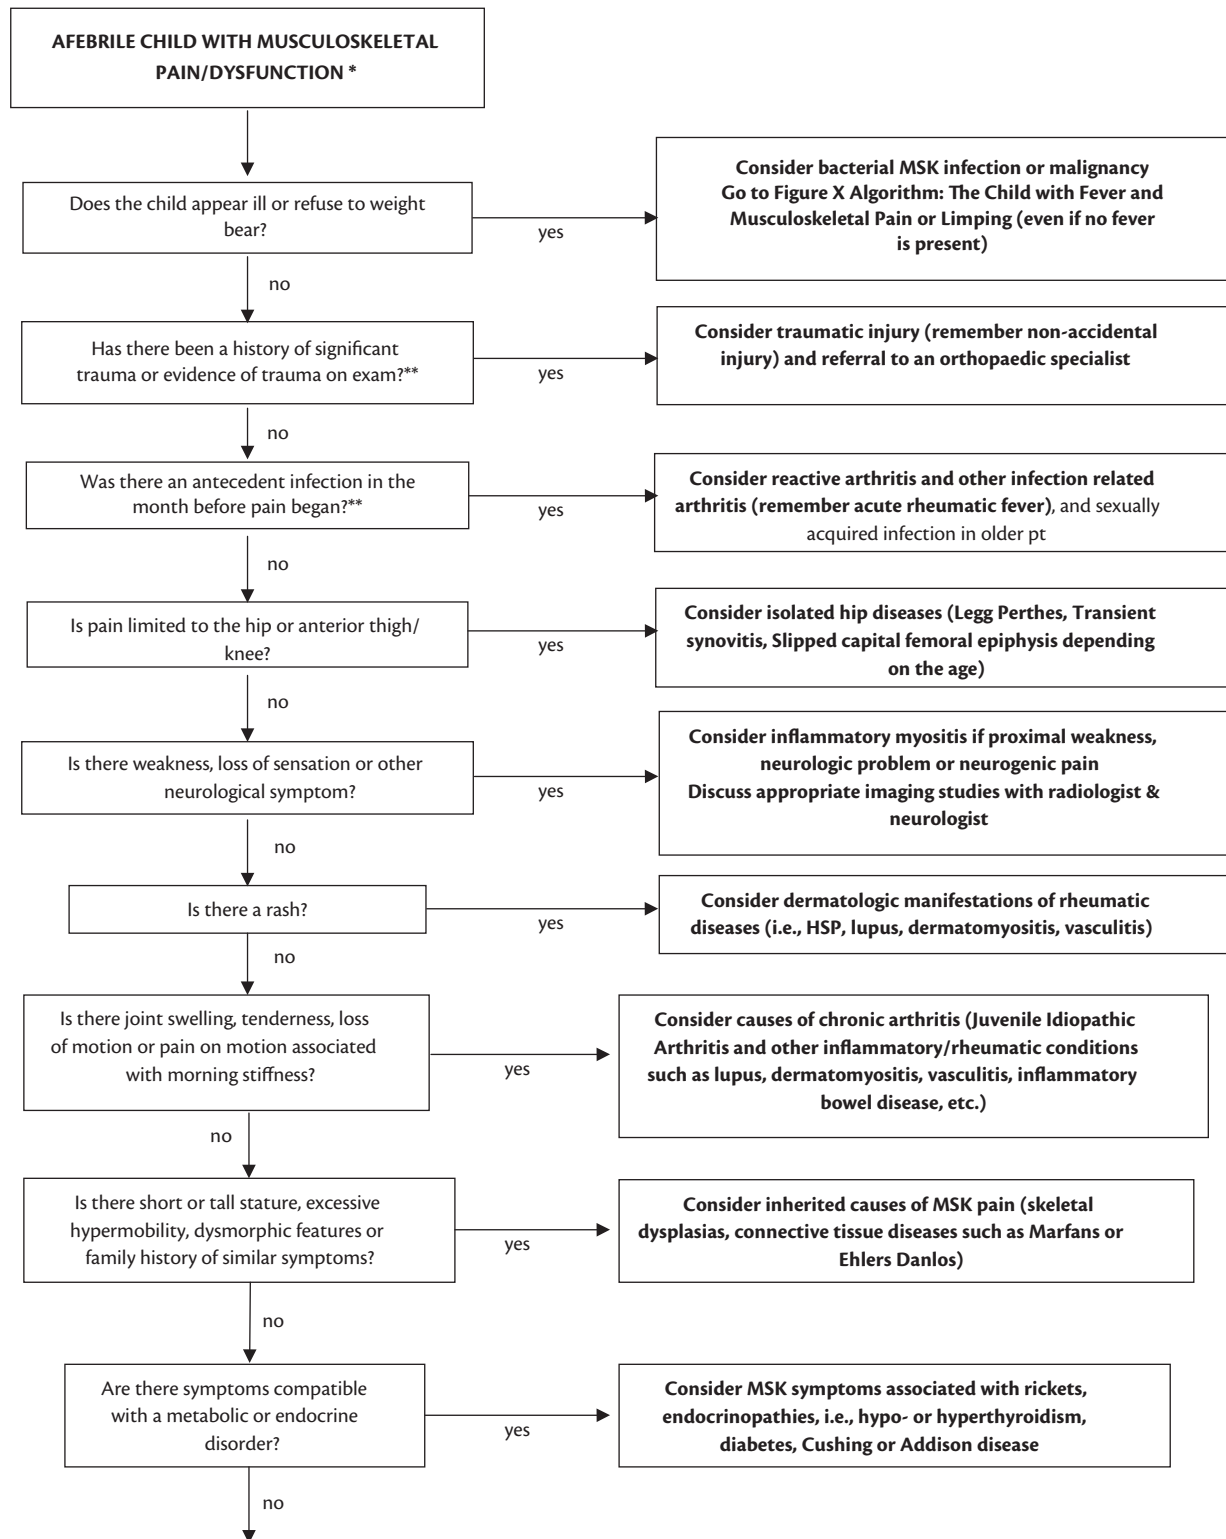
The Trendelenburg gait is characterized by a lateral trunk lean toward the supported limb during the stance phase. The trunk will bend toward the affected side to keep the centre of gravity directly over the hip joint. When viewed from behind as the foot lifts off the ground, it is clear that the unsupported side of the pelvis (the non-stance side) will drop and the sagittal plane of the pelvis will tilt laterally towards that side. This is due to weakened core stability muscles (hip abductors especially). It is usually seen in diseases of the hip joint, and also in muscle weakness.


Fig. 13.2 Algorithm: the child with musculoskeletal pain or limping (without fever).

Reproduced with permission from Oxford University Press Y Kimura. "Common Presenting Problems," in IS Szer, Y Kimura, PN Malleson and TR Southwood, eds., Arthritis in Children and Adolescents. Oxford, UK: Oxford University Press 2006.

Is the pain mainly related to or worsened with physical activity?

yes → **Consider mechanical joint/bone problems, i.e., patellofemoral syndrome, joint hypermobility syndromes, etc.**

no

Is the pain only in the evening or night and not associated with any MSK dysfunction?

yes → **Consider "Growing Pains" if child's age is toddler to school age**

no

Consider Fibromyalgia if pain is diffuse
Suggestive symptoms:
Fatigue
Sleep disturbance
Symmetrical tender points
Pain in excess of physical signs
Normal blood count/ESR

Consider localized pain syndromes such as Complex Regional Pain Syndrome I if pain is localized to one extremity
Suggestive symptoms:
Hyperaesthesia/allodynia
Hypervigilance
Bizarre posture
Normal blood count/ESR
NB may have swelling (usually diffuse)

Consider Somatization
Suggestive symptoms:
Pain in excess of physical signs
Parent – child disparity
School avoidance
Stress

Consider Munchausen or Munchausen by proxy
Suggestive symptoms:

Bizarre physical signs
Disparity between reported and observed signs
Signs in presence of care giver

*IMPORTANT NOTES:

Children with persistent musculoskeletal pain should have the following work-up considered:

◆ Complete/full blood count with differential
◆ Acute phase reactants (ESR, C-reactive protein)
◆ Routine serum chemistries (including creatinine, liver and muscle enzymes)
◆ Urinalysis
◆ Imaging studies (plain X-rays of involved area, other studies as indicated in the algorithm(s))
◆ Testing for mycobacterial infection

**CAVEATS:

◆ Minor trauma and infections are common in children and may not necessarily be related to the diagnosis
◆ Remember infection, malignancy and non-accidental injury (child abuse) at each stage

Fig. 13.2 (Continued)

Weak gait

The weak gait is characterized by poor lateral stability and a tendency to waddle. There is a tendency to walk with a toe–toe pattern and exhibit bilateral drop-foot through the swing phase. Increased lumbar lordosis, due to weak abdominal muscles, and an exaggerated arm swing to aid in forward propulsion will often be noted. A Gower sign, a series of manoeuvres necessary to achieve an upright position in the presence of pelvic and trunk weakness, is a hallmark of muscle weakness. This is most often seen in myopathies such as Duchenne muscular dystrophy and dermatomyositis.

Leg-length discrepancy

Any condition which increases the length of one leg over the other will tend to result in a circumduction gait. The longer leg is swung laterally to avoid catching the big toe on the ground. This is typically seen in JIA, especially if there is asymmetrical knee involvement, other idiopathic conditions such as Blount's disease, and in any disease associated with hemihypertrophy. An effective leg-length discrepancy type gait can also be seen in peripheral neuropathy with foot drop, when the functional length of the leg is increased due to the lack of toe clearance. Leg shortening (e.g. in Perthes' disease) may also result in a leg-length discrepancy and a similar gait pattern.

Spasticity

Spasticity can also cause abnormal gaits. Patients with spastic diplegia may have a waddling gait due to the upper motor neuron lesion of the lower limbs; waddling, plantar grade foot deformities, and poor coordination are observed. Patients with hemiplegia often

Table 13.2 Laboratory tests in the investigation of a child with limp

Laboratory investigation	Abnormalities	Interpretation
Full blood count	Anaemia	Chronic inflammation, blood loss
	Leukopaenia	SLE, MAS
	Leukocytosis	Sepsis, JIA, systemic arthritis
	Thrombocytopaenia	ALL, SLE
	Thrombocytosis	Kawasaki's disease, JIA
Acute-phase reactants	ESR, CRP	Inflammation
		ALL
Biochemistry	Disordered renal function	SLE
	Elevated liver enzymes	MAS
	Elevated LDH	Malignancy
	Elevated muscle enzymes	Dermatomyositis
Urinalysis	Haematuria, proteinuria	SLE, vasculitis
Autoantibodies	Anti-nuclear antibody	SLE
	Double-stranded DNA	SLE

Non-accidental injury	Periostitis, fractures
Autistic spectrum disorder	Musculoskeletal pain

have flexed posturing of the affected upper extremity, a supinated and inverted affected foot through the swing phase, and retraction of the hemipelvis on the involved side.

Range-of-motion assessment of the lower limb

It is important to perform the range-of-motion examination in the lower extremities with the patient supine. **Passive range of motion** refers to the amount of movement that a joint displays when the examiner manipulates the joint. **Active range of motion** refers to the motion of the joint when the patient performs the movement. Significant weakness in a muscle group may result in a decrease in the active motion of a joint without a decrease in passive motion. A contracture in a joint will result in loss of motion of the joint in the active and passive modes. Tendinitis may cause loss of active motion in a joint without loss of passive motion.

When assessing passive range of motion, it is important to push the joint to the full endpoint of motion to accurately assess the full mobility of the joint and not just to see if the joint moved. It is important to always examine at least one joint above and at least one joint below the symptomatic joint, because joint pain can be referred proximally and distally, which can lead to the patient complaining of pain in a particular joint although the abnormality is in the joint proximal or distal to the symptomatic joint. A common example of this phenomenon is when a child complains of knee pain but may in fact have a hip problem such as transient synovitis with pain referred to the knee. Another example is that sometimes patients experiencing pain around the hip, especially down the buttocks, may actually have a spinal injury. It is equally important to always compare the affected limb with the non-affected limb.

It is important for paediatricians to understand that there is a relatively wide range of normal passive and active motion for all body joints. The inability of a joint to achieve full motion in the plane of flexion or extension is a joint contracture, which can be due to arthritis, postsurgical arthrofibrosis, skeletal dysplasias, and other conditions.

It must be remembered that decreased mobility can also be due to **spasticity**. Spasticity manifests as an increase in tone that occurs in a muscle or muscle group when forcefully stretched. Once the muscle relaxes, the tone decreases and the muscle will stretch further.

Joint laxity is usually due to a ligamentous abnormality, not to a muscular or tendinous problem. Laxity can be acute when it occurs after a complete rupture or tear of the anterior cruciate ligament. Chronic laxity that occurs with **hypermobility syndromes** can range from benign hypermobility syndrome to more extreme examples, such as Ehlers–Danlos syndrome.

Laboratory studies and imaging

Laboratory tests should be requested in most cases of a limping child unless there is a history of significant trauma (Table 13.2).

Plain radiographs of affected area(s) can assist in excluding occult traumatic injury, tumours, bone dysplasias, and other bony lesions, and should be performed in most cases. However, a normal radiograph does not rule out many conditions, such as inflammatory arthritis (unless there has been damage from long-standing disease), early osteomyelitis (radiographic changes such as periostitis take 10–14 days to develop), non-displaced fractures, septic arthritis, or sprains. Beyond plain radiographs, other imaging tests (MRI, CT scan, bone scan) may be helpful depending on the clinical situation. MRI is useful for detecting osteomyelitis, anatomical abnormalities, and joint effusions but should be obtained with contrast (gadolinium) if an inflammatory disorder,

such as arthritis, or tumour is suspected. A bone scan can also help in situations where symptoms are poorly localized in a child with a limp.

Conclusion

Many conditions with a wide range of medical urgency can present as a child with a limp. This chapter presents a systematic process of evaluation that will allow the busy practitioner to first assess the urgency of the problem, and then proceed through logical steps in order to make the correct diagnosis.

CHAPTER 14

The systemically unwell child

Athimalaipet V. Ramanan and
Jonathan D. Akikusa

Introduction

The systemically unwell child is a common clinical problem in paediatrics. For the purposes of this chapter, the term systemically unwell refers to the presence of fever, with or without associated non-specific symptoms such as lethargy and weight loss. In the majority of cases a cause is found following a round of simple investigations. This will usually be infection, and depending on the causative agent, the child will improve spontaneously or following appropriate antimicrobial therapy. When routine investigations fail to reveal an aetiology and the child remains unwell, the differential diagnoses should be broadened to include, among others, paediatric rheumatic diseases. Figure 14.1 presents the important rheumatologic differentials of systemic illness in children according to the age at which they typically occur.[1–14] Table 14.1 provides a summary of the key clinical and laboratory features of these conditions. Once rheumatologic differentials relevant to the age of the child under evaluation are identified, they can be refined based on knowledge of the incidence and clinical and laboratory features of the diseases concerned. This chapter provides a brief overview of these conditions focusing on key clinical features, common diagnostic pitfalls, and investigations important in their diagnosis.

Kawasaki's disease

Kawasaki's disease (KD) is a self-limiting primary systemic vasculitis with a peak incidence in pre-school-aged children and a propensity to cause arterial aneurysms, particularly of the coronary vessels. It is the most common cause of acquired paediatric heart disease in developed countries. Of all the recognized paediatric primary systemic vasculitides (Box 14.1), KD is the one that most commonly presents with fever. The diagnosis is made in the presence of fever for more than 5 days with at least four of five defined clinical features: mucocutaneous changes, polymorphic rash, changes in the extremities, non-purulent conjunctivitis, and cervical lymphadenopathy (see Chapter 130 for more details). Some children with KD may lack the number of clinical features required to satisfy diagnostic criteria and are considered to have an 'incomplete' form. Although KD is usually seen in children between 6 months and 5 years of age, it is recognized in children outside this age range; these children are more likely to present with the incomplete form, which may lead to a significant delay in diagnosis. Infants under 6 months of age, in particular, have a high risk of incomplete disease and coronary artery aneurysms, mandating a high index of suspicion and low threshold for treatment in this age group.[15] There is a higher risk of KD in children of Asian origin (including children from the Indian subcontinent),[16,17] and it is being increasingly recognized in the developing world where infectious conditions are prevalent.

Key clinical features

Fever is the predominant symptom and is required for diagnosis although it is important to remember that not all the other diagnostic features need to be present at the same time. This is a common misconception that may lead to the diagnosis being missed.
sJIA – Systemic Juvenile Idiopathic Arthritis; PAN – Polyarteritis Nodosa; SLE – Systemic Lupus Erythematosus; ANCA- Anti-neutrophil Cytoplasmic Antibodies; NOMID – Neonatal Onset Multisystem Inflammatory disease; HIDS – Hyper IgD syndrome; FMF – Familial Mediterranean Fever, TRAPS- Tumor Necrosis Factor Receptor Associated Periodic Syndrome; MWS – Muckle-Wells Syndrome
* By definition cannot occur >16yrs, similar syndrome may occur after this age as Adult Onset Still's Disease.
** Refers to age at onset of symptoms. Diagnostic delay common in these syndromes.
Fig. 14.1 Average age (peak shading) and age range at diagnosis of important rheumatologic conditions associated with fever in children.

Table 14.1 Summary of key clinical and laboratory features of these paediatric rheumatic diseases

Condition	Key clinical features	Typical results of important laboratory investigations
KD	Fever ≥ 5 days Combination of ocular, mucosal, cutaneous, peripheral and lymph node changes per KD criteria Flare at BCG scar site in Asian children GI symptoms in older children	Increased ESR/CRP Increased WCC, PLT (subacutely) Mild increase in LFTs Decreased albumin Sterile pyuria
sJIA	Fever- 1–2 spikes per day (quotidian) Evanescent, salmon-pink rash Hepatosplenomegaly, lymphadenopathy Arthritis not always present initially	Increased ESR/CRP Increased WCC, PLT Decreased Hb Increased ferritin (typically >1000 µg/L) Increased CD163 staining of bone marrow
Vasculitis (AAV/TA/PAN)		
All	Non-specific constitutional symptoms	Increased ESR/CRP Decreased Hb Serum creatinine may be abnormal
ANCA-associated	Skin—palpable purpura (leukocytoclastic) Dyspnoea, cough, haemoptysis Symptoms of uraemia Sinusitis Scleritis/episcleritis	ANCA positive >80% (usually specific for PR3 or MPO) Urinalysis may be abnormal
Takayasu's arteritis	Hypertension, claudication, bruits	Large-vessel imaging—wall thickening with stenosis or aneurysms
Polyarteritis nodosa	Skin—livedo, tender nodules Myalgia Mono/polyneuropathy	Medium-vessel imaging—aneurysms
SLE	Rash—malar/discoid Photosensitivity Oral/nasal ulcers—typically painless Polyarthritis—typically painful Oedema if nephrotic, symptoms of uraemia. Behaviour/cognitive changes; headache; seizures	Positive ANA May have positive anti-ENA, dsDNA and phospholipid antibodies Increased ESR (CRP typically normal unless infection/arthritis/serositis) May have haemolytic anaemia, thrombocytopenia May have renal impairment, decreased albumin, increased LFTs
MAS	Persistent fever Purpuric rash Multiorgan failure Features of underlying rheumatic disease	Pancytopenia Increased ferritin >10 000 µg/L Abnormal LFTs
Periodic fever syndromes		
All	Well between febrile periods NB: NOMID patients typically have persistent rash and other non-fever-related manifestations	ESR/CRP elevated during fever, normal between episodes NB: NOMID patients usually have chronic elevation of acute-phase reactants
FMF	Fever usually <72 h Serositis Monoarthritis Erysipeloid rash	Elevated serum amyloid A Mutation testing of *MEFV* (≥1 identifiable mutation in 70–80%)
HIDS	Fever typically 4–6 days Cervical lymphadenopathy Maculopapular rash Abdominal pain	Urine mevalonic acid elevated during febrile episodes Elevated IgD Mutation testing of *MVK* (≥1 mutation in >50%)

<div align="right">(Continued)</div>

Table 14.1 (Continued)

Condition	Key clinical features	Typical results of important laboratory investigations
TRAPS	Fever frequently >1 week Migratory rash Periorbital oedema Arthralgia/ myalgia	Mutation testing of *TNFRSF1A* (detectable mutation in 10–50%)
FCAS/MWS	Fever usually <24 h Urticarial rash	Mutation testing of *CIAS1* (detectable mutation in 70–90%)
NOMID	Fever—non-remitting Urticarial rash from birth Lymphadenopathy Aseptic meningitis Arthropathy	Mutation testing of *CIAS1* (detectable mutation in 50%)

ANA, antinuclear antibodies; ANCA, anti-neutrophil cytoplasmic antibody; BCG, bacille Calmette–Guérin; CRP, C-reactive protein; ENA, extractable nuclear antigens; ESR, erythrocyte sedimentation rate; GI, gastrointestinal; Hb, haemoglobin; KD, Kawasaki's disease; LFT, liver function tests; MAS, macrophage activation syndrome; MPO, myeloperoxidase; PLT, platelet; PR3, proteinase 3; SLE, systemic lupus erythematosus; WCC, white cell count. For other abbreviations see text.

Box 14.1 Overview of main forms of primary systemic vasculitis in children

Predominantly affecting large vessels

◆ Takayasu's arteritis

Predominantly affecting medium vessels

◆ Childhood polyarteritis nodosa

◆ Cutaneous polyarteritis

◆ Kawasaki's disease

Predominantly affecting small vessels

◆ Wegener's granulomatosis
  (now granulomatosis with polyangiitis) } ANCA - associated
◆ Microscopic polyangiitis   vasculitides

◆ Churg–Strauss syndrome

◆ Henoch-Schönlein Purpura (HSP)

◆ Isolated cutaneous leukocytoclastic vasculitis

◆ Hypocomplementaemic urticarial vasculitis

Apart from the clinical features required for diagnosis, another useful clinical clue is a flare of the BCG scar site, particularly in children of Japanese or Indian origin.[18]

Older children tend to present with more gastrointestinal symptoms compared to children under 5 years of age.[19] Abdominal symptoms such as diarrhoea and vomiting are seen in up to 25% of younger children with KD. This figure increases to more than 50% in those older than 5 years.

A change in the extremities with redness of palms and soles is a characteristic feature of KD. Common pitfalls/atypical presentations which result in a delay in, or not making, the diagnosis include: presence of just prolonged fever with/without cervical lymphadenopathy; sterile pyuria in child with fever; diagnosis of

meningitis/encephalitis in a young child presenting with irritability; and rash in a child with fever being wrongly attributed to antibiotics.[18]

KD should be considered in any child with fever for more than 5 days. Clinical and laboratory features that might potentially help make the diagnosis should then be actively looked for to avoid missing KD and the risk of future poor coronary outcome that may result.

Useful investigations

Although there is no laboratory finding diagnostic of KD, there are patterns of abnormality that aid the diagnosis. These include elevated erthrocyte sedimentation rate (ESR) and C-reactive protein (CRP), high white cell count, transient mild elevation of liver enzymes, low albumin, and eosinophilia.[20] Hypoalbuminaemia and hyponatraemia are associated with more severe and prolonged acute disease.[18,21] There are important caveats to the above. An elevated platelet count is characteristically seen in the second week of illness, but a low platelet count in the first week of illness does not exclude the diagnosis and is potentially a marker of poor prognosis.

Systemic juvenile idiopathic arthritis

Systemic juvenile idiopathic arthritis (sJIA) is characterized by fever, rash, and arthritis. The diagnostic criteria include fever of at least 2 weeks' duration with arthritis and one or more of the following: evanescent, erythematous rash; serositis; generalized lymphadenopathy or hepatomegaly and/or splenomegaly. sJIA is an important and common rheumatological diagnosis to consider in a child of any age presenting with fever. Case series from the literature highlight the significant prevalence of this condition in children with fever of unknown origin.[22–25] More detail about sJIA is given in Chapter 116.

Key clinical features

There are several characteristic clinical features of sJIA which can be useful pointers to the diagnosis. The fever pattern is quotidian, with one or two daily spikes of variable duration, in between which

Fig. 14.2   The typical salmon pink macular rash of sJIA.

the temperature returns to normal. During periods of fever the children appear ill and a 'Still's rash' typically appears. In contrast, during periods without fever, the child often appears well and the rash is absent. The rash consists of salmon pink macules, typically on the proximal limbs and torso (Figure 14.2) with demonstrates the Koebner phenomenon. The rash can be hard to identify in dark-skinned individuals.

Arthritis may not always be present initially and there are reports of 'formes frustes' of this disease without arthritis.[26] It can be difficult to exclude malignancy in these children and a formal work-up, including a bone marrow aspirate and trephine, may be required. Systemic JIA can also present with macrophage activation syndrome (MAS) at onset (see Chapter 168). In this situation the children are more likely to be very ill with coagulopathy, raised transaminases, and very high ferritin (>10 000μg/L). It is important to diagnose and treat these children quickly as MAS may be fatal if appropriate therapy is delayed.

Useful investigations

The characteristic laboratory picture is of anaemia, leukocytosis, thrombocytosis, and raised inflammatory markers (CRP and ESR), but this picture is not unique to sJIA. Autoantibodies are not helpful as they are usually negative in these children. A markedly elevated serum ferritin is characteristic of sJIA—typically reaching levels higher than 1000 μg/L. However, again this is not unique to sJIA as other processes, including infection and malignancy, may result in hyperferritinaemia.[27,28] If a bone marrow biopsy is performed then staining for CD163 (a marker for macrophages) might help in the diagnosis of sJIA.[29]

Primary systemic vasculitis

The primary systemic vasculitides (PSVs) are a heterogeneous group of disorders characterized by inflammation of vascular walls and distinguished by the size and pathologic appearance of affected vessels and associated clinical and laboratory features (see Chapter 136). Box 14.1 summarizes the main types of primary systemic vasculitis in children based on recent consensus criteria.[30]

Some PSVs, such as Henoch–Schonlein purpura (HSP) and isolated cutaneous leukocytoclastic vasculitis, are rarely associated with systemic illness. Others, in particular Takayasu's arteritis, polyarteritis nodosa, and the anti-neutrophil cytoplasmic antibody (ANCA)-associated vasculitides (AAV), may be associated with a prolonged period of non-specific constitutional symptoms before the diagnosis becomes apparent.[1,3,31] KD is discussed earlier in this chapter (see section 'Kawasaki's disease').

Key clinical features

ANCA-associated vasculitides

The commonest types of AAV in the paediatric population are granulomatosis with polyangiitis (GPA) and microscopic polyangiitis (MPA). Constitutional symptoms, such as fever, weight loss, and fatigue, are the most frequent symptoms at presentation of GPA.[1,3] Symptoms related to pulmonary, renal, ear, nose and throat disease, and skin, are the next most common and typically manifest as dyspnoea, haemoptysis/pulmonary haemorrhage, pulmonary nodules, fixed pulmonary infiltrates, active urinary sediment, sinusitis, upper airway mucosal ulceration, and skin purpura.[1,3] The symptom complex and frequency of organ involvement in MPA is similar to GPA with the exception that ear, nose and throat involvement is not seen and lung involvement occurs primarily as pulmonary haemorrhage.[12,32,33]

Takayasu arteritis

Common symptoms of Takayasu arteritis (TA) include headache (reported in up to 64% of patients), arthralgia (43%), weight loss (36%), and fever (29%).[31] Hypertension is the most common clinical sign, reported in more than 80% of patients.[31,34] In this context, signs of vessel stenosis including bruits, reduced or absent peripheral pulses, and differential blood pressure between limbs are an important clue to the presence of large-vessel disease.

Polyarteritis nodosa

The commonest clinical features of polyarteritis nodosa (PAN) involve the skin, muscles, gastrointestinal system and nervous system.[12] They include livedo reticularis, tender subcutaneous nodules, significant myalgia and associated muscle tenderness, abdominal pain, and a mono- or polyneuropathy, which represent many of the recently validated classification criteria for this condition in children.[30]

Useful investigations

Acute-phase reactants, such as CRP and ESR, are typically elevated in these forms of vasculitis. Anaemia and thrombocytosis may also occur, and provide further evidence of underlying systemic inflammation. The absence of abnormalities in at least one of these parameters makes the diagnosis of active TA, PAN, or AAV unlikely. Other useful routine investigations include urinalysis and a chest radiograph, which may reveal an active urine sediment or pulmonary changes suggestive of AAV, respectively. Tests for ANCA, with specificity for either proteinase 3 (PR3) or myeloperoxidase (MPO), will be positive in more than 80% of patients with AAV.[1,3,12,32]

An important objective in the diagnosis of any of the vasculitides is confirming inflammation within the vascular tree. In
Fig. 14.3 (A) Three-dimensional reconstruction of a CT angiogram demonstrating narrowing of the suprarenal abdominal aorta (white arrow) in a patient with Takayasu arteritis. (B) Axial CT image from the same patient demonstrating luminal narrowing secondary to significant wall thickening (between small and large white arrows).

TA, ultrasound, CT, or MRI may be used to detect large-vessel wall abnormalities; typically thickening with consequent stenosis (Figure 14.3), but occasionally aneurysmal dilation.[35] In PAN, medium-vessel vasculitis may be demonstrated in biopsies of skin lesions, or typical aneurysmal dilatation of medium-sized vessels may be seen on abdominal angiography.[36] Although the AAV may occasionally involve medium-sized vessels, small-vessel involvement is the hallmark of this group of diseases. This may be demonstrated in biopsies of the skin, upper respiratory tract, and other involved organs. Vasculitis is rarely demonstrated in renal tissue in AAV; however, pauci-immune necrotizing glomerulonephritis is typical.[1]

Connective tissue disease

The term 'connective tissue disease' encompasses the clinical entities of juvenile systemic lupus erythematosus (JSLE), scleroderma, juvenile dermatomyositis, mixed connective tissue disease, and overlap/undifferentiated connective tissue disease, which are covered in detail in other chapters. Of these, JSLE is the most likely to present with systemic illness such as malaise, fatigue, and fever. Although fever may occur at presentation in other forms of connective tissue disease, it is not usually a prominent feature.[37–40] The diagnosis of JSLE is requires the presence of at least four of the clinical and laboratory features listed in the current American College of Rheumatology classification criteria for SLE,[41,42] which function as diagnostic criteria in both adults and children. Although it is found in all ethnic groups, SLE has a higher incidence in non-white populations.

Key clinical features

Skin and joint disease are frequent features of JSLE in children at presentation, seen in 44–70% and around 65% of children, respectively.[6,7,43] Skin involvement occurs typically as a photosensitive malar rash which characteristically spares the nasolabial folds. Less commonly, a non-photosensitive discoid rash may be seen. Mucous membrane involvement may occur as oral or nasal

Fig. 14.4 Oral ulceration in SLE, demonstrating the typical appearance and location on the hard palate.

ulceration. The ulceration is usually painless and in the mouth typically occurs on the hard palate, which may be missed if not specifically examined (Figure 14.4). The arthritis of SLE tends to be a painful peripheral polyarthritis. Renal and haematological disease are also common at presentation, seen in 20–47% and 55% of patients, respectively.[6,7] Other clinical features which may occur at presentation include serositis, as pleural or pericardial effusions, and central nervous system disease, such as headache, psychosis, and cognitive dysfunction.

Useful investigations

The most useful investigation in the work-up for SLE is an assay for anti-nuclear antibodies (ANA), which are found in most, if not all,

patients.[7] Their absence virtually excludes the diagnosis. If ANA are found to be present, further testing should be done for antibodies against double-stranded DNA, extractible nuclear antigens (e.g. anti-Smith, -Ro, and -La antibodies) and phospholipids (i.e. anti-cardiolipin and lupus anticoagulant). A urinalysis should be performed looking for active urine sediment, suggestive of glomerulonephritis. A full blood count may reveal anaemia, leukopenia (particularly lymphopenia), and thrombocytopenia. If haemolysis is suspected a Coombs test should be performed to confirm an immune basis.

Macrophage activation syndrome

Haemophagocytic lymphohistiocytosis (HLH) is a clinical syndrome of hyperinflammation resulting from immune dysregulation. It may occur as a primary phenomenon, in which immune the dysregulation has a genetic basis, or as a secondary phenomenon in the context of infection, malignancy and autoimmune diseases.[44] HLH complicating rheumatic disease is termed macrophage activation syndrome (MAS). sJIA is the rheumatic disease most commonly associated with MAS, although it may also be seen in JSLE and KD. Children with this condition are usually very unwell, with cytopenias, coagulopathy resembling disseminated intravascular coagulation (DIC), and multiorgan failure.

Key clinical features

The clinical presentation of HLH can vary depending on the underlying trigger. Children may present with prolonged fever and gradually worsening clinical status, or acutely unwell with fever and multiorgan failure. The diagnostic criteria for HLH/MAS are usually met only in the late stages of the disease. Patients may have signs of expansion of the reticuloendothelial system, such as lymphadenopathy and hepatosplenomegaly, and evidence of capillary leak in the form of oedema. A purpuric rash may occur in those with significant coagulopathy. In children with sJIA, the fever associated with MAS is more likely to be sustained or have several spikes as opposed to the one or two spikes seen with active systemic disease.

Useful investigations

The diagnosis of HLH should be considered in any febrile child with the combination of pancytopenia (or two cell line cytopenia), raised liver enzymes, and coagulopathy. A falling ESR, secondary to low fibrinogen, can also be a useful clue to the diagnosis. Serum ferritin is perhaps the most useful 'routine' investigation in the work-up for HLH; a serum ferritin of more than 10 000 μg/L has a specificity of 96% and a sensitivity of 90% for the diagnosis.[45]

The current HLH diagnostic criteria have some limitations when applied to everyday practice, as they include tests for sCD25 and NK cell function, which are not available at all centres. The criteria are also limited in their applicability to MAS. The requirement for significant cytopenias may not be met in those with significant pre-existing elevated counts, such as children with sJIA. In these children, a fall in previously elevated cell counts in the setting of ongoing fever is concerning for MAS, even though the counts may still be within the 'normal' range. These children will also have low ESR in spite of inflammation, due to the low fibrinogen associated with a consumptive process.

Periodic fever syndromes

The periodic fever syndromes come under the category of autoinflammatory disease. They result from defects in the pathways which initiate and regulate the inflammatory response and are characterized by recurrent episodes of inflammation, stereotypical for each condition. They have a strong genetic basis; mutations in specific genes have been identified for many of these conditions. Although the prevalence of some of these disorders is strongly influenced by ethnicity (e.g. familial Mediterranean fever (FMF) in those from the Mediterranean region), sporadic mutations occur. Further detail for each of the conditions is given in Chapter 164.

Key clinical features

The onset of symptoms in most of these syndromes is in early childhood (Figure 14.1) with recurrent episodes of fever and associated symptoms and signs. A good clinical history, paying attention to the features typical of each condition, is essential (see Chapter 5). The duration of attacks, in particular, may help in distinguishing between the various syndromes. The use of a symptom diary assists in the documentation the specific features of the episodes, their duration and frequency. Affected children are well between attacks, demonstrating normal growth patterns. This is a useful distinguishing feature from autoimmune disease.[46,47]

- ◆ **FMF** typically causes episodes lasting less than 72 hours. Associated features include abdominal and chest pain as a result of sersositis, joint pain, and erysipeloid rash. The abdominal pain may be severe, and in the context of fever a surgical cause may be mistakenly suspected.
- ◆ **TNF receptor associated periodic fever syndrome (TRAPS)** causes attacks of fever lasting longer than a week with skin manifestations in most. Conjunctivitis, abdominal pain, arthralgia, myalgia, and periorbital oedema may also occur.
- ◆ **Hyper IgD syndrome (HIDS)** is characterized by fever with cervical lymphadenopathy, arthralgias, skin lesions, and abdominal pain. The fevers usually last for 4–6 days and attacks are classically seen every 4–6 weeks.
- ◆ **Cryopyrin associated periodic fever syndromes (CAPS)** are usually characterized by an urticarial rash. Some of the CAPS conditions also have low grade fever, headaches, blurred vision, and arthralgia during attacks.

Useful investigations

Most children with periodic fever syndromes have elevated acute-phase reactants during an episode of fever. The diagnosis is usually made by identifying the underlying genetic mutation.[47]

The acute-phase reactants are usually normal in between attacks, which helps to distinguish them from chronic infectious and autoimmune diseases. Urine mevalonic acid can be raised during attacks in children with HIDS.

Other conditions

Sarcoidosis

Early onset sarcoidosis (EOS) is a distinct clinical entity quite different from the sarcoidosis seen in adults and older children. It is increasingly recognized that most children with early-onset

sarcoidosis possibly have a form of Blau's syndrome with underlying mutations in the *NOD2* gene.[48]

Key clinical features

The characteristic triad of manifestations is rash, arthritis, and uveitis. Many children will also have low-grade fever.[49] The presence of low-grade fever, rash, and arthritis may lead to confusion with sJIA.[50] The presence of uveitis, unusual in sJIA, is a clue to the correct diagnosis. A slit lamp examination of the eyes should therefore be obtained in children under 5 years with fever and arthritis.

The rash of sarcoidosis is different from the sJIA rash. In sJIA there is an evanescent macular rash, whereas the rash in EOS is more likely to be papular or occur as plaques with scaling (Figure 14.5). The arthritis seen with EOS is also more likely to be painless, boggy, synovial thickening without much restriction in the range of movement.

Useful investigations

Anaemia, leucopenia, and eosinophilia are common. Angiotensin converting enzyme (ACE) levels are increased in more than 50% of those with late-onset sarcoidosis. Genetic testing in the EOS patients looking for mutations in the *NOD2* gene is helpful where feasible.

Kikuchi's disease

Kikuchi's disease is a necrotizing lymphadenitis which typically presents in adolescents or young adults with fever and lymphadenopathy.[51] Less frequent symptoms include night sweats, weight loss, nausea and vomiting. Although self-limiting, it can evolve into lupus in some.[52,53] These children typically have raised inflammatory markers and elevation of lactate dehydrogenase (LDH), and almost half will have leukopenia. The diagnosis is usually made on the histological appearances of the lymph node.

Castlemans's disease

Castleman's disease is characterized by lymph node hyperplasia. It can present as unicentric or multicentric variants. Although uncommon in children, it may occur during adolescence. The unicentric variant is more likely to present with lymph node swelling, with systemic features in some. The multicentric variant almost always presents with significant systemic symptoms. Laboratory tests may

Fig. 14.5 The scaly papular rash of sarcoidosis.

reveal anaemia, thrombocytopenia, and significantly elevated CRP. The condition is secondary to high levels of IL-6, of which the CRP can be a useful surrogate marker. The diagnosis is usually made on lymph node histology.[54]

Malignancy

An important aspect of the rheumatologic evaluation of the systemically unwell child is consideration of mimics, especially malignancy. Three malignancies in particular—acute leukaemia, neuroblastoma, and lymphoma—may present with clinical and investigational features, such as arthritis and elevation of acute-phase reactants, that overlap with those of the rheumatic diseases discussed in this chapter.[55] A high index of suspicion should therefore be maintained during the evaluation. Many children with rheumatic diseases who are systemically unwell will ultimately require steroid therapy. It is essential to be certain that malignancy is not the cause of symptoms before such treatment is begun, as in many cases this will result in partial treatment and make subsequent diagnosis on tissue samples difficult. At times it is not possible to be certain that malignancy is not present, and investigations such as a bone marrow aspirate and trephine are required to rule it out. Leukaemia and lymphoma may present at any age whereas neuroblastoma typically presents in children under 6 years. Important clues to the possible presence of malignancy are pain and disability in excess of physical signs, bone pain, pain that wakes the child from sleep, cytopenias, elevated ESR in the face of a low-normal platelet count, and a significantly elevated serum LDH.[55–57]

CHAPTER 15

Primary care presentation

Elspeth Wise

Primary care

Primary care physicians, also known as family practitioners or general practitioners (GPs), perform a unique role within the United Kingdom National Health Service (NHS). They are generally the first healthcare professional that patients access, and act as the gatekeeper to other services, including secondary care. Primary care doctors manage 90% of the conditions that they see, along with the help of the primary healthcare team.[1]

The roles of a primary care doctor (adapted from WONCA[2]) are:

- The provision of comprehensive and continuing care to every individual seeking medical care, irrespective of age, sex, and illness.
- Caring for individuals in the context of their family, their community, and their culture.
- Management plans, which should be holistic and utilize the knowledge and trust engendered by repeated contacts.
- Health promotion/disease prevention.

Primary care in the United Kingdom has changed over recent years. At the inception of the NHS in the mid-20th century, patients used to register to be on a specific doctor's list and this was the doctor they saw if they were unwell. Group practices and health centres began to develop after the introduction of a new contract in 1966, but even then the patient still had to register with a particular doctor.[3] This was referred to as a 'personal list'. In more recent years this idea of a personal list has disappeared. Most GPs work in group practices or health centres, the patient registers with a particular surgery and they can see any doctor they choose. This allows both patients and doctors to benefit from the different skills that individual primary care physicians may have. Many doctors now develop a special interest in a particular area and so there can be internal referring of patients between them, e.g. for contraceptive advice, joint injections, or minor surgery.

Consultation patterns have also changed over recent years. The length of a general practice consultation has increased to around 10 minutes per patient.[4] The number of telephone consultations has increased, and nurses have a more involved role in patient care. Specially trained practice nurses now coordinate care and perform disease monitoring for chronic illnesses, particularly those specified in the Department of Health's Quality and Outcomes Framework. There are also more salaried doctors, who often work part time, which can have implications on continuity of care.

Patients still appreciate the role of the primary care physician as being 'their doctor' who has looked after them and also members of their family for a number of years. The idea of a GP looking after a patient from 'cradle to grave' remains, and is a cherished part of their identity.

Prevalence of musculoskeletal conditions

Musculoskeletal conditions are common in primary care in the United Kingdom. There are varying estimates suggesting that they form 15–30% of a GP's workload, i.e. in their average surgery most GPs will see one or two patients presenting with a musculoskeletal condition.[5,6] Their musculoskeletal complaint may often be an aside—'while I'm here, doctor' or may be the main reason for their presentation. Primary care physicians may also find themselves having to deal with other associated problems in addition to the musculoskeletal complaint, e.g. the effect on the patient's working life, their mental health, and their family. The focus of the consultation may therefore be on other things rather than the complaint itself, which can become secondary. The prevalence of musculoskeletal conditions is expected to rise as the proportion of elderly people in the population rises, as do other causative factors such as obesity.[7]

The prevalence data for musculoskeletal conditions in the United Kingdom is variable in quality. Different sources have to be used with some being more up to date than others.[8] Table 15.1 shows the prevalence of different musculoskeletal conditions in the United Kingdom. The third column uses the prevalence data to show, as an estimate, how many patients a GP may expect to have on their list with the conditions mentioned, using a suggested list size of 1800 patients per GP. This table highlights how few patients a GP may see with conditions that are considered to be reasonably common in secondary care, and who may form the majority of some specialist's workload.

Accurate data for the prevalence of conditions in primary care is not available, partly for reasons already documented. GPs are encouraged to give a problem code to every consultation they have, but doctors often work with symptoms and do not make a formal diagnosis when dealing with a patient. For example, primary care doctors may treat a patient as having 'knee pain' rather than osteoarthritis of the knee. This is evidenced in studies that have looked at the different general practice databases available.[10,11] There are a number of putative reasons as to why this may occur, including not making a definitive diagnosis until investigations/secondary care

Table 15.1 Prevalence of different musculoskeletal conditions in the United Kingdom

Condition	Prevalence	Estimated no of patients per GP
Rheumatoid arthritis (England)[a]	0.8%	14
JIA (UK)[a]	0.07%	1
Ankylosing spondylitis[a] (consulting annual period prevalence in the UK)	0.04%	0.7
Gout[b]	1.4%	25
SLE	0.03%	0.5
Scleroderma	0.003%	0.05
Back pain	?5%	90

JIA, juvenile idiopathic arthritis; SLE, systemic lupus erythematosus.
[a] Data from Parsons et al.[8]
[b] Data from Annemans et al.[9]

opinion is available, or that the doctor is not confident in making a definitive diagnosis. In many cases it may be difficult to make a definitive diagnosis early in the course of the condition, as symptoms may be vague and not fit a recognized pattern. In these cases primary care doctors may use time as part of their treatment to see how the condition develops.

Patient presentation

As already discussed, many of the musculoskeletal conditions that form the focus of textbooks and teaching are not commonly seen in primary care. Back pain is the most frequent presenting complaint and can account for about 20% of all musculoskeletal consultations, although very little time is focused on it during medical school training.[11]

A consultation in primary care is generally around 10 minutes in length. During this time the doctor must take a history, examine their patient, formulate a diagnosis, create a management plan, and then act on this plan. GPs are encouraged to allow patients to say their piece. It has been shown that if patients are left to talk, their initial opening statement lasts, on average, 92 seconds, and 78% of people will finish their initial statement in 2 minutes.[12] This limits the amount of time the doctor has to complete the rest of the consultation. Patients often save up their problems before coming to see a doctor, and can cite struggling to get an appointment as a reason for this. Their musculoskeletal problem may be the last one on their list and may be mentioned just before they leave, as their 10 minutes is drawing to a close. This can mean that little time is spent discussing it, or the patient may be asked to come back at a later date—which they may fail to do.

Patients present to doctors with symptoms such as back pain or knee pain, whereas textbooks are generally ordered/categorized by diagnoses. Many primary care doctors have limited experience at managing musculoskeletal conditions before starting in primary care, and may struggle to find a suitable diagnosis that fits with the constellation of symptoms and signs that their patient has.[13] This could be a reason why GPs work with vague diagnoses such as shoulder pain or hip pain. Another reason could be that the early signs of a condition can be non-specific. One area where this may

be detrimental to the patient's health is when diagnosing inflammatory arthritis. It is recognized that the early signs of inflammatory arthritis can be non-specific and that it can take time for the characteristic symptoms and signs described in textbooks to develop. This, coupled with the fact that primary care doctors have very little musculoskeletal experience and may only see a new case of rheumatoid arthritis (the second most common inflammatory arthritis after gout) every other year, means that patients can often be referred later than desired.[8,14,15]

One way to try to improve the management of conditions in primary care is to create guidelines. Many interested parties develop guidelines, with primary care as one of their target audiences, but they may not disseminate them appropriately and so they are not even read, let alone followed. Primary care doctors receive a large number of guidelines each year and can receive different recommendations from different sources for the same condition,[16,17] causing some confusion as to which is best to follow. Other areas exist where the flow of information from secondary to primary care is not ideal. Examples of these which are highlighted in the literature include educating primary care doctors about new medications and their side effects (e.g. anti-tumour necrosis factor medication) and the requirement for annual influenza vaccination in patients with inflammatory joint diseases.[18,19]

Primary care doctors play a pivotal role in the management of musculoskeletal diseases, as they are the first point of call for patients in many healthcare systems. The majority of patients in these systems are looked after in primary care and it is only the tip of the iceberg that is seen by specialists. Education of primary care physicians is essential, improving both patient management and their confidence.

CHAPTER 16

Obstetrics and pregnancy

Monika Østensen, Radboud Dolhain, and Guillermo Ruiz-Irastorza

Fertility

Rheumatic diseases can impair fertility and fecundity (time to achieving pregnancy) in several ways. Factors involved are active disease, fetotoxic therapy, autoimmunity, hormonal imbalance, and periods with impaired sexual functioning.[1] The influence of biological factors is often impossible to separate from other reasons such as a decrease in the frequency of intercourse relating to pain and functional disability from arthritis. Several studies have shown reduced fertility in patients with rheumatoid arthritis (RA), other inflammatory chronic arthritis, and juvenile idiopathic arthritis (JIA).[2] Compared to healthy women, patients have fewer children, need a longer time to conceive, and have prolonged interpregnancy intervals.[3] Reduced family size in spite of normal fertility and fecundity can be a result of pregnancy loss either as miscarriage or stillbirth, or can be due to perinatal deaths as in connective tissue diseases (CTD) and vasculitis. Smaller family size need not necessarily be attributed to lower fertility; it may also reflect the choice of rheumatic patients to limit their family size.[4]

Pregnancy and rheumatic disease

Rheumatoid arthritis

RA remits during pregnancy and flares after delivery. Since the first description of this phenomenon by Hench in 1938, this finding has been reconfirmed in several studies.[5] In the earlier studies, predominantly of retrospective study design and relying upon patient's self-report, remission rates of up to 90% were demonstrated.[5]

More recently, two large prospective studies have been published.[6,7] In the first study, from late pregnancy until 6 months after delivery, 63% of women retrospectively reported improvement of disease activity during pregnancy, whereas 16% of women were in total remission during the third trimester, which was defined as having no swollen joints and receiving no antirheumatic therapy. In this study 66% of women experienced a flare after delivery.[5]

In the second study, disease activity was prospectively assessed from pre-pregnancy until 6 months after delivery, using the disease activity score for 28 joints (DAS28). In this study it was shown that remission (as defined by DAS28 <2.6) increased from 17% during the first trimester to 27% during the third trimester. According to the DAS28-based EULAR response criteria, 48% of patients had at least a moderate response during pregnancy.[7] Despite the improvement of disease activity during pregnancy, functionality as determined by the health assessment questionnaire (HAQ) worsened.[8] This phenomenon is not specific for RA, however, but can also be observed in healthy pregnant women due to pregnancy itself. After pregnancy almost 40% of patients experienced a flare, despite restarting medication.[7] A prospective study with a 12 year follow up found no significant influence of pregnancy on long-term RA outcome, but found a trend for patients with multiple pregnancies to have less radiographic joint damage and a better functional level.[9]

The disease response during previous pregnancies seems predictive for the disease response in subsequent pregnancies.[5] Furthermore, RA patients who are negative for rheumatoid factor (RF) and anti-citrullinated protein antibodies (ACPA) are more likely to improve during pregnancy.[10] In the Dutch prospective study of 118 patients, 75% of patients negative for RF and cyclic citrullinated peptide (CCP) antibodies improved compared to only 39% of those positive for RF and CCP antibodies. Breastfeeding has been associated with the occurrence of the postpartum flare in RA patients.[5] The interpretation of this association is difficult, however, since women who breastfeed are in general not receiving medication and hence are more likely to flare.

Several theories have been put forward to explain the improvement of RA during pregnancy. The basis of all these theories is that profound changes of the maternal immune system take place during pregnancy, in order to accommodate the fetal allograft.[11] Because of the small sample size of most studies, it often cannot be concluded whether the observed changes only represent a general adaptation of the immune system during pregnancy or whether these changes are also responsible for the ameliorating effect of pregnancy on RA.

New studies have shown that pregnancy outcome is less favourable in RA than previously thought.[12,13] Several studies report a small but increased risk for small for gestational age infants, intrauterine growth restriction, hypertensive disorders, preterm delivery, and caesarean sections.[12,13] Adverse pregnancy outcomes, particularly lower birthweight, seem to be associated with disease activity in RA.[12] Lower birth weight, even within the normal range, has been associated with increased risk of future developmental delay, metabolic syndrome, and cardiovascular disease. Whether the same holds true for the lower birth weight of children born to women with active RA is not known.

New data have questioned the general medical opinion about a prevailing beneficial effect of pregnancy on RA. Although RA improves during pregnancy, the effect is less impressive than previously thought and a high percentage of women still have considerable disease activity.[6,7] Furthermore, despite improvement of disease activity, functionality worsens. Tight disease control, if necessary with sulfasalazine, hydroxychloroquine, and low-dose prednisone during pregnancy, is essential to secure good maternal and fetal outcomes.

Other chronic inflammatory arthritides: ankylosing spondylitis, psoriatic arthritis, and juvenile idiopathic arthritis

Inflammatory arthritis in peripheral joints and/or the spine characterizes ankylosing spondylitis (AS), psoriatic arthritis (PsA), and JIA. Increased B cell activity with autoantibody production or extensive organ involvement is, with the exception of some subtypes of JIA, not a feature of these diseases. Interactions between pregnancy and AS, JIA, and PsA have been much less investigated than in RA. AS and JIA share an aggravation of disease within the first 6 months after delivery, occurring in 52–90% of cases, particularly in patients with active disease at conception.[14,17–18]

The few reports on PsA and pregnancy do not allow any definite statement,[15] but in the absence of reports to the contrary, no major influence of pregnancy on PsA may be anticipated.

Ankylosing spondylitis

Both retrospective and prospective studies of AS have shown that disease activity is not substantially altered during pregnancy.[14,16] The typical pattern is active disease during the first and early second trimester, sometimes accompanied by a flare around week 20, and some mitigation of symptoms in the third trimester. Though some AS patients experience improvement of peripheral joint disease during pregnancy, complete subsidence of spinal symptoms has not been observed. The frequency of acute peripheral arthritis or anterior uveitis is reduced 1.5–3 times during pregnancy compared to postpartum.[14]

Juvenile idiopathic arthritis

For 40–50% of JIA patients the disease persists into adulthood with ongoing disease activity and need for therapy. Patients with onset of JIA in early childhood and severe involvement may suffer as adults from sequelae such as growth retardation, osteoporosis, hip joint replacement, and functional disability interfering with reproductive performance.

Retrospective studies have shown that subsets of JIA differ in their response to pregnancy. Improvement occurs in about two-thirds of patients with polyarticular and oligoarticular JIA, whereas only 29% with systemic disease improve during pregnancy.[17] Patients in complete remission at the start of pregnancy seldom suffer a relapse of arthritis during pregnancy. Chronic uveitis remains unchanged during pregnancy.[18] Most patients with inactive JIA in adulthood, and those with monoarticular JIA, will have uneventful pregnancies and deliver healthy children of normal birth weight.[17,18]

Outcome of pregnancy

An increase in miscarriage or pre-eclampsia has not been documented for AS, PsA, or JIA. A large population-based case-control study of women with chronic inflammatory arthritides including RA, AS, PsA, and JIA found an increase in the rate of caesarean section, and premature and small for gestational age infants.[13] The children had also lower mean birth weight (P = 0.01) and higher perinatal mortality (OR 3.26 [95% CI 1.04–10.24]).

Connective tissue diseases

Systemic lupus erythematosus and antiphospholipid syndrome

No systemic autoimmune diseases are so closely related with pregnancy complications as systemic lupus erythematosus (SLE) and anti-phospholipid syndrome (APS).

Maternal complications

SLE activity can increase during pregnancy and the puerperium in more than 50% of patients.[19] Women with current or recent activity at the time of conception and those who withdraw hydroxychloroquine are more likely to suffer a disease flare.[20,21] Although most flares are mild, severe renal involvement has been reported in some series.[22] Pregnancy can be especially harmful for women with a high degree of irreversible organ damage. The progressive increase of plasma volume during pregnancy demands adaption to higher load from the kidneys, heart, and lungs. Women with severe renal failure, cardiac insufficiency, pulmonary hypertension, or severe restrictive pulmonary disease are at a high risk for deteriorating organ dysfunction and even for maternal death. Women with baseline serum creatinine levels higher than 2.5–2.8 mg mg/dL (220–250 μmol/L) are most likely to suffer postpartum renal function decline.[23] A modest increase in global irreversible damage postpartum, determined by disease activity and the presence of damage before conception, has been found in women with SLE.[24]

APS is a well-known cause of arterial and venous thrombosis. Women with previous thrombotic events, especially those with stroke, can suffer recurrent thrombosis during pregnancy.[25] This risk seems to be lower for women with only obstetric manifestations of APS and for asymptomatic carriers of antiphospholipid antibodies (aPL).[26]

Obstetric complications

Women with high lupus activity during pregnancy have a two- to fourfold higher chance of suffering prematurity and perinatal death and have a lower frequency of live births.[20] Increasing doses of prednisone used to treat flares may contribute, at least in part, to such complications.

A recently published systematic review and meta-analysis has found a higher likelihood of suffering hypertension and prematurity in lupus women with active nephritis, whilst those with past lupus nephritis had a higher risk for hypertension and pre-eclampsia.[27]

The presence of aPL is one of the most important predictors of adverse pregnancy outcomes, in women with and without SLE. Women with aPL are at a higher risk for hypertension, pre-eclampsia, fetal death, placental insufficiency with growth restriction, and prematurity.[28,29] Combined positivity for lupus anticoagulant (LA), anticardiolipin antibodies (aCL), and anti-β_2-glycoprotein I, as well as a history of maternal thrombosis, multiplies the risk for obstetric complications.[30,31] Treatment of obstetric APS is still subject to debate. Aspirin and heparin are the drugs of choice, but there is still controversy regarding the specific role of each of these, alone or in combination, especially in women with recurrent early miscarriages.[26]

Primary Sjögren's syndrome

Most patients with primary Sjögren's syndrome (pSS) have completed their families before disease onset. The few studies that have investigated pregnancy outcome in pSS found no major changes of sicca symptoms during pregnancy.[32,33]

Recent studies have not shown an increase in adverse outcomes and concluded that neither pSS itself nor the presence of anti-SSA and anti-SSB antibodies influenced the outcome of pregnancy.[32] However, transmission of maternal anti-Ro/SSA or anti-La/SSB antibodies during pregnancy can cause neonatal lupus syndromes in neonates.

Neonatal lupus and congenital heart block

Neonatal lupus syndrome (NNLS) is a rare complication closely related to the presence of maternal anti-Ro/SSA and anti-La/SSB antibodies, affecting children born to mothers with lupus, Sjögren's syndrome, other autoimmune diseases or asymptomatic carriers of those antibodies.[34] Anti-Ro/SSA and anti-La/SSB gain access to the fetal circulation during the physiological active transport of IgG across the placenta, starting from early second trimester and increasing throughout gestation. The most serious form of presentation is congenital heart block (CHB), but skin rashes, thrombocytopenia, and elevated liver enzymes may also occur. The risk of CHB among newborns of anti-Ro/SSA-positive women is around 2%,[35] but this risk increases to around 20% in younger siblings of an infant with CHB or other forms of NNLS.[34,36] Most children affected with CHB will need a permanent pacemaker and around 20% may die in the perinatal period.[34]

In case of incomplete heart block, myocarditis, ascites, or hydrops therapy with fluorinated steroids—dexamethasone or betamethasone, which cross the placenta—is recommended since there is a chance for reversibility (total or partial).[37] Recently, two clinical trials have failed to reduce the expected rate of recurrent CHB (20%) in women treated with intravenous immunoglobulin (IVIG) during pregnancy.[38,39] On the other hand, a recent case-control study has suggested a protective effect of hydroxychloroquine on the development of cardiac manifestations in children with NNLS born to mothers with lupus and anti-Ro/anti-La antibodies.[40] Noncardiac postnatal manifestations of NNLS subside spontaneously as maternal antibodies are cleared from the baby's circulation.

Systemic sclerosis

Early case reports and small series described adverse, sometimes fatal maternal outcomes in pregnant patients with systemic sclerosis (SSc). Large retrospective case-control studies and one prospective study showed that pregnancy does not profoundly alter the disease.[41] In a study of 133 pregnancies in 69 patients no change in disease-related symptoms was found in 88%, improvement in 5%, and aggravation in 7% of pregnancies.[42] Cutaneous disease did not change much and progression of skin disease was uncommon during pregnancy or postpartum in any of the studies. Usually, Raynaud's phenomenon improved and arthralgias and reflux worsened during pregnancy, whereas cardiopulmonary problems essentially remained unchanged in women with SSc.[41,42]

Serious organ manifestations of SSc such as renal disease or pulmonary hypertension (PHT) can threaten the outcome of pregnancy. A fourfold increase in hypertensive disorders, including pre-eclampsia, was found in a retrospective study of 504 pregnancies in women with SSc.[43] Risk factors for renal crisis are early

diffuse systemic sclerosis and rapidly progressing skin disease. Treatment with high dose prednisolone may be an additional risk factor. Case-control studies have shown that renal crisis does not occur more frequently in pregnant compared to non-pregnant SSc patients. Pulmonary hypertension has still a poor survival rate of about 2.8 years, with a 25–50% risk of maternal mortality in case of pregnancy. Fortunately, a multidisciplinary team approach has now improved pregnancy outcome even in these high-risk pregnancies.[43]

The rate of miscarriage is not increased in patients with SSc, except for women with long-standing diffuse scleroderma.[41] The most prominent adverse outcome in SSc is prematurity and an increased rate of full-term small infants.[41–43] The risk of adverse pregnancy outcome is greater in patients with the diffuse form than with the limited form of SSc. Women with early diffuse and rapidly progressing disease should postpone conception until SSc is less active. Patients with severe organ involvement such as cardiomyopathy, severe restrictive lung disease, pulmonary hypertension, malabsorption, or severe renal insufficiency should probably be discouraged from becoming pregnant.

Polymyositis and dermatomyositis

The few data from case reports and small series indicate that most women with polymyositis (PM) or dermatomyositis (DM) with inactive disease at conception have normal pregnancies with a good outcome.[44–46] Relapses at a quiescent stage of PM/DM seem rather infrequent during pregnancy. In contrast, women with active disease at conception or disease onset during pregnancy are at high risk of pregnancy loss, intrauterine growth restriction, preterm delivery, and neonatal death. It is important to control the disease before pregnancy and promptly treat a disease flare if it occurs during pregnancy.[46]

Vasculitis and pregnancy

With the exception of Takayasu's arteritis (TAK), which preferentially affects young women of childbearing age, systemic vasculitides (SV) are rare diseases in women in general and particularly those under the age of 40 years. As a consequence, pregnancy experience in polyarteritis nodosa (PAN), granulomatosis with polyangiitis (Wegener's) (GPA), eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome, EGPA), and microscopic polyangiitis (MPA) consists altogether of less than 100 pregnancies described in case reports and small series collected over several decades with variance in patient characteristics and management.[46,47]

Takayasu's arteritis during pregnancy

Reports of more than 150 pregnancies in women with TAK show that disease activity is not influenced by pregnancy.[46,48] Complications during pregnancy and the outcome are related to whether the extent of arteritis is confined to the aortic arch or extends to the descending and abdominal aorta and its branches. The risk of TAK associated with pregnancy is mainly due to arterial hypertension and/or pre-eclampsia, with a greater risk in more severe and extensive cases of large-vessel arteritis.[48] Complications occurred preferentially in the third trimester, during delivery, or in the immediate postpartum period. No case of maternal death has been reported. Patients with complications such as hypertension, retinopathy, aortic incompetence, or aneurysm must be regarded as high risk, with need for close monitoring and therapy during

pregnancy and delivery. Patients with severe aortic valvular disease or aortic aneurysm should be discouraged from pregnancy because of the risk of maternal morbidity and mortality.

In spite of a moderate increase in miscarriage and prematurity, the outcome of pregnancy was favourable in 70–85% of cases. Neonatal outcome has been good in most studies, but in mothers with one severe or several complications of TAK the birthweight of neonates was slightly reduced.[48]

Vasculitis of medium and small vessels

The most common manifestations of necrotizing vasculitides (PAN, GPA, EGPA, and MPA) are in the respiratory tract and the kidneys. Old case reports tend to describe more adverse pregnancy outcomes than recent ones, due to less developed obstetric medicine and fewer available treatment modalities. The extent of vasculitis, type of organs involved and resulting organ damage as well as disease activity at conception influence maternal and fetal outcome. However, a state of remission before conception does not guarantee the absence of a relapse, which occurs in 20–25% of pregnancies. In recent publications, reported global pregnancy outcomes were good; there were no maternal deaths and all live-born infants were healthy.[46,49,50] In most cases SV required only minor adjustments of immunosuppressive therapy during pregnancy. However, the rate of miscarriage and of prematurity is increased, and life-threatening complications can occur in the mother.[46] Whether pregnancy increases or decreases the activity or the relapse rate of necrotizing vasculitis compared to the non-pregnant state has not been investigated. Disease onset of PAN, EGPA, CSS, and MPA during pregnancy or active disease during pregnancy limit the option for effective therapy, particularly with cyclophosphamide. New onset or aggravation of renal disease during the second and third trimesters of pregnancy render diagnosis of pre-eclampsia difficult. Prematurity and pre-eclampsia are the most common complications in pregnancies with renal involvement.

Behçet's disease

Available data suggest that pregnancy does not aggravate maternal disease, though a relapse may occur in about 20% of Behçet's disease (BD) pregnancies. Three retrospective series reporting on 25, 44, and 77 pregnancies of women with BD respectively showed improvement or even remission in 53–80%.[46] Flares consisted of oral or genital ulcers, arthritis, and eye inflammation. Serious maternal complications were rare.

A case-control study comparing 77 pregnancies in BD patients and 288 pregnancies in healthy controls showed a significantly higher rate of adverse outcome in BD patients than in the control group (26% vs 2%). Miscarriage occurred in 21% of BD patients compared to 5.2% in healthy women.[51] Surgical delivery was more frequent in women with BD (15% vs 5%). Hypertension and gestational diabetes mellitus occurred more often in pregnant BD patients. No difference was found in regard to neonatal health or birthweight.

Preconception counselling and monitoring during pregnancy

Pregnancy in patients with CTD requires preconception counselling. The task of the physician is to discuss disease-related problems, identify maternal and fetal risks, and organize the adequate monitoring during pregnancy and postpartum. In general, a higher

risk for the mother and the fetus is marked by an early stage of disease, an active disease at conception, the presence of aPL or anti-Ro/SS-A and/or anti-La/SS-B, and some types of drugs before or at certain stages of pregnancy (Box 16.1). An early stage of disease implies that the pattern of disease severity is not yet apparent and complications could still develop in the near future. A patient with active rheumatic disease should postpone pregnancy until remission or stable disease is achieved and has persisted for at least 6 months. A review of the previous obstetric history of the patient reveals past adverse events during pregnancy which are highly predictive of complications during subsequent pregnancies. Also, a high degree of damage in vital organs, such as the heart, lung, or kidneys, markedly increases the probability of further maternal deterioration and decreases the likelihood of a term live birth. A suggested list of items to be checked in the preconception visit is given in Box 16.1.

Before pregnancy, access to familial and social support should be evaluated, so it is advantageous to include the patient's partner or a family member in the preconception counselling. In order for the patient with impaired function to prepare for the task of childcare after delivery, consulting an occupational therapist is advisable. All patients should be informed about the influence of lifestyle factors, and be advised to stop smoking and to take supplementary folic acid before conception.

At the start of pregnancy a complete clinical and laboratory assessment is necessary in order to monitor disease activity. High-risk pregnancies are best monitored by an interdisciplinary specialist team including the obstetrician and the rheumatologist/internist, and, occasionally, the paediatrician. The frequency of visits depends on disease severity, type of therapy, and stage of pregnancy. Regular assessment of fetal growth can predict whether the fetus is at risk. Doppler flow techniques allow evaluation of the uteroplacental and umbilical circulation, and help predict complications such as pre-eclampsia and intrauterine growth restriction. The negative predictive value of Doppler studies is very high, so a normal examination is reassuring. Women with a previous history

Table 16.1 Drug therapy of complications of rheumatic diseases during pregnancy

Disease	Complication	Drugs compatible in case of pregnancy complication	Time of treatment during pregnancy	Drugs to be discontinued before pregnancy
Rheumatoid arthritis, ankylosing spondylitis, JIA, psoriatic arthritis	Active arthritis during pregnancy	NSAIDs	1st + 2nd trimester, discontinue at week 32	Rituximab, abatacept, tocilizumab, anakinra methotrexate, leflunomide, misoprostol
		Paracetamol	Throughout pregnancy	
		Antimalarials, salazopyrine	Throughout pregnancy	
		Prednisone	Throughout pregnancy	
		Intra-articular corticosteroids	Throughout pregnancy	
		TNF inhibitors	1st trimester	
Systemic lupus erythematosus	Active disease during pregnancy	Antimalarials, prednisone	Throughout pregnancy	MMF, cyclophosphamide, rituximab, belimumab
		Azathioprine	Throughout pregnancy	
	Lupus nephritis	Ciclosporin, tacrolimus	Throughout pregnancy	
		IVIG	Throughout pregnancy	
Antiphospholipid syndrome	Prevention of fetal loss	Low dose aspirin alone or plus LMWH*	Throughout pregnancy at prophylactic dose LMWH	
	Prevention of thrombosis	Low dose aspirin + LMWH	Throughout pregnancy at therapeutic dose LMWH	Coumarin derivatives
Systemic sclerosis	Renal crisis	Antihypertensives, e.g. methyldopa, nifedipine, atenolol	Throughout pregnancy	ACE inhibitors, endothelin receptor antagonists, coumarin derivatives
	Pulmonary hypertension Restrictive lung disease	Prostaglandin analogues, sildenafil, LMWH	Throughout pregnancy	
Polymyositis/dermatomyositis	Active disease during pregnancy	Prednisone, azathioprine, IVIG	Throughout pregnancy	Methotrexate, cyclophosphamide, MMF
Systemic vasculitis	Active vasculitis	Prednisone, azathioprine, IVIG	Throughout pregnancy	Cyclophosphamide, rituximab
Neonatal lupus syndromes	1st or 2nd degree AV block Myocarditis, ascites, hydrops fetalis	Preferentially betamethasone, dexamethasone (more side effects on child)	2nd and 3rd trimester	

AV, atrioventricular; IVIG, intravenous immunoglobulin; LMWH, low molecular weight heparin; MMF, mycophenolate mofetil; NSAIDs, non-steroidal anti-inflammatory drugs.

of pre-eclampsia, placental insufficiency, hypertension, renal disease (even if in remission and with normal renal function), and aPL, as well as those with multiple pregnancies, are candidates for Doppler studies starting at week 20. Serial fetal echocardiography between weeks 18 and 28 is important for detecting early incomplete heart block and myocarditis in a fetus with anti-Ro/SS-A and/or anti-La/SS-B-positive mother, since both conditions have the potential for improvement after treatment.

Specific therapy of the different rheumatic diseases during pregnancy should be guided by disease severity and fetal safety (Table 16.1). Prophylactic withdrawal of safe drugs must be avoided, since the risk of a disease flare, with harmful consequences for both the mother and the fetus, is high.

CHAPTER 17

Skin

Christopher Griffiths and Amy Foulkes

How to approach the patient with a rash

Background

Structure and function of skin

A basic overview of the structure and function of skin allows a greater understanding of the morphology of skin disease. Skin is composed of three layers: epidermis, dermis, and subcutis (Figure 17.1). Epidermis, the outermost avascular layer, is composed primarily of keratinocytes. Pathology affecting the epidermis leads to a change in the texture of the skin, such as scaling or erosion. Other important epidermal cells are melanin-synthesizing melanocytes and antigen-presenting Langerhans cells.

The dermis is vascular and less cellular than the epidermis. Fibroblasts predominate; the main extracellular matrix constituents are collagen and elastin. Pathology affecting the dermis may alter skin morphology, e.g. swelling/lump with a normal skin surface. Below the dermis is the subcutaneous layer, the subcutis. This layer is composed primarily of adipose tissue, blood vessels, nerves, and the base of hair follicles and sweat glands.

The primary functions of the skin are its barrier function, immune surveillance, prevention of desiccation, temperature control, and sensory function.
Fig. 17.1 Structure of skin.

History taking

Taking a history from a dermatology patient requires asking specific questions in order to elucidate the relevant details. Questions are divided into consideration of site/distribution, and morphology of the rash.

Site

◆ Where is the rash at present?
◆ Where did the rash start?
◆ How has the rash changed since it started?
◆ Did each lesion progress or were they stationary?
◆ Was the rash transient (e.g. urticarial wheals lasting less than 24 hours)?

Distribution

Many diseases have a characteristic pattern, e.g. psoriasis vulgaris over extensor surfaces, chronic cutaneous lupus erythematosus at photoexposed sites (scalp, face, anterior chest, dorsa of hands).

◆ Did the rash cover all areas of the body equally or are there areas of sparing?
◆ Did the rash migrate?
◆ Does the rash vary with season and/or exposure to sunlight?

Morphology

◆ What is the appearance of each area of affected skin?
◆ Is the rash painful?
◆ Does it itch?
◆ Did the rash ever bleed/weep/crust over?

Other questions

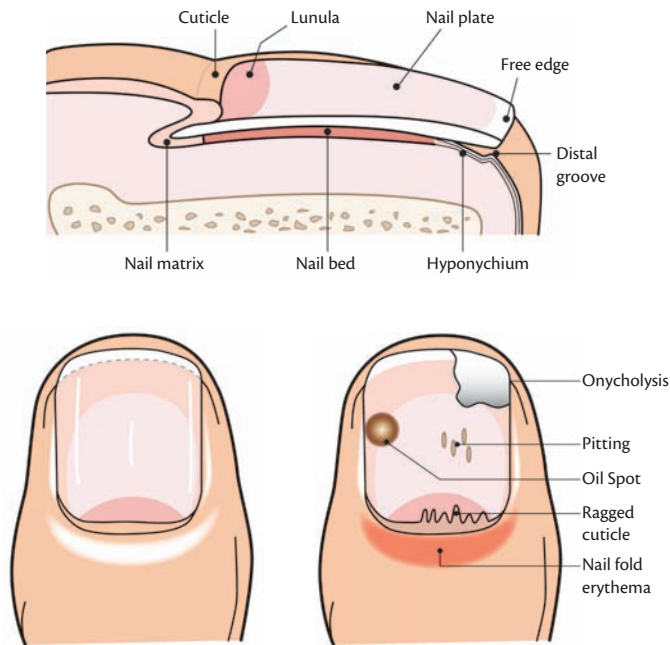
◆ Is there anything that provokes the rash or helps it resolve such as antihistamines?
◆ Drug history: For dermatology this should include use of topical agents, treatment with phototherapy, and systemic agents as well as the use of over-the-counter preparations
◆ Family history of skin disease.


Fig. 17.2 Normal nail anatomy and pathology.

How to examine the skin

Before examining the skin, the set-up of a room and the positioning of the patient are important.

Site and distribution

The examination room should be well lit (ideally with natural light) with a couch that can accommodate the patient lying down and be raised in order to view lesions on the back or feet. The patient must be adequately undressed to view the rash.

Specific areas are frequently missed, for example scalp, nails, and mucous membranes. Nail structure and nail pathology seen in rheumatological disease are illustrated in Figure 17.2.

Patients frequently photograph their rashes and these may provide valuable clinical clues. The distribution of a rash can only be evaluated if the whole of the skin is examined.

Morphology

Description of a rash

An accurate description of the rash may allow diagnosis or gain a swift referral diagnosis perhaps by telephone. For example a papular, pruritic erythematous eruption affecting the trunk and limbs sparing the face, palms, and soles would be a typical description of a classic drug eruption. Similarly, accurate detailed description may aid diagnosis, e.g. the distribution of dermatomyositis over the extensor surfaces of the fingers. Dermatological descriptors are listed in Figure 17.3.The colour of a rash is important. Pigmentation is variable and not merely brown or black. 'Erythematous' means redness, but rashes may also appear purple or violaceous, e.g. lichen planus (rashes that have similar histology and phenotypically appear purple are termed 'lichenoid', e.g. dermatomyositis).

Skin lesions may have a characteristic or diagnostic appearance, e.g. targetoid with erythema multiforme (Figure 17.4).

Investigations

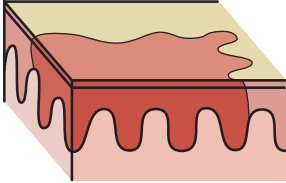
Where clinical morphology is insufficient for a firm diagnosis, investigative techniques may be employed. In dermatology these include:

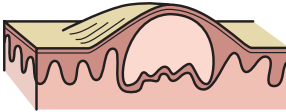
- Blood tests
  - Autoantibodies
  - Indirect immunofluorescence
- Histology
  - Haematoxylin and eosin (H&E)
  - Direct immunofluorescence
- Other
  - Nailfold capillary microscopy/videocapillaroscopy

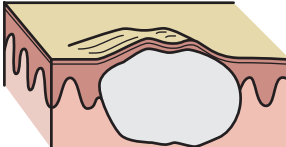
Although a skin biopsy is a commonly performed minor procedure, we recommend that all diagnostic biopsies be taken by a dermatologist, or a by healthcare professional adequately trained in the technique with expert dermatopathology support available.

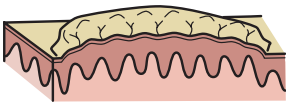
Clinico-pathological correlation is required, with dermato-histopathology support in order to facilitate accurate diagnosis. Where possible, a link provided to a clinical photograph or a sketch of the initial distribution or eruption may be of assistance to the pathologist.

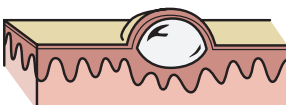
Histology may not always yield a diagnosis. Immunohistological techniques allow for the detection of antigens, antibodies and other tissue components to aid a specific diagnosis.[1] Immunofluorescence (IMF) utilizes an antibody to bind to a required antigen and a fluorochrome dye to detect the position of the antibody. Direct IMF is used on skin biopsy samples and indirect IMF may be used on blood samples. The primary application in dermatology is the recognition of autoimmune bullous disorders, where autoantibodies are directed against adhesive proteins such as desmogleins in the epidermis and basement membrane. Another example is the detection of IgA in dermal vessels in Henoch–Schonlein purpura.

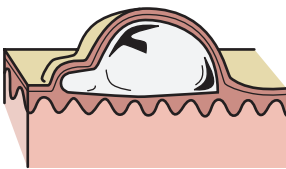
In connective tissue disease, distortion in capillary architecture may be viewed at the nailfold by the use of capillary microscopy. This area is easily accessible for examination and the arrangement of the capillaries in the nailfold allows visualization of the complete capillary loop. In addition, vascular abnormalities appear earlier in the course of the disease than at other sites of the skin of the finger. Reduced density but increased luminal diameter of dermal capillaries in patients with idiopathic inflammatory myopathies may be quantified using nailfold capillaroscopy, and abnormalities monitored over time.[2] Nailfold videocapillaroscopy, an extension of the original technique, may be employed as a safe, non-invasive, and inexpensive technique in the evaluation of early and advanced microangiopathy in systemic sclerosis (SSc).[3] The European League against Rheumatism (EULAR) Scleroderma Trial and Research Group have proposed criteria for the very early diagnosis of SSc, one major criterion being abnormal nailfold videocapillaroscopy.[4] Simple naked-eye assessment of the nailfold may be valuable where advanced techniques are not routinely available.


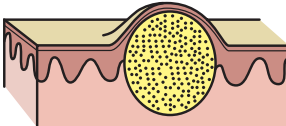


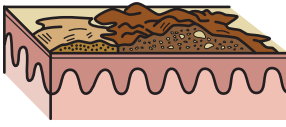


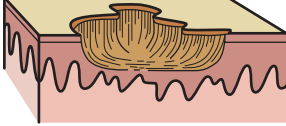


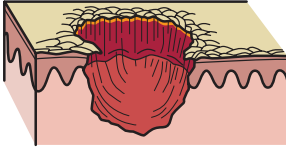


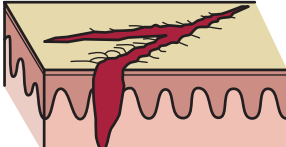




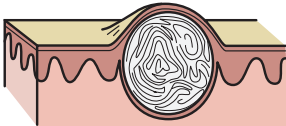


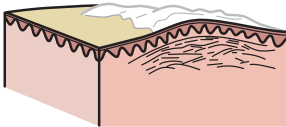


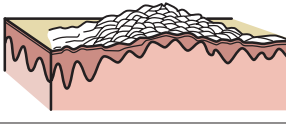


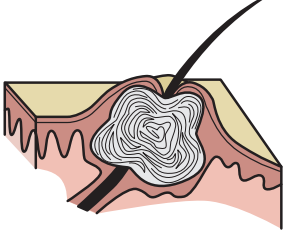


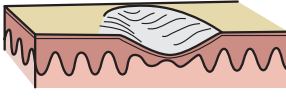
Lesion	Definition	Morphology	Examples
Primary skin lesions			
Macule	A flat impalpable area of altered skin pigmentation		Ephelides (freckle) Lentigo ('liver spot') Café au lait macule
Papule	A palpable (raised) area under 0.5cm in diameter		Acrochordon (skin tag), viral wart, lesion of widespread eruption
Nodule	A large papule 0.5–1cm in diameter		Basal cell carcinoma
Plaque	Raised area of over 1cm diameter		Plaque of psoriasis
Vesicle	A small blister (fluid-filled lesion) >0.5cm in diameter		Herpes simplex
Bulla	A blister >0.5cm in diameter		Oedema blister, blister of bullous pemphigoid
Pustule	Pus filled papule		Acne, impetigo, folliculitis, pustular psoriasis
Secondary skin lesion			
Crust	Collection of cellular debris, dried serum and blood—a scab. Usually follows a vesicle, bulla or pustule		
Erosion	Partial focal loss of epidermis. May heal without scarring. A linear erosion produced by scratching is an excoriation.		
Ulcer	Loss of epidermis and dermis 'full-thickness' heals with scarring		Pyoderma gangrenosum
Fissure/crack	Vertical loss of epidermis +/− dermis with sharply defined walls		Complicates palmo-plantar pustulosis or hand and foot eczema

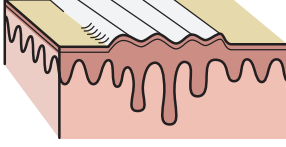
Fig. 17.3 Dermatological descriptors.












Cyst	Fluid filled nodule		Acne, epidermal cyst
Scar	A collection of new connective tissue; may be raised (hypertrophic) or indented (atrophic). Proceeded by epidermal/dermal damage.		
Scale	Thick stratum corneum that results from hyperproliferation or increased cohesion of keratinocytes		Psoriasis, chronic cutaneous lupus erythematosus
Comedo	Collection of sebum & keratin around a hair follicle. May be open 'blackhead' or closed 'whitehead'		Acne
Atrophy	Thinning of the epidermis, dermis or subcutis. Epidermal atrophy may lead to wrinkled appearance. Atrophy with telangiectasia is termed poikiloderma.		Steroid atrophy in patient with chronic cutaneous lupus erythematosus
Lichenification	Focal area of thickened skin produced by scratching/rubbing.		
Telangiectasia	Small dilated superficial blood vessels that disappear with pressure		Dermatomyositis

Fig. 17.3 (Continued)

Fig. 17.4 Erythema multiforme; characteristic 'target lesions' on palms.

Dermatological manifestations of rheumatological disease

Note on treatment modalities in dermatology

Dermatological therapies can be broadly divided into three groups: topical therapy, phototherapy, and systemic/biological therapy. Therapeutic agents from each group may be combined to form the optimum management for an individual patient. The British Association of Dermatologists has published a number of clinical guidelines in the *British Journal of Dermatology*.[5,6] Up-to-date versions are available via their website www.bad.org.uk/site/622/default.aspx.[7]

Rheumatoid arthritis

Rheumatoid arthritis (RA) is discussed in Chapters 109–112.

Patients with RA may have general or specific cutaneous extra-articular manifestations of their disease The possible cutaneous

manifestations of RA have been well reviewed,[8,9] and a comprehensive overview of individual manifestations may be found elsewhere.[10]

General cutaneous extra-articular manifestations of RA include palmar erythema (a general reddening of the palms) skin fragility with atrophy, easy bruising, and pseudo-sclerodermatous changes, particularly of the hands. Nail changes include longitudinal ridging (onychorrhexis) and clubbing.[9]

Specific cutaneous extra-articular manifestations are described in the following sections.

Rheumatoid vasculitis

Vasculitis refers to inflammation of blood vessels (arteries and/or veins). Rheumatologists may encounter vasculitis as a component of systemic disease including RA, systemic lupus erythematosus (SLE), Sjögren's syndrome, dermatomyositis, and mixed connective tissue disease, amongst others. Rheumatoid vasculitis refers to the spectrum of inflammation of blood vessels seen in RA. Vasculitis may be local or systemic, primary or secondary, and any size of vessel may be affected. Many vasculitides have a cutaneous component and classification is confusing. For a comprehensive review of cutaneous vasculitides, see Cox et al.[11]

The mounting evidence for vascular pathology in RA, with the occurrence of large-vessel atherosclerosis, is discussed in Chapter 109.

Demographics

Rheumatoid vasculitis occurs in less than 1% of patients with RA.[12] Livido reticularis, a condition where dilatation of capillaries leads to mottled reticular discolouration of the skin, may also occur, most frequently on the extremities (Figure 17.5).

Cutaneous small-vessel vasculitis (otherwise known as leucocytoclastic or hypersentivity vasculitis) is the most common cutaneous vasculitis, affecting both children and adults, more commonly in women.

Key clinical features

Palpable purpura of the distal extremities (Figure 17.6). Purpura may coalesce, leading to erosion or ulceration, and bullae may occur (Figure 17.7). Other cutaneous lesions may include digital infarcts. Associated features may include peripheral neuropathy.

Fig. 17.5 Livedo reticularis; right thigh of hospitalized patient.

Fig. 17.6 Cutaneous small-vessel vasculitis; symmetrically distributed across lower legs.

Fig. 17.7 Cutaneous small-vessel vasculitis; bullae forming across oedematous feet.

Rheumatoid vasculitis must be considered where leg ulcers develop in a patient with RA.

Investigations   The evaluation of a patient with suspected vasculitis should include clinical evaluation to examine the extent of disease with regard to skin and internal organ involvement, an attempt to discern the aetiology, and histopathological correlation of the clinical diagnosis. Although extensive investigations may fail to elucidate an underlying cause, blood pressure measurement and urinalysis are essential initial investigations.

Biopsy of an affected area may confirm the clinical diagnosis as vasculitis but provide few clues to the underlying cause, and should be carefully considered where the affected limb is swollen, as poor healing may occur. Classic histology of cutaneous small-vessel vasculitis would demonstrate endothelial swelling, fibrinoid necrosis of vessel walls, extravasation of erythrocytes, and an infiltrate of neutrophils with fragmentation of nuclei (leucocytoclasia).

Management   Overall, cutaneous small-vessel vasculitis has a benign course. Rest with elevation of the affected limbs is essential,

as is expert meticulous topical skin care of purpuric lesions/erosions or ulceration to prevent trauma and secondary infection.

Nailfold infarction has no specific treatment.

Rheumatoid nodule

This is discussed in Chapter 111.

Demographics

Classic rheumatoid nodules occur in approximately 25% of cases of RA and are the most common extra-articular manifestation.[9] Although most common on the ulnar border of the forearm, they may be found elsewhere, including dorsa of the hands, ears, and over the scapulae.[10] They may also appear in other organs, including the lungs. Classically firm in consistency, with a propensity to ulcerate with trauma, they may also demonstrate overlying skin changes such as violaceous discolouration. Rheumatoid nodules are more likely to be associated with severe disease, positive rheumatoid factor,[9] and anti-nuclear factor.[10] Histologically, rheumatoid nodules show palisading fibroblasts and histiocytes, with foci of fibrinoid necrosis.

Differential diagnoses

Rheumatic fever, Still's disease, erythema elevatum diutinum.

Investigations

Unlikely to require investigation, unless there is either superadded infection—staphylococcal secondary infection can lead to septic arthritis, or diagnostic uncertainty, where histopathology may distinguish from the aforementioned differential diagnoses.

Management

Patient advice and topical treatment of ulceration may be required.

Felty's syndrome

The triad of RA, leucopenia, and splenomegaly is discussed in Chapter 111.

Demographics

The incidence of Felty's disease in RA is approximately 1%.[13]

Key clinical features

Cutaneous manifestations include rheumatoid nodules, hyperpigmentation and leg ulcers.[14] Patients may also be at an increased risk of malignant melanoma.[15]

Differential diagnoses

Rheumatoid nodules, hyperpigmentation, and leg ulcers may also be seen in RA.

Management

Treatment of the RA.

Rheumatoid neutrophilic dermatosis

Demographics

Rheumatoid neutrophilic dermatosis is a rare condition, occurring in patients with severe, active RA.

Key clinical features

Typically asymptomatic, characterized by symmetrically distributed erythematous papules, plaques and/or vesicles over the extensor surfaces.

Differential diagnosis

Sweet's syndrome (another form of neutrophilic dermatosis, Figure 17.8), pyoderma gangrenosum associated with RA.

Fig. 17.8 Sweet's syndrome: plaques on forearm and dorsa of hand.

Investigations

Diagnostic skin biopsy will demonstrate dense dermal neutrophilic infiltration that may extend upwards into the epidermis and/or deeply into the subcutaneous fat.

Management

Immunosuppression of the active RA may lead to resolution of the associated condition. Topical corticosteroid, dapsone or hydroxychloroquine may be effective.[10]

Pyoderma gangrenosum

Pyoderma gangrenosum is an uncommon chronic ulcerative condition, part of the spectrum of neutrophilic dermatoses.

Demographics

Commonest in women over the age of 50 years.[16] More than 50% of patients have associated systemic disease, classically inflammatory bowel disease.

Key clinical features

Painful ulceration rapidly develops, with a characteristic overhanging purple/blue edge. Ulceration may commence at a site of recent trauma known as 'pathergy' (Figure 17.9).

Differential diagnoses

Can be difficult to distinguish clinically from infective causes of ulceration, malignancy, and venous ulceration.

Investigations

Diagnosis is made on clinical features and exclusion of other ulcerative conditions. Histology is variable and non-specific but should always be performed to exclude malignancy, specifically squamous cell carcinoma.

Management

Potent immunosuppression; if the ulcer is small this could be local high potency topical corticosteroid or systemic therapy with

Fig. 17.9 Pyoderma gangrenosum; ulceration developing at site of needle entry (pathergy response).

Fig. 17.10 Psoriasis vulgaris; characteristic scaly plaque.

prednisolone, ciclosporin, or a TNF-antagonist biologic such as infliximab.

Psoriasis

Demographics

Psoriasis is a common chronic inflammatory skin disease affecting 1.5–3% of the population.[17] Often dismissed as simply 'a skin disorder', psoriasis is associated with a significant reduction in a patient's quality of life[18] comparable to that of cancer or diabetes.[19] It is associated with a seronegative inflammatory arthritis (psoriatic arthritis) in 7–26% of patients.[20] Patients suffer reduced employment and income[21] and serious comorbidities such as cardiovascular disease[22] and depression.[23] The pathogenesis of psoriasis is incompletely understood. There exists a complex interplay of genetic and environmental factors, leading to a disease-predisposing environment. Most cases of chronic plaque psoriasis present prior to the age of 40 years and are classified as early-onset or type I psoriasis. Late-onset disease, after the age of 40 years, may be classified as type II disease.[24]

Key clinical features

The most common type of psoriasis, psoriasis vulgaris, has a characteristic phenotype; well-delineated erythematous plaques with overlying silvery scale develop symmetrically, with a predominance for the extensor surfaces (Figures 17.10 and 17.11).[17] Where psoriasis covers more than 90% of the body surface area, it is termed erythrodermic (Figure 17.12). Common nail changes include pitting, onycholysis (where nail plate has lifted from nail bed, seen as white patches at distal nail) and translucent yellow/red nail bed discolouration, termed 'salmon patches' or 'oil drops' (Figures 17.2 and 17.13–17.15). Emerging evidence associated the nail changes more closely with enthesitis rather than the accompanying skin disease.

Differential diagnoses

Due to the variety of presentations and clinical manifestations of psoriasis, it may resemble numerous other dermatological conditions such as facial psoriasis and the common inflammatory skin condition seborrhoeic dermatitis, and psoriasis vulgaris may resemble pityriasis rubra pilaris, a rare skin condition characterized by orange/red scaly plaques.

Investigations

Histologically, plaques of psoriasis demonstrate; hyperplasia, increased vascularity in the dermis and a dermal and epidermal

Fig. 17.11 Psoriasis vulgaris; severe disease with small plaques across trunk.

Fig. 17.12 Erythrodermic psoriasis involving the hands in an elderly man with psoriatic arthritis.

Fig. 17.13 Psoriasis: nail pits with early onycholysis.

Fig. 17.14 Psoriasis: onycholysis with 'salmon patch'.

Fig. 17.15 Psoriasis: onycholysis, gross pitting, and nail deformity.

inflammatory infiltrate of leucocytes (predominantly CD4 +ve and CD8 +ve T cells).[17]

There are numerous measures for the assessment of severity of psoriasis and its effect on quality of life indices. The psoriasis area and severity index (PASI) was introduced in the 1970s by Fredriksson and Pettersson and is the most extensively studied psoriasis clinical severity score,[25] although it has limitations, including low responsiveness in mild disease.[26] To calculate a PASI, the erythema, induration, and desquamation at body areas are recorded to form a score between 0 and 72, where 72 is the most severe.

Management

The British Association of Dermatologists has published clear guidelines on the use of biologic therapies in severe psoriasis.[6]

Of note, both the use of potent topical corticosteroids and systemic corticosteroids may lead to severe recurrence of chronic plaque psoriasis (rebound psoriasis) on withdrawal of therapy or the serious complication of generalized pustular Von Zumbusch psoriasis, a variant with appreciable morbidity and mortality.

Connective tissue disorders

Lupus

Lupus erythematosus comprises a group of autoimmune multisystem disorders associated with antibodies against components of the cell nucleus.

Lupus may be divided into two main forms; SLE, which is covered in Chapters 118–119, and chronic cutaneous lupus erythematosus (CCLE) or discoid lupus erythematosus.

Demographics

Discoid lupus is the most common form of cutaneous lupus.[27] The disease typically occurs in adults, with a preponderance for women over the age of 40 years;[28] 80% of patients with CCLE are smokers.[29]

Key clinical features

Clinically, CCLE leads to erythematous scaled, inflamed patches, which heal with scarring and frequently hypopigmentation, thus are cosmetically unsightly (Figure 17.16 and 17.17). The rash tends to occur in a photosensitive distribution. Prominent adherent scale is seen at the hair follicles, with keratotic spikes projecting and resembling carpet tacks, thus the 'carpet tack sign'. CCLE in the scalp is a cause of scarring alopecia (Figure 17.18).

Differential diagnoses

Psoriasis, pityriasis rosea (a self-limiting scaly erythematous rash typically preceded by a 'herald patch').

Fig. 17.16 Discoid lupus erythematosus affecting the external ear.

Fig. 17.17 Scaling plaque of discoid lupus erythematosus on a light-exposed area of forehead.

Fig. 17.18 Scarring alopecia of the scalp in discoid lupus erythematosus.

Investigations

Histopathological evaluation reveals degeneration of the basal layer of the epidermis and connective tissue and an intradermal infiltrate of lymphocytes. Epidermal atrophy with plugging of the hair follicles may also occur.[10]

Management

Hydroxychloroquine is the treatment of choice. Factors affecting response to hydroxychloroquine therapy are unclear, and whilst cigarette smoking has been suggested to be associated with poor outcome, a multicentre observational pharmacogenetic study demonstrated that neither cigarette smoking nor cytochrome P450 polymorphisms are associated with clinical outcome of therapy.[30]

Photoprotection with a high-factor sunscreen is advised and patients may benefit from cosmetic camouflage.

Sarcoid

Sarcoidosis is a multisystem granulomatous disease discussed in detail in Chapter 167.

Demographics

Discussed in Chapter 167.

Key clinical features

The clinical morphology of cutaneous sarcoidosis is variable, with the disease being termed 'the great imitator'. Cutaneous sarcoid may appear as plaques occurring on the extremities, buttocks, and trunk with a brown-yellow 'apple jelly' colour on diascopy. Lupus pernio refers to purple plaques occurring on the nose and face (Figure 17.19). In young women persistent erythema in the nasolabial region should raise the possibility of sarcoid or lupus. Sarcoid is a cause of scarring alopecia.

Sarcoid exhibits the Koebner phenomenon, where skin lesions form in areas of trauma, e.g. a surgical wound or an excoriation. Other diseases that exhibit the Koebner phenomenon are listed in Table 17.1.

Investigations

Histopathological examination is not diagnostic, as several skin diseases are associated with granuloma formation.

Management

Many lesions are asymptomatic and may remain under observation alone. Potent topical corticosteroids or injected corticosteroids may be beneficial for limited plaques. For widespread disease, oral corticosteroids, hydroxychloroquine, methotrexate or azathioprine may be used.

Dermatomyositis

Dermatomyositis (DM) is an acquired autoimmune disease comprising inflammation of skeletal muscles and skin, part of the group of idiopathic inflammatory myopathies.

Fig. 17.19 Cutaneous sarcoid in an Afro-Caribbean patient: yellowish papules around the eyelids.

Table 17.1 Conditions that exhibit the Koebner phenomenon

Psoriasis	See 'Psoriasis' section
Sarcoid	See 'Sarcoid' section
Lichen planus	Lichen-like appearance to skin rash of this chronic condition affecting skin and mucosal surfaces; purple polygonal pruritus papules
Lichen nitidis	Chronic disease of pruritic small, uniform, red-brown papules
Vitiligo	Autoimmune skin depigmentation
Viral warts	Skin lesions caused by HPV infection
Lichen sclerosus	Chronic condition with purple polygonal pruritic papules

HPV, human papillomavirus.

Demographics

DM is discussed in detail in Chapter 124.

Key clinical features

Cutaneous features of DM may occur in the absence of musculoskeletal changes: dermatomyositis sine myositis. Characteristically, the lichenoid (purple-ish) eruption is recognized by prominent periocular involvement, termed a heliotrope rash, as it is the same colour as the alpine flower of that name. Involvement of the dorsa of the hands has a characteristic pattern, referred to as Gottron's papules and plaques (Figure 17.20). The key clinical feature is prominent nailfold telangiectasia (Figure 17.21). The rash is photosensitive and may occur in a shawl-like photosensitive distribution (across neck and back). Patients can progress to erythroderma. The rash may remain prominent despite treatment, and where it is associated with malignancy it may persist despite treatment of the underlying neoplasm.

Investigations

See Chapter 124.

Management

Corticosteroids remain the mainstay of therapy for control of both skin and muscle disease. Biologic therapies have been added to the traditional therapeutic options of immunosuppressive agents such as methotrexate, ciclosporin, azathioprine, and the cytotoxic agent cyclophosphamide. In the United Kingdom, Department of Health guidelines for the use of immunoglobulin consider DM as a condition for which treatment is considered highest priority.[31]

Fig. 17.20 Dermatomyositis: 'Gottron's papules', purple papules, and plaques across bony prominences of dorsa of hand. Prominent nailfold telangiectasia also seen.

Fig. 17.21 Dermatomyositis: nailfold telangiectasia.

Dermatological guidelines for the management of DM were last published in 1996,[32] and highlighted the use of additional measures for the control of skin disease, such as photoprotection and potent topical corticosteroid for pruritus.

Scleroderma

Systemic sclerosis (SSc), a multisystem connective tissue disease characterized by fibrosis and ischaemic atrophy, is discussed in Chapter 121. The term scleroderma should strictly refer to sclerosis of the skin, either localized or generalized. Morphoea is a condition of unknown cause characterized by localized cutaneous sclerosis.

Demographics

The incidence of systemic sclerosis is 1 and 6 per million in males and females respectively.[33] Morphoea may occur at any age, with peak incidence between the ages of 20–40 years and a female to male ratio of 3:1.

Key clinical features

There are five distinct phenotypic variants of scleroderma: plaque, generalized, bullous, linear, and deep. Rare variants include a nodular or keloidal scleroderma.[34]

Along with the hallmark skin features, vascular changes such as Raynaud's phenomenon and multiple cutaneous telangiectases may be seen.[35] Digital ulcers, vasculitis, and pruritus may occur.

Clinical subtypes of morphea include plaque type, profunda, bullous, and linear morphea where occurrence on the forehead is termed 'en coup de sabre'. Plaque type morphoea presents as smooth indurated plaques, initially purplish in colour, subsequently pale with a purplish edge.

Differential diagnoses

Lichen sclerosus.

Investigations

See Chapter 121.

Management

For SSc, see Chapter 121. Plaque morphoea improves with time, often with post-inflammatory hyperpigmentation, so intervention may be avoided in uncomplicated cases. Potent topical or intralesional corticosteroids may be useful.

Panniculitis

Subcutaneous fat has many important roles, such as provision of padding and a role in thermoregulation. It also has a cosmetic function, contributing to the contours of the face and body that are characteristic of youth. Their loss may have profound social consequences. Panniculitis refers to a group of conditions characterized by inflammation of the fat.

Key clinical features

Clinically, skin over an area of panniculitis feels thickened or 'woody' and is often red and tender (Figure 17.22). Resolution with atrophy of the involved fat may lead to normal-looking skin tethered to an overlying area of inflammation. Septal panniculitides include erythema nodosum (EN), where inflammation also affects the overlying dermis. Sudden-onset painful symmetrical erythematous plaques develop typically on the lower legs (although they may occur at any site). The diagnosis of EN should be clinical and resolution usually occurs without treatment. Lupus panniculitis is a rare condition often associated with overlying chronic cutaneous lupus (Figure 17.23).

Fig. 17.22 Panniculitis of arm.
Fig. 17.23 Facial panniculitis in patient with systemic lupus erythematosus.

Differential diagnoses

Malignancy, including lymphoma.

Investigations

Diagnosis relies on adequate biopsy (deep enough to obtain a sufficient sample of affected fat), which cannot be done with a conventional punch technique. Panniculitis may be classified histologically as septal, lobular or mixed, with or without vasculitis

Management

Management should begin with treatment of the underlying disease. Conservative management with rest, elevation, compression, and analgesia are key. Therapy common to multiple forms of panniculitis includes potent topical corticosteroid, which may be delivered topically under occlusive dressings to increase potency or by intralesional injection.

Drug eruptions

Overview

Drug eruptions are a significant cause of morbidity and mortality. There are no reliable estimates of the incidence of drug eruptions. Sources of information are sparse; the British National Formulary is poor at separating skin diseases due to drugs (often simply listed as 'rash').

Diagnosis

Although definitive treatment for any drug eruption is discontinuation of the offending agent, this may not always be possible. Identification of the culprit drug may be difficult due to polypharmacy. In this instance, referral to dermatology, with biopsy of the eruption as necessary, may be vital. Clinicopathological correlation is required, as drug eruptions do not always have diagnostic histological appearances. Often a diagnosis remains uncertain despite discontinuation of the putative agent and rechallenge with a suspected offending agent may be an unavoidable clinical scenario. The dermatology team may be able to provide supportive measures for any ensuing eruption.

Individual drugs can cause several patterns of cutaneous eruption, and diagnosis is aided by clinicopathological correlation from a skin biopsy. The eruption may persist beyond clearance of the putative agent and cutaneous signs such as pigmentation may be permanent.

Types of drug eruption

Common and serious forms of drug eruption seen with rheumatological treatments are described in Figure 17.24.

Anti-tumour necrosis factor alpha
Anti-tumour necrosis factor alpha-induced psoriasis

Specific mention should be made of the phenomenon of induction and exacerbation of psoriasis in arthritis patients treated with anti-tumour necrosis factor alpha (TNFα) biologic therapies. An association is supported by data from the British Society for Rheumatology Biologics Register (BSRBR) indicating an increased incidence of psoriasis in patients treated with anti-TNFα therapy.[36] Two scenarios have been seen: a true psoriasis vulgaris picture or palmoplantar pustulosis (PPP), which is now believed to be genetically distinct from chronic plaque psoriasis.[37]

A proposed mechanism for the development of PPP or psoriasis during TNF blockade is dysregulation of interferon-α. It is thought that in some cases TNFα is a modulating cytokine in psoriasis and its blockade allows breakthrough of interferon-α driven disease.

The outcome of reported cases is varied. The largest case series to date reported resolution in 15.4% cases where anti-TNFα agent was switched,[38] suggesting a class effect. Management of mild or moderate cases may be conducted with topical agents or phototherapy, whereas in severe cases treatment may involve discontinuation of the anti-TNF agent and provision of systemic treatment such as ciclosporin.

Eruption	Illustration	Description	Possible drug precipitants	Treatment/comment
Morbilliform drug eruption		Most common form of drug eruption. Erythematous macules or papules seen across trunk and limbs, classically sparing the face, mucous membranes, palms and soles. May resemble viral rash.	Antibiotics, non-steroidal anti-inflammatory agents (NSAIDs) Penicillamine, gold	Withdrawal of offending agent. Supportive measures with emollient for pruritus and anti-pyretic if associated fever.
Fixed drug eruption		Well-delineated lesions develop rapidly after drug ingestion. Lesions vary in morphology, may be erythematous macules or bullae, more commonly occurring on limbs than trunk. Frequently resolve with hyperpigmentation.	NSAIDs	Mechanism of eruption unknown. Re-challenging key to confirmation of the diagnosis.
Bullous eruptions		Bullous drug eruptions include fixed drug eruptions with bullae, porphyria cutanea tarda, erythropoeitc protoporphyria and pseudoporphyria. Pseudoporphyria may be seen with NSAIDs. Drug eruptions may mimic immunobullous disorders such as variants of pemphigus or pemphgoid.	Direct (from skin) and indirect (from blood) immunohistochemistry are required to establish a diagnosis.
Urticaria		Mast cell degranulation leads to pale urticarial weals, surrounded by an erythematous flare. Accompanied by intense pruritus.	NSAIDs	5% of population will exhibit dermographism, where stroking skin provokes an urticarial weal. Oral antihistamines treatment of choice for uncomplicated urticaria.
Pigmentation change		Many pigmentary disturbances are possible as drug adverse events. Antimalarials may lead to a deep slate-grey pigmentation. As with fixed drug eruptions (see above), eruptions often leave darker 'postinflammatory hyperpigmentation' following resolution. Pigmentation may or may not be associated with photosensitivity.		Pigmentary disturbances are often lasting or permanent due to only slow possible resolution with macrophage clearance of deposited pigment. Postinflammatory pigmentation often lasts 3–6 months. Ochronosis is often permanent.
Photosensitivity		Reactions may be phototoxic, where UV activates a photosensitising agent, or photoallergic, an immune response in which the antigen is the UV activated photosensitising agent.	Sulphasalazine, tetracyclines, quinine	Photo-drug testing possible at some specialist centres to allow identification and thereafter avoidance.
Stevens Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) suggest splitting these two and the diagnostic test is skin biopsy which will demonstrate keratinocyte necrosis in TEN they are different conditions		Rare severe drug eruptions. Prodromal phase often precedes acute onset painful erythematous eruption with varying morphology e.g. targetoid or macular. Painful mucous membrane involvement and less than 10% skin surface involvement features of SJS whereas with TEN patient tends to have >10% skin surface involved and can be erythrodermic. Sheets of skin slough on minor pressure 'Nikolsky sign'.	Sulphasalazine Allopurinol Diclofenac	Emergency dermatological conditions requiring specialist care. Early diagnosis and withdrawal of culprit drug essential.
Erythema multiforme		Polymorphic eruption with targetoid lesions composed of erythematous/dusky centre, pale pink swollen (dermal oedema) ring then outer bright erythematous ring.	Allopurinol, NSAIDs, anticonvulsants	Most commonly triggered by herpes viruses, drug causes are uncommon
Acute generalised exanthematous pustulosis		Acute development of multiple widespread small pustules, often with associated fever and malaise	Hydroxychloroquine	Skin peeling seen with resolution.

Fig. 17.24 Common and serious forms of drug eruption seen with rheumatological therapy.

Drug hypersensitivity syndrome	Severe drug eruption, known also as Drug Reaction with Eosinophilia and Systemic Symptoms (DRESS)	Allopurinol, sulphonamides, anticonvulsants
Pruritus	Pruritus/itch can lead to excoriations and lichenification as well as sleep disturbance and depression	Gold

Nervous system

Andrew Graham and Clare Galton

Introduction

Many rheumatological disorders may be complicated by nervous system involvement; either as a direct or indirect consequence of the underlying disease process or occasionally as an adverse effect of treatment. Sometimes neurological symptoms may be the presenting feature of an underlying rheumatological condition—e.g. systemic lupus erythematosus (SLE) presenting with seizures, or a systemic vasculitis presenting with multiple mononeuropathies— but more commonly neurological complications arise on the background of an already established rheumatological diagnosis. As in all branches of medicine, the recognition and accurate diagnosis of neurological disorder depends primarily on careful clinical assessment, but this evaluation can be challenging (even to an experienced neurologist) in the face of significant rheumatological disease. Pain and joint stiffness, swelling and deformity can cloud the assessment and sometimes a final diagnosis will only be reached through investigations, primarily imaging with MRI and/or CT for central nervous system (CNS) syndromes and neurophysiology for the peripheral nervous system (PNS).

Principles

The most crucial skill in neurological assessment is the ability to take and appropriately organize the history.[1] Evaluation has three main aspects:

- **Organization**. Neurological symptoms such as headache and tingling are ubiquitous even in the normal population and are not necessarily an indicator of underlying disease. All potentially neurological symptoms must be accurately defined, arranged in chronological order, and grouped into coherent clusters. Not every symptom is relevant, and symptoms such as fatigue are very non-specific.

- **Localization**. Each cluster of neurological symptoms may suggest either a process (e.g. syncope or seizure), or an anatomical localization. For an intermittent process such as seizures, examination is often uninformative and the diagnosis is typically made from the history alone. For symptoms that localize well, the anatomy can often be specified precisely from the history alone (e.g. tingling and numbness of both legs rising to a level on the trunk, difficulty in walking, and urinary hesitancy all suggest spinal cord disease), but sometimes there is a differential (e.g. with a foot drop it may not be evident from the symptoms alone whether

this is due to a peripheral nerve or root lesion). Structured examination then helps to define the localization further.

- **Causation**. Having established the source of symptoms, their onset and time course often give a clue to causation. For example, in a patient with myelopathy an acute onset may suggest a vascular event (e.g. spinal cord stroke); subacute onset may suggest inflammation or demyelination (e.g. transverse myelitis); and a chronic course suggests a structural or degenerative process (e.g. compressive myelopathy). The point here is that the signs on examination may be similar in all three cases; it is the history that tells them apart.

Clinical reasoning

Rheumatological disorders may involve almost any aspect of the nervous system. A brief guide to neurological localization is given in Table 18.1 and a sample case history is given to exemplify clinical reasoning, but for further details readers are advised to consult one of the classic texts.[2,3]

Case history

A 47 year old woman with a 2 year history of primary Sjögren's syndrome (persistent ocular and oral dryness, positive anti-Ro antibodies, and a positive Schirmer test) complains of left facial numbness and numbness and weakness of both legs, with dragging of the right leg on walking.

The symptoms sound neurological; it is difficult to explain the facial and leg symptoms on the basis of a single anatomical lesion, so they will be treated separately. The facial numbness suggests a trigeminal sensory neuropathy. For the legs the differential in localization is between cervical/thoracic spinal cord and a polyneuropathy. The next step is to define the symptoms further. Does the numbness extend up onto the trunk, indicating spinal cord disease, or follow a glove and stocking distribution, indicating a polyneuropathy? Are there symptoms of bladder dysfunction, usually indicating a myelopathy but also seen with a conus/cauda equina lesion in association with saddle numbness? What has been the time course of each symptom?

(Continued)

(Case history)

Numbness extends to a vague level on the trunk. She complains of pain and tingling in the right hand at night but no fixed numbness in the hands, and mild urinary hesitancy. The facial numbness has evolved over 6 months but the leg symptoms over a fortnight.

The distribution of numbness and the bladder symptoms suggest a myelopathy rather than a polyneuropathy. The right hand symptoms could be significant, but may equally represent a separate peripheral nerve lesion. The difference in time courses supports the idea that there is more than one process at work. The next step is to examine the patient. Is there evidence of upper or lower motor neuron weakness in the legs, are reflexes brisk or depressed, and what is the distribution of sensory loss?

Numbness of the left face extends back to the vertex. There are no signs in the arms. In the legs, tone is increased with a spastic character; there is a mild asymmetric pyramidal weakness (right more so than left); reflexes are generally brisk but absent at both ankles; the right plantar is extensor; and sensation is reduced to joint position in the right leg and to pinprick on the left, extending to an uncertain level on the abdomen.

The facial numbness is consistent with a trigeminal sensory neuropathy. The lack of signs in the right hand suggests that symptoms here are most likely due to carpal tunnel syndrome. The signs in the legs confirm a spinal cord lesion, specifically a predominantly right-sided thoracic myelopathy (a Brown–Séquard syndrome). From the history this is subacute and likely inflammatory/demyelinating. The next step is to investigate, with imaging of the spinal cord and other tests as appropriate.

An MRI of the cervical and thoracic spine shows a longitudinally extensive high signal cord lesion from approximately T1 to T5. An MRI brain scan is normal, with no evidence of any trigeminal lesion. Anti-aquaporin antibodies are positive. Cerebrospinal fluid (CSF) is not examined. Nerve conduction studies confirm a mild median neuropathy at the right wrist but also a mild predominantly sensory axonal polyneuropathy

The longitudinally extensive transverse myelitis due to anti-aquaporin disease may be treated acutely with steroids and/or plasma exchange, with consideration of a second line immunosuppressant to prevent recurrence. No treatment is currently indicated for the trigeminal neuropathy. The mild carpal tunnel syndrome can be treated conservatively with neutral wrist splints or a local steroid injection if it worsens. The incidental polyneuropathy does not need attention, although most neurologists would probably check blood glucose and protein electrophoresis as screening tests for a secondary cause.

Rheumatoid arthritis

The most common neurological complication of rheumatoid arthritis (RA) is entrapment neuropathy, particularly carpal tunnel syndrome in patients with active hand flexor tenosynovitis. Wrist splints at night or a steroid injection may afford some relief, but the definitive treatment is surgical decompression. A generalized, typically mild, length-dependent sensory polyneuropathy may be seen in patients with longstanding or severe disease, but rarely requires specific treatment. Systemic (as opposed to cutaneous) rheumatoid vasculitis is rare, affecting less than 1% of patients,[4,5] but when present may be associated with multiple mononeuropathies and require immunosuppression. Direct CNS involvement is also rare, but occasional patients develop a chronic pachymeningitis with thickening and enhancement of meninges on MRI. Treatment here is speculative.

Otherwise, the most significant neurological complication of RA is cervical myelopathy due to anterior atlantoaxial subluxation and compression by soft tissue pannus. Subluxation is rare in early disease but present in more than 25% of patients with disease duration of more than 15 years.[6] Early subluxation is usually asymptomatic, but 1 in 50 patients with RA will eventually develop a clinically significant compressive cervical myelopathy.[4] This is usually chronic but may present acutely or be unmasked by provocation, e.g. following neck trauma or injudicious manipulation. Surgical stabilization of anterior subluxation can prevent further neurological deterioration but will not usually improve existing symptoms. With disease progression subluxation may be succeeded by vertical atlantoaxial impaction, in which the skull descends and the odontoid process passes superiorly through the foramen magnum, causing lower brainstem compression. Surgical treatment of atlantoaxial impaction is challenging and may involve both odontoid process resection (transorally) and posterior fusion (e.g. of the occiput to C2).

Connective tissue diseases

Systemic lupus erythematosus

SLE may be associated with a bewildering variety of neurological disorder; in 1999 the American College of Rheumatology proposed case criteria for 19 separate CNS and PNS syndromes,[7] often collectively referred to as neuropsychiatric SLE (NPSLE; see Box 18.1).

Estimates of the prevalence of the various NPSLE syndromes vary widely depending on study size, population, focus, and ascertainment methods. A recent meta-analysis of 17 studies involving a total of 5057 patients with SLE found an overall prevalence of 28.2% for all NPSLE syndromes, rising to 56.3% (95% confidence intervals 42.5% 74.7%) when only the highest-quality prospective studies were considered.[8]

However, many syndromes reported are of minimal clinical significance and in any case not all symptoms can be directly attributed to SLE disease activity. First, neurological disorder in patients with SLE may result both from direct nervous system involvement (e.g. due to vasculopathy, antibody-mediated effects, and inflammation) and as a secondary consequence of other factors (e.g. hypertension, renal failure, infections, and drug toxicity). In one series, more than 40% of neurological syndromes in patients with SLE were due to indirect causes.[9] Second, some neurological symptoms are so common that they are bound to be seen in patients with any chronic disease. Although headache is often listed as a common neuropsychiatric manifestation of SLE, a meta-analysis of 7 controlled studies involving 478 patients found that the prevalence of all headache types, including migraine, was not different from controls, with no evidence to support a separate entity of 'lupus headache'.[10]

A reasonable conclusion is that while up to half of all patients with SLE may experience neurological symptoms at some stage in their illness, the cumulative incidence of neurological disorder is

Table 18.1 Common localizations in neurology

Localization	Symptoms	Signs	Common causes
Median nerve	Sensory > motor; pain and tingling in the lateral hand, particularly at night	Tinel's and Phalen's tests are notoriously unreliable; thenar wasting and weakness of APB or opponens pollicis generally only seen in severe cases	Entrapment at the wrist, e.g. carpal tunnel syndrome in RA
Ulnar nerve	Sensory = motor; pain and tingling in the medial hand with weakness of grip	Sensory loss classically involving the little finger and splitting the ring finger; wasting and weakness of FDI and all intrinsic hand muscles except for those supplied by the median nerve	Vasculitic mononeuropathy, e.g. in Churg–Strauss syndrome
Radial nerve	Sensory < motor; wrist drop	Weakness of wrist and finger extensors plus brachioradialis; triceps also weak in proximal lesions, brachioradialis spared in distal lesions (posterior interosseous nerve palsy); minimal sensory loss	Compression in the spiral groove, i.e. Saturday night palsy—causes a classic radial nerve palsy sparing triceps
Peroneal nerve	Sensory < motor; foot drop	Weakness of ankle dorsiflexion plus inversion and eversion; minimal sensory loss over dorsum of foot	Vasculitic mononeuropathy, e.g. in Churg–Strauss syndrome
Spinal cord	Sensory, motor and sphincters; tingling and numbness of both legs rising to a level on the trunk, difficulty in walking and urinary hesitancy	Spastic increase in tone; pyramidal weakness (flexors weaker than extensors in lower limbs, converse in upper limbs), brisk reflexes, extensor plantars, sensory level on trunk	Transverse myelitis, e.g. LETM in SLE
Polyneuropathy	Sensory and motor; distal numbness, tingling, and weakness, typically legs > arms in a length-dependent manner	Distal weakness, reduced or absent reflexes, glove and stocking sensory loss	Distal symmetric polyneuropathy, e.g. in Sjögren's syndrome

APB, abductor pollicis brevis (thumb abduction); FDI, first dorsal interosseous (index finger abduction); LETM, longitudinally extensive transverse myelitis; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus.

probably less than 20% when syndromes such as headache, minor cognitive dysfunction, anxiety, mood disorder, and symptoms of polyneuropathy with negative neurophysiology are excluded.[11,12] Significant neuropsychiatric events may precede, coincide, or follow the diagnosis of SLE but commonly occur within the first year after SLE diagnosis and in the presence of generalized disease activity. The most common manifestations (cumulative incidence 5–15%) are stroke and seizures, while serious cognitive dysfunction, delirium, and PNS disorders are uncommon (1–5%) and myelitis, aseptic meningitis, cranial neuropathies, and movement disorders are all well recognized but rare (<1%).[11] The spectrum of psychiatric and psychological disorder in rheumatic diseases is wide and forms the subject of a separate chapter (see Chapter 26).

Stroke

Patients with SLE are at increased risk of ischaemic stroke and transient ischaemic attack (TIA) due to a variety of mechanisms; haemorrhagic stroke is rare. Atherosclerosis is accelerated in SLE,[13] and patients often require aggressive management of conventional vascular risk factors such as smoking, hypertension, hyperlipidaemia, and diabetes. Patients with SLE have a five- to sixfold increased risk of ischaemic heart disease overall (in younger women the excess risk may be 50-fold) and are at risk of cardioembolism due to rhythm disorder or structural heart disease. In addition, SLE is closely associated with the presence of antiphospholipid antibodies (APAs), an important risk factor for both venous and arterial thrombosis.

Acute stroke or TIA management is similar to that in the general population, consisting of immediate clinical evaluation, imaging with CT and/or MRI, thrombolysis where indicated or antiplatelet treatment unless contraindicated, and then full secondary prevention measures including carotid endarterectomy where appropriate. For ischaemic stroke in association with positive APAs the usual consensus is also to anticoagulate with warfarin, although in trials the benefits of warfarin over aspirin have not been clearly established[14] and for most patients there is no clear advantage of high-intensity over low-intensity anticoagulation.[15,16] However, patients with APAs are a heterogeneous group and data specifically relating to antiphospholipid syndrome in association with SLE is lacking. For a younger patient with SLE and a first ischaemic stroke in association with persistent high-titre anti-cardiolipin/anti-β_2-microglobulin antibodies and a positive lupus anticoagulant test, most physicians would have no hesitation in anticoagulating long-term, quite possibly aiming for a higher target INR of 3–4; whereas for an older patient with weakly positive anticardiolipin antibodies not meeting full criteria for antiphospholipid syndrome, aspirin alone and attention to conventional risk factors may be more appropriate. Stroke due to cerebral vasculitis is very rare in SLE and immunosuppression post stroke is not usually indicated unless it is to control accompanying generalized disease activity.

Seizures

Seizures are common in SLE, again due to a variety of mechanisms. Sporadic seizures may be provoked by metabolic derangement or intercurrent infection, while for recurrent seizures the most important pathology is probably underlying vascular disease (particularly in association with APAs). In some patients with negative brain

Box 18.1 (Neuropsychiatric SLE syndromes)

Central nervous system

imaging a more specific antibody-mediated mechanism may be suspected, but of the many non-APA autoantibodies reported in NPSLE none has proven diagnostic or therapeutic utility in seizure disorders.

The general management of seizures in SLE is similar to that in the general population. Brain imaging, ideally with MRI, is required to exclude any structural lesion and to assess the extent of any vascular disease. EEG is not usually helpful in diagnosis but may help to specify the epilepsy syndrome and can add information about the risk of further seizures. In the United Kingdom antiepileptic drug treatment is not usually given following a single or provoked seizure unless there are risk factors for recurrence such as a structural lesion on MRI or clear continuing epileptiform activity on the EEG; in such cases, or if seizures are already recurrent, treatment is symptomatic with the usual range of antiepileptic medications. Fulminating seizures may require further investigation, for example an MR venogram to exclude dural sinus thrombosis (requiring anticoagulation, particularly in association with the antiphospholipid syndrome) or CSF examination to exclude infection (requiring antiviral or antibacterial treatment). Immunosuppression is rarely indicated unless it is to control accompanying generalized disease activity; lupus 'encephalitis' or 'cerebritis' is not an ACR-defined neuropsychiatric syndrome and in patients who are unwell with

encephalopathy and seizures it is usually worth investigating for a more specific (primary or secondary) cause.

Myelitis

Myelitis is an uncommon neurological complication in SLE but deserves mention because it may be associated with particular underlying pathology and requires specific treatment. In recent years the investigation and management of inflammatory spinal cord disease has been reshaped by the identification of a specific antibody to the aquaporin-4 (AQP4) water channel in patients with the demyelinating condition of neuromyelitis optica (NMO) or Devic's syndrome, consisting of so-called longitudinally extensive transverse myelitis (LETM—myelitis extending over three or more spinal segments) and optic neuritis.[17] Studies show that a positive anti-AQP4 antibody test is strongly associated with the NMO phenotype, but not typical multiple sclerosis (MS),[18] and is a predictor of a severe disease course with a high likelihood of future relapses.[19] However, unlike in MS, relapse rates in patients with anti-AQP4-positive NMO can be reduced by aggressive treatment with steroids, second line immunosuppressants such as azathioprine and mycophenolate mofetil, and antibody-directed treatment such as rituximab. Accurate diagnosis of NMO spectrum disorders is therefore very important, and anti-APQ4 antibodies are increasingly recognized in patients with SLE and either myelitis or recurrent optic neuritis. One recent study of 28 patients with NPSLE found positive anti-APQ4 antibodies in 6/6 patients with LETM and 2/2 patients with recurrent optic neuritis; testing was negative in patients with all other neuropsychiatric syndromes including chorea, psychosis, seizure disorders, and polyneuropathy.[20] Conversely, non-organ-specific autoantibodies are frequently found in NMO spectrum disorders, with at least some patients meeting clinical criteria for SLE.[21]

A reasonable conclusion is that anti-aquaporin disease should be excluded in any patient with SLE and LETM or recurrent optic neuritis, and that when NMO is diagnosed it should be regarded as a coexisting disorder rather than a direct complication of SLE, often requiring separate treatment. Neurologists are now very familiar with this condition, but where local advice is not available a national service has recently been established in the United Kingdom, offering anti-AQP4 antibody testing and guidance on management for all National Health Service patients with NMO (www.nmouk.nhs.uk).

Sjögren's syndrome

Sjögren's syndrome is associated with a wide spectrum of PNS syndromes.[22] The hallmark complication is sensory ataxic neuronopathy, usually subacute but occasionally acute and dramatic. Patients develop gait and limb ataxia with severe loss of posterior column sensation (vibration and joint position), often leading to significant disability. Treatment is speculative but the syndrome may occasionally respond to steroids, intravenous immunoglobulin (IVIG), or other immunosuppressants. Sensory trigeminal neuropathy and an autonomic neuropathy are also seen: individual patients may present with symptoms of more than one syndrome or an unclassifiable overlap syndrome. Neuropathy may sometimes be the presenting feature of underlying Sjögren's syndrome, in which case patients are more likely to present to a neurologist than a rheumatologist.

CNS involvement in Sjögren's is less common but just as in SLE LETM has historically been well described, responding to treatment with steroids and azathioprine.[23,24] The current view is that,

similarly to SLE, many if not all of these cases are due to coexisting anti-aquaporin disease.[20,21]

Systemic sclerosis

As in Sjögren's syndrome, systemic sclerosis is more often associated with PNS than CNS manifestations. Up to a quarter of patients develop carpal tunnel syndrome, and trigeminal sensory neuropathy and a mild autonomic neuropathy are also seen. More significant polyneuropathy or multiple mononeuropathies are rare. Basal ganglia calcification is a common finding on brain imaging but is not usually of clinical significance.

Mixed connective tissue disease

Mixed connective tissue disease (MCTD) may be associated with both CNS and PNS disease; the pattern of central involvement is similar to that seen in SLE, while peripheral involvement mirrors that seen in systemic sclerosis, particularly trigeminal sensory neuropathy. In addition, inflammatory muscle disease histologically resembling dermatomyositis is a common complication of MCTD.

Spondyloarthropathies

Neurological involvement in ankylosing spondylitis is usually due to mechanical cord or root compression. The spectrum of neurological involvement in reactive arthritis is much wider, including aseptic meningoencephalitis, seizures, psychosis, cranial neuropathies, radiculopathy, and polyneuropathy. Neurological involvement in psoriatic arthropathy is rare.

Vasculitis

Nervous system involvement in systemic vasculitis is common, with differing patterns according to the specific vasculitis syndrome.[25]

ANCA-associated vasculitis

The syndromes of ANCA-associated vasculitis (Churg–Strauss syndrome, Wegener's granulomatosis, microscopic polyangiitis and classical polyarteritis nodosa [PAN]) are associated with PNS complications in up to 40% of patients, most notably in Churg–Strauss syndrome where neurological manifestations are the first symptoms of vasculitis in up to 25% of patients and presentation is almost as likely to be to a neurologist as a rheumatologist.[25] CNS manifestations are less common, but still relatively frequent: stroke, seizures, and altered mental status occur in up to 10% of patients.

PNS involvement in Churg–Strauss syndrome, microscopic polyangiitis and classical PAN typically takes the form of acute or subacute single or multiple mononeuropathies, usually sensorimotor and painful. The commonest nerves affected are the peroneal nerve in the lower limb (causing foot drop) and the ulnar nerve in the upper limb (causing intrinsic hand weakness);[26] when sufficient individual peripheral nerves are involved the end result may be indistinguishable from a generalized sensorimotor axonal polyneuropathy. Although pain, swelling, and asymmetry of symptoms and signs should all alert the clinician to the possibility of underlying vasculitis, stepwise progression is not always seen and a significant minority of patients present with a distal symmetric polyneuropathy from the outset.[26] PNS involvement is less common in Wegener's granulomatosis and is rarely the presenting feature. However, Wegener's is associated with a range of other neurological syndromes related to orbital mass formation and granulomatous infiltration originating from the ear, nose, and throat (ENT) tract, including multiple cranial nerve palsies (most commonly optic

neuropathy), pachymeningitis, and pituitary gland involvement. The treatment of primary ANCA-associated vasculitis is discussed elsewhere in this volume but generally involves steroids and pulsed IV cyclophosphamide for induction and then a second line agent such as methotrexate. For refractory granulomatous disease, anti-CD20 therapy such as rituximab has been used with some success (see Chapter 141).

Large-vessel vasculitis

Takayasu's arteritis is associated with carotid or vertebral artery inflammation, stenosis, or occlusion, with a predilection for the anterior circulation. Extracranial artery involvement is often asymptomatic but may be complicated by ischaemic stroke in up to 10% of patients. Takayasu's arteritis does not usually affect the intracranial vessels or the PNS. Temporal arteritis is classically associated with occlusion of the posterior ciliary artery causing anterior ischaemic optic neuropathy, but may also involve the vertebral arteries, leading to posterior circulation stroke in up to 5% of patients. When treating temporal arteritis, low-dose antiplatelet therapy as stroke prophylaxis is recommended in addition to steroids.[27]

Behçet's disease

Behçet's disease is associated with significant neurological complications in perhaps 10% of patients, with two main patterns of involvement.[28,29] First, parenchymal neuro-Behçet's disease, in which CNS inflammation (typically affecting the upper brainstem and basal ganglia but sometimes extending more diffusely through brain and spinal cord) results in a range of corresponding manifestations including ophthalmoplegia, pyramidal and extrapyramidal dysfunction, seizures, and behavioural change. Symptoms usually evolve over a few days or weeks, often associated with headache; MRI shows a varying distribution of inflammatory lesions, occasionally with contrast enhancement, while CSF generally shows a pleiocytosis and raised protein with absent oligoclonal bands. Steroids are the mainstay of management, but second line treatment is speculative.[29] The second main pattern is non-parenchymal or vasculo-Behçet's disease, usually manifesting with dural sinus thrombosis and raised intracranial pressure. In this situation parenchymal lesions are absent on MRI but sinus thrombosis may be seen on MR venography; CSF examination shows raised pressure but is usually otherwise unremarkable. Dural sinus thrombosis is typically treated with anticoagulation unless there is an obvious contraindication.

Drug effects

Many of the medications used to treat rheumatological disease have potential for neurological side effects. Non-steroidal anti-inflammatory drugs (NSAIDs), commonly prescribed as symptomatic therapy, may be associated with an aseptic meningitis (which must be borne in mind when examining CSF in patients on long-term NSAIDs). The associations of older disease-modifying drugs such as gold (with neuropathy) and penicillamine (with myasthenia gravis) are well known. Modern first line disease-modifying therapies such as low-dose methotrexate are not often associated with neurological complications, but newer second line agents have been reported to cause a number of central and peripheral nervous system syndromes. Leflunomide may be associated with a distal sensory or sensorimotor axonal polyneuropathy;[30] in some patients symptoms improve with discontinuation, but in others symptoms persist (suggesting irreversible axonal loss). The TNFα

inhibitors etanercept, infliximab, and adalumimab may be associated with both CNS[31] and PNS[32] demyelinating disease. Centrally, TNFα inhibitors are associated with an increased relapse rate in already established MS;[33] it is uncertain whether their use in rheumatic conditions induces CNS demyelination *de novo* or simply exposes latent disease.[34] Peripherally, TNFα inhibitors can also induce chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) with positive anti-ganglioside antibodies, or multifocal motor neuropathy (MMN). Discontinuation of TNFα inhibitor therapy is typically associated with improvement of CNS and PNS inflammation, without the need for more specific treatment, but recovery may be slow and incomplete. In rare cases a leukoencephalopathy has been described that may continue to progress despite withdrawal of treatment.

Cardiovascular system

J. Gerry Coghlan and Benjamin E. Schreiber

Introduction

Rheumatologists face a huge task in identifying potentially highly lethal multisystem diseases, often hidden among large numbers of patients with painful but non-threatening conditions like fibromyalgia and osteoarthritis. In addition, they must provide chronic care for relapsing remitting conditions, while monitoring for adverse effects of increasingly toxic therapeutic regimens. Given the exercise limitation that is common to virtually all such patients and the fact that most cardiac patients notice symptoms only on effort, particular skill is required to identify cardiac complaints among this population.

Yet cardiac problems are prevalent in the average rheumatological clinic, whether simply fortuitously (those with osteoarthritis are often elderly) or due to a generic increase in cardiac risk associated with inflammation[1] and metabolic syndrome[2] or a recognized complication of specific rheumatological conditions.[3] In this chapter we address the general problem of identifying cardiac conditions among rheumatological patients and the generic association between inflammation and cardiac disease, explore in particular the relationship between rheumatological disease and coronary heart disease, and finally provide an overview of cardiac conditions thought to be associated with rheumatological conditions in tabular form (Table 19.1).

Identifying cardiac disease in rheumatology patients

Cardiac symptoms

Coronary artery disease progresses asymptomatically for a variable period of time and may in a significant minority present abruptly with myocardial infarction or sudden death. However, more usually it presents with stable effort limitation due to chest discomfort or progressive reduction in effort tolerance over days to weeks preceding myocardial infarction.[4] In many patients with rheumatological disease exercise ability is already limited either in terms of magnitude of task performed or the ease with which such tasks are performed, thus masking the symptoms of coexisting coronary artery disease.

Dyspnoea on effort is another common cardiac symptom typically due to systolic and diastolic myocardial dysfunction, valvular heart disease, tachycardia myopathies, and pulmonary hypertension. Syncope on significant effort may occur in conditions that limit cardiac output such as aortic stenosis, hypertrophic cardiomyopathy, and pulmonary hypertension. Arrhythmias usually present with palpitations, or alterations in consciousness, but may present as sudden death. Finally, fatigue may limit effort in constrictive pericarditis and slowly progressive cardiac conditions such as mitral stenosis.

Presentation of cardiac disease in rheumatological conditions

Rheumatological conditions may not only mask cardiac symptoms through chronic effort limitation; they may also mimic them, being a known cause similar of symptoms (fatigue, dyspnoea), resulting in failure to explore possible cardiac pathology. Finally, expert patients may filter their symptoms to fit preconceptions as to the most desirable consult outcome. Difficulty in diagnosing cardiac conditions is compounded by an increase prevalence of cardiac disease as exemplified in rheumatoid arthritis (RA),[5] lupus,[3] and systemic sclerosis.[6]

Diagnosing cardiac disease in rheumatology clinics

Improved access to highly discriminatory diagnostic tools, coupled with a heightened index of suspicion, is required in the average rheumatological clinic. Patients should be assessed annually for traditional cardiac risk factors and their additional cardiac risk level associated with their rheumatological diagnosis considered. For example, patients with RA have a doubling of coronary risk,[5] those with systemic sclerosis a thousandfold increased risk for pulmonary hypertension[7] (Figure 19.1). Young women with systemic lupus erythematosus (SLE) have a fiftyfold increased coronary risk,[8] and patients with gout, and indeed all others with elevated urate, may exhibit increased cardiovascular risk.[9] In patients whose effort tolerance changes over a short period of time, consideration should always be given to whether the change is adequately explained by manifest change in the activity of their rheumatological condition or whether detailed investigation is required. Finally, probing of the patient's symptoms may be particularly revealing—patients often offer explanations for symptoms that seem sensible and fit with their disease profile, but gentle probing often reveals that the symptom pattern does not hold and suggests alternate causes. Of particular note, chronic obesity tends to limit effort tolerance through pain rather than dyspnoea,[10] and advancing age does not cause rapid deterioration in effort tolerance.[11]

A simple blood test (N-terminal proBNP or BNP) will identify most patients with systolic or diastolic heart failure[12]; thus, wherever such a differential exists this test should be requested. Coronary calcification

Table 19.1 Cardiovascular risks associated with rheumatological conditions

Disease	Associations	Comment
RA	Pericarditis	Effusions are common but clinical episodes are uncommon, and are associated with seropositive disease, active synovitis
	Myocarditis	Rare as a clinical manifestation, though subclinical abnormalities common at autopsy, can be granulomatous or interstitial
	Valvular disease	Rare as a clinical manifestation, rheumatoid granulomata on 3–5% of autopsies, minor valvular abnormalities in over 10% on echo
	Coronary disease	See discussion above, may also cause a small-vessel arteritis
	Conduction	First degree heart block up to 10%, bifasicular block more common. High grade block rare. Rheumatoid nodules may affect conduction system
	Aortitis	Previously found in 5% of autopsy series, may now be recognized more frequently with PET scanning. Aneurysm formation rare
	Iatrogenic	Hydroxychloroquine (cardiac toxicity) NSAIDs may unmask heart failure
	Amyloidoisis	Patients with longstanding active disease are at risk of AA amyloidosis causing an infiltrative cardiomyopathy
SLE	Coronary disease	See discussion above. Note: was rare in pre-steroid era
	Valvular disease	Asymptomatic verrucous valvular lesions are common (up to 75%). More severe form, Libman–Sacks endocarditis, associated with mitral regurgitation (much less common with effective therapy)
	Pericardial disease	Clinical pericarditis is the most common cardiac manifestation (up to 30% with active disease). Treatment of lupus resolves it, though effusions may persist
	Myocarditis	Clinically uncommon, subclinical involvement in up to 40%
	Conduction	Congenital heart block associated with anti-Ro/SSA and anti-La/SSB antibodies. Atrial and more rarely ventricular arrhythmias may accompany myocarditis, pericarditis and coronary disease.
	Thrombotic	Typically associated with APS, venous and arterial thrombosis, including leading to stroke and myocardial infarction
	Pulmonary hypertension	PAH in approximately 1%, may have vasculitis component and respond to immunosupression. Also PH secondary to lung disease may occur
Systemic sclerosis	Pulmonary hypertension	7–12% develop PAH associated with a very poor prognosis requiring aggressive treatment. Approximately 3% develop postcapillary PH (due to left heart disease) and another 3% lung disease associated PH
	Coronary disease	No definite association; however, small-vessel disease purported to underlie myocardial scarring in this condition
	Pericardial disease	Symptomatic disease uncommon, fibrinous pericarditis especially during active early phase. Later transudates secondary to pulmonary hypertension or heart failure
	Myocarditis	Myocardial scarring in a non-coronary distribution is common and may lead to heart failure or arrhythmias. Whether due to microvasculopathy or myocarditis is unresolved
	Conduction	All types of heart block, septal infarction pattern, atrial and ventricular arrhythmias described. ECG abnormal in 50% slightly more than in age-matched population
Osteoarthritis	Increased cardiovascular mortality[61]	Possible confounders include exercise, obesity, use of NSAIDs
Gout	Coronary heart disease[62]	Hyperuricemia is also associated with obesity, hypertension, and diabetes[63]
Sjögren's syndrome	Pericarditis	Acute pericarditis is rare, but effusions are common
Takayasu's arteritis	Aorta and major branches	Granulomatous arteritis progressing to intimal hyperplasia and adventitial sclerosis. Coarctation and major vessel stenoses cause most complications – including hypertension (renal artery) and heart failure (hypertensive and aortic regurgitation). Pressure differential between limbs is a major clinical sign
	Coronary disease	Involvement of the coronaries occurs in ~10% causing angina, infarction. and heart failure
Giant cell arteritis	Aortic aneurysm, aortic dissection, large-artery stenosis[64]	Medium-vessel arteritis dominates clinical course, larger head and neck vessel involvement leads to stenotic lesions. Aortic involvement may produce no cardiovascular symptoms unless aneurysm formation results
Churg–Strauss	Endomyocarditis and heart failure[65]	Involvement of pericardium, myocardium, endocardium, and coronaries all described and in total affect over half of patients. Patients with marked eosinophilia at particular risk

(Continued)

Table 19.1 (Continued)

Disease	Associations	Comment
Polyarteritisnodosa	Coronary disease	Coronary arteritis affecting small subepicardial vessels, modest aneurysm formation. Infarction may result as may pericarditis
Behçet's	Inflammatory vasculopathy	Previously Behçet's was thought to be associated with frequent cardiac involvement. More recent data suggests dominant involvement of the pulmonary arteries, large aortic branch vessels, and large veins, leading to aneurysm formation and occlusion
Spondyloarthropathies	Aorta	Adventitial scarring with intimal proliferation and scarring typically seen in ankylosing spondylitis, less common in Reiter's and rare in psoriasis. Aortic root dilation and aortic regurgitation due to leaflet shortening and distortion are characteristic
	Conduction	Fibrosis of the AV node associated with all degrees of heart block in Ankylosing Spondylitis. In Reiter's responsiveness to immunosupression suggests inflammatory component
	Coronary disease	Rare involvement of the coronary ostia may cause angina

scoring (Figure 19.2) requires minimal radiation exposure and will reliably exclude prognostically significant coronary disease[13]; further, where positive this test identifies individuals at increased risk of coronary events and in need of secondary prevention and investigation for ischaemia. The recent National Institute for Health and Clinical Excellence (NICE) guidance on chest pain[14] should result in widespread availability of this technique in the next few years.

Symptom profile may be altered: in patients with RA and coronary disease, as in patients with diabetes mellitus, chest pain may not be experienced.[15] Thus changes in dyspnoea burden should lead to consideration of atypical angina in the differential.

Failure to recognize symptoms of cardiac disease may occur for many reasons: breathlessness may already be present from associated parenchymal lung disease, chest wall arthritis, and respiratory muscle weakness or reflux oesophagitis, thus changes in dyspnoea may never even be reported. Chest wall discomfort and reflux may also mask cardiac pain.

Other cardiac conditions may appear abruptly without preexisting abnormalities to detect: thus coronary thrombosis in normal arteries occur in lupus; stroke and pulmonary emboli typically in antiphospholipid syndrome (APS)[16]; and major vessel thrombosis or aneurysms in Behçet's syndrome.[17] Subtle myocardial fibrosis or microvascular disease in lupus[3] or systemic sclerosis[6] (Figure 19.3) may manifest as tachyarrhythmia, sudden death, or conduction disorders without prodrome.

Inflammation and cardiac disease

Although some cardiac diseases are obviously inflammatory in nature (pericarditis, myocarditis) and inflammation plays a pivotal
Fig. 19.1 MRI showing grossly dilated pulmonary artery (PA) and right ventricle (RV) secondary to pulmonary arterial hypertension in a patient with systemic sclerosis. The left ventricle (LV) is compressed by the pressure overloaded RV.

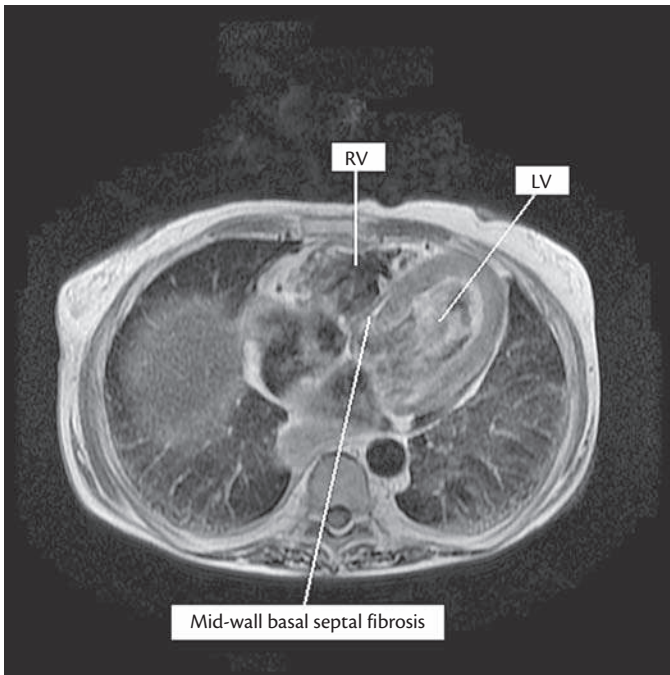
Fig. 19.2 CT coronary angiogram showing heavy calcification of the anterior descending artery–first diagonal bifurcation, indicative of the presence of significant coronary disease at this location. RV, right ventricle; LV, left ventricle.


Fig. 19.3 Late gadolinium MRI of a patient with systemic sclerosis and myocardial fibrosis. Gadolinium sequesters in the interstitial space in collagen, clearing very slowly, remaining enhanced on delayed imaging. RV, right ventricle; LV, left ventricle.

role in the evolution of myocardial infarction and heart failure, it has become increasingly evident that inflammation is pathogenic in atherosclerosis and hypertension as well. How precisely this relates to systemic inflammatory conditions is as yet unclear, though it is apparent that rheumatological conditions are strongly associated with increased cardiac event rates. One link between inflammation and accelerated atherosclerosis which has been elucidated is the increased myeloperoxidase-catalysed lipoprotein carbamylation which accelerates atherosclerosis.[18]

While studies of C-reactive protein (CRP) as a risk factor[19] provide strong support for inflammation being an important contributor to in cardiovascular disease, they tell us little of the mechanism and do not give insight into the possible mechanisms by which rheumatological conditions might lead to heart disease. Likewise, elevated urate levels associate with cardiovascular mortality but, other than speculation about the role of intracellular oxidative stress, provide little illumination.[20]

The first specific proinflammatory cytokine to be associated with heart failure was tumour necrosis factor alpha (TNFα.[21] Unfortunately anti-TNF therapy has not proved successful.[22] It is presently postulated that physiological levels of TNFα may be required for remodelling and repair.[23] Although the early promise has not materialized, it is still held that improved understanding of the role of TNFα, dosing of anti-TNF agents, and exploration of the different actions of available agents may yet lead to a therapeutic role for anti-TNFα agents in heart failure.[24]

Monocyte chemoattractive protein-1 (MCP-1) levels are predictive of acute and chronic outcome in acute coronary syndromes[25] and heart failure.[26] The monocyte response to myocardial infarction is complex, however, with inflammatory monocytes peaking at day 3 and reparative monocytes at day 5.[27] While in theory it would be attractive to downregulate the inflammatory response and upregulate

the reparative response, the protean roles of cytokines make the outcome difficult to predict. Thus fractalkine appears to promote reparative monocyte response but may also enhance atherosclerosis.[28]

Chronically elevated IL-6 levels were found to be associated with a doubling of risk for fatal and non-fatal myocardial infarction in a large United Kingdom population-based study.[29] More recent data suggests that IL-6 may explain the association between markers of inflammation (serum viscosity, fibrinogen, leucocyte count, CRP) and coronary disease as well as ischaemic stroke, as IL-6—unlike other inflammatory markers—retains significance when corrected for traditional risk factors.[30] Elevated IL-6 levels have also been associated with adverse outcomes in heart failure[31] and with an increased incidence of sudden death.[32] Circulating Il-6 levels are increased after myocardial infarction and associated with an adverse prognosis.[33] However, discrepant findings in animal models (a protective effect of gp130 activation) suggest that disruption of downstream effects in the setting of infarction may reset the balance of effects toward inflammation rather than protection.[34]

Thus the precise relationship between circulating and tissue levels of IL-6 and variable downstream effects make predictions of the possible therapeutic impact of IL-6 antagonist therapy difficult to predict. This is of course of immediate relevance in RA where tocilizumab (an IL-6 receptor inhibitor) is in use. The impact on myocardial inflammation and repair is not well understood; in addition, adverse effects on lipid profile have been observed.[35]

Systemic hypertension is associated with inflammation via the metabolic syndrome. In addition, in experimental studies there is some supportive evidence for a direct relationship between hypertension and inflammation. The role of angiotensin II (ATII) in hypertension is not doubted: ATII has proinflammatory effects mediated via NF-κB, IL-6, and IL-1β.[36] ATII infusions in humans have been shown to increase IL-6,[37] but as yet there is no clear evidence that hypertension can be directly caused by inflammation.

Inflammation may also play a significant role in pulmonary hypertension (PAH), as reviewed recently.[38] The strong association between PAH and rheumatological conditions, the reversal of PAH in some patients with immunosuppressive therapy, the frequent autoimmune abnormalities in idiopathic PAH, the histological findings of inflammatory cell infiltrates and the monocrotaline models all argue for a pivotal role of inflammation in PAH, the precise nature of which has yet to be defined.

Not only can one point to immunological perturbations associated with cardiovascular disease, but also the increased incidence and prevalence of cardiac disease in virtually all rheumatological conditions.

Coronary disease in rheumatoid arthritis and lupus

Rheumatoid arthritis

A recent meta-analysis of 24 observational studies including 111 758 patients found that cardiovascular disease mortality is increased by approximately 50% in RA patients compared to the general population.[5] Possible explanations include traditional cardiovascular risk factors, novel risk factors associated with inflammation, and therapies such as glucocorticoids and non-steroidal anti-inflammatory drugs (NSAIDs). An analysis of the Nurses' Health Study compared women with RA to those without, and found no difference in the prevalence of diabetes, hypertension, current smoking, or dyslipidaemia.[39] As expected, CRP levels were significantly higher in patients with RA.

Several other novel risk factors, whose significance is not clear, are associated with RA.[40] It is speculated that active inflammation in RA may accelerate atherosclerosis. Although high CRP is highly associated with ischaemic heart disease,[41] recent studies have shown that the association is not likely to be causal.[42]

A study from the British Society of Rheumatology Biologics Register compared the rate of myocardial infarction in 8670 patients with active RA treated with anti-TNF inhibitors to the rate in 2170 patients treated with traditional disease-modifying antirheumatic drugs (DMARDs). Following adjustment for baseline cardiovascular risk factors, they found no significant difference between the two groups. However, myocardial infarction rates were lower in patients who responded to anti-TNF therapy compared to those who did not (adjusted incidence rate ratio 0.36, 0.16–0.69).[43]

Glucocorticoid use is associated with an increased risk of ischaemic heart disease, in patients with RA[44] as well as in the general population.[45] However, this has not been shown to be causal. The effect of glucocorticoids on the lipid profile is also not clear.[46]

NSAIDs are associated with increased risk of cardiovascular disease. Of all NSAIDs, including COX-2 selective NSAIDs, naproxen is associated with least harm.[47]

SLE is associated with a substantial increase in the risk of stroke and coronary events.[48] The association with atherosclerosis is supported not just by evidence of much higher rates of clinical events such as angina and myocardial infarction,[49,50] but also much greater prevalence of coronary calcification,[51,52] carotid intimal thickening,[53] and disordered endothelial function.[54] Despite the impressive excess of atherosclerosis and atherosclerotic events shown in many studies, all cohorts are small and only one has a truly rigorous control cohort of adequate size.[52]

From the available studies it is evident that traditional risk factors in part explain the excess observed[51]; other factors such as the age at onset of disease,[53] duration of disease,[53] renal involvement,[55] and nature of immunosuppressive therapy used[56] also play a role. In addition, genetic variants such as homozygosity for mannose-binding lectin variant alleles are associated with an increased risk of arterial thrombotic events in SLE.[57] Nevertheless, the failure to recruit to treatment trials[58] means that one cannot assert that managing patients differently will alter outcome. It follows that for the moment optimal assessment of and management of traditional risk factors is the goal,[59] and this goal is not presently being met.[60]

Conclusion

Rheumatologists require a heightened index of suspicion and access to the latest investigational strategies to diagnose cardiac diseases prevalent in their patients. The population provides immense opportunities for research into the links between inflammation, autoimmunity, and heart disease.

CHAPTER 20

Respiratory system

Rachel K. Hoyles and Athol U. Wells

Introduction

Pulmonary involvement is common in the connective tissue diseases (CTDs) and is associated with significant morbidity and mortality. Improved management of systemic disease has led to increasing numbers of surviving patients with clinically significant pulmonary disease. Screening for pulmonary complications highlights the frequency of subclinical involvement. In this chapter, the pulmonary manifestations of the more common CTDs are detailed, including rheumatoid arthritis (RA), systemic sclerosis (SSc), systemic lupus erythematosus (SLE), polymyositis/dermatomyositis (PM/DM), Sjögren's syndrome (SS) and, more briefly, ankylosing spondylitis (AS); the discussion is stratified by pulmonary complication. A broad spectrum of pulmonary disorders are seen in association with the CTDs or the drugs used to treat the underlying disorder. In many cases, two or more pulmonary manifestations of CTD coexist or there are other concurrent diseases such as asthma and lung cancer, resulting in potentially confusing mixed imaging and pulmonary function abnormalities.

Respiratory symptoms

Exertional dyspnoea is non-specific and common, especially in SSc, but is an unreliable marker of lung involvement, as it may result from an increased work of locomotion (arthritis, myositis); moreover, in severe systemic disease, patients may be unable to exercise sufficiently to experience dyspnoea, despite significant lung function impairment. Wheeze more specifically localizes pathology to large or small airways, including asthma, chronic obstructive pulmonary disease (COPD), bronchiolitis, or bronchiectasis. Cough is a common symptom, which is often nocturnal in asthma and reflux, is associated with purulent sputum in bronchiectasis or pneumonia, is typically dry and unrelenting in the interstitial lung diseases, and is common in SS, due to tracheobronchial involvement. Pleuritic pain is a common initial manifestation of RA and SLE. Digital clubbing is common in patients with advanced rheumatoid lung but is extremely rare in the other CTDs. The rate of onset of respiratory symptoms, or temporal association with disease-modifying therapies, often provide clues to the underlying aetiology. There is increasing recognition that lung involvement often precedes the systemic manifestations of CTDs.

Spectrum of lung disease in the connective tissue diseases

Pulmonary complications of connective tissue diseases (CTDs) potentially involve the entire respiratory tract, including large and small airways, lung parenchyma, pulmonary vasculature, pleura, and respiratory muscles. In this chapter, considerable focus is placed on the interstitial lung diseases (ILD), as these disorders provide the most significant diagnostic and management challenges.

Interstitial lung disease

Prevalence

Pulmonary fibrosis (PF) is most prevalent in SSc, forming part of the American Rheumatism Association minor diagnostic criteria for SSc.[1] Lung function impairment is seen in up to 90%, chest radiography abnormalities in 25–65%, with high-resolution CT (HRCT) identifying many patients with subclinical disease.[2] Estimates of clinically significant SSc-PF approximate 30%, with many patients experiencing disabling breathlessness. ILD is also frequent in PM/DM, with at least 30% of patients having clinically overt disease.[3] Clinically important ILD is uncommon in RA, although lung diffusing capacity (DL_{CO}) is reduced in 40%. Less than 5% of SLE patients have clinical or chest radiographic evidence of ILD at presentation and a further 5% develop progressive ILD during follow-up. Clinically overt ILD approximates 10% in primary SS, although 35% have CT abnormalities, and there is a high prevalence of respiratory symptoms, especially cough.[4] AS is frequently associated with limited non-specific CT abnormalities, but clinically significant upper zone fibrobullous disease is rare. In summary, clinically significant PF occurs in approximately 30% of patients with SSc and PM/DM, in 10% with SS, and in less than 5% with SLE or RA, with a much higher prevalence of subclinical disease in all of these disorders.

Aetiology and predisposing factors

There are genetic associations with ILD in SSc (HLA DR3, 52a) and RA (HLA-B8 and HLA-Dw3). Genetic predilections are amplified by the autoantibody status. In PM/DM, significant ILD is often seen with the anti-synthetase syndrome, associated with aminoacyl tRNA synthetases including Jo-1. In RA, ILD is associated with high rheumatoid factor titres. In SSc, titres of anti-topoisomerase (ATA) and anti-centromere (ACA) antibodies are a strong determinant of lung and pulmonary vascular disease respectively.[5] Smoking is

a risk factor for the development of overt ILD in RA. Other extrinsic triggers, such as rapeseed cooking oil denatured with aniline in SSc, may be cofactors for the development of pulmonary disease.

Pathogenesis

The pathogenesis of PF has been most extensively studied in SSc; a widely accepted model is that the accumulation of connective tissue in the lung is autoimmune, with environmental factors triggering initial alveolar epithelial cell injury and a subsequent amplification of the immune and inflammatory response in genetically susceptible individuals.[6] Mediators including transforming growth factor beta, tumour necrosis factor alpha (TNFα), connective tissue growth factor, and a T-helper cell 1 (Th1) to Th2 cytokine shift, promote a profibrotic microenvironment. The ATA antibody may have an immunopathogenetic role.

Pathology

Histological appearances can be broadly subdivided into fibrotic and inflammatory abnormalities. The fibrotic histological patterns of ILD in the CTDs are usual interstitial pneumonia (UIP) and non-specific interstitial pneumonia (NSIP). UIP is characterized by heterogeneous thickening of alveolar walls by inflammatory and connective tissue matrix cells, type II pneumocyte proliferation, and vascular obliteration; the disease is maximal subpleurally and basally with evolution to honeycombing in advanced disease. In NSIP, there is a more homogeneous distribution of septal inflammation and fibrosis, with a basal predominance. In SSc, fibrosing NSIP and, less frequently, cellular NSIP predominate. There is no difference in survival between NSIP or UIP subgroups, in contrast to outcome differences in idiopathic disease.[7] In RA, UIP is slightly more prevalent than NSIP, with prominent peribronchiolar lymphoid follicles a frequent finding. Fibrotic disease in PM/DM and SS almost always has a pattern of fibrotic NSIP. Clinically significant chronic irreversible disease is rare in SLE with anecdotal reports suggesting that fibrotic NSIP predominates.

In RA and PM/DM, inflammatory lung disease most often takes the form of organizing pneumonia (OP), consisting histologically of plugs of granulation tissue in the air spaces distal to and including the terminal bronchioles, associated with lymphocytic infiltration. OP presents with multifocal consolidation, a restrictive functional defect, and is usually responsive to corticosteroids. However, the good prognosis with treatment seen in cryptogenic OP is not invariable in the CTDs as supervening fibrosis is not infrequent.

Other forms of inflammatory interstitial disease are less frequent. Lymphocytic interstitial pneumonitis (LIP) is reported in RA and PM/DM, but is more prevalent in SS. In general, in SS, lymphocytic interstitial infiltration is the usual form of interstitial inflammation, ranging from LIP (characterized by a diffuse lymphocytic infiltrate, prominent around bronchioles), through pseudolymphoma (with the formation of lymphoid follicles) to pulmonary lymphoma.

Rare but clinically important histological patterns exist in CTD lung disease. Acute interstitial pneumonia (AIP), an accelerated course of ILD, with the histological features of diffuse alveolar damage, is seen most often in PM/DM. Diffuse alveolar damage may also contribute to the poor outcomes seen in some patients with the entity of 'acute lupus pneumonitis', occurring in up to 2% of SLE patients. In AS, histological appearances consist of a variable admixture of lymphocytic infiltration, fibrosis and bullous change.

Prognosis

In SSc and PM/DM, pulmonary disease (including ILD, aspiration pneumonitis, and pulmonary vascular disease) is now the most common cause of death. In SSc, ILD is associated with a 30% 10 year mortality rate, and is usually most progressive within 4 years of the onset of systemic disease: however, a significant subgroup of patients with subclinical or mild lung involvement remain stable during prolonged follow-up. In PM/DM, ILD carries a 5 year survival of 60–85%; the clinical course of these patients tends to be dominated by pulmonary disease.[8] AIP has a mortality of over 50%, once respiratory failure has supervened. In general, severe pulmonary involvement identifies progressive disease with a poor outcome; for example, in RA with PF requiring hospitalization, the 5 year survival is less than 50%.

Fibrobullous disease

Although rare, ILD confined to the upper zones is a well-described feature of AS. Cavities within distorted fibrotic apical tissue may be colonized by mycobacteria or fungi. An increased prevalence of pneumothorax probably reflects subpleural bullous degeneration. Apical fibrosis is rarely seen in RA and MS, but localized apical bulla formation and emphysema is a more prevalent and striking finding in MS, associated with a high (5–10%) prevalence of pneumothoraces.[9]

Pulmonary infection

The CTDs have an increased prevalence of pulmonary infection, due to lowering of host defences both by the presence of the systemic disease, and by immunosuppressive treatments. Bronchopneumonia is a common terminal event in RA and PM/DM, accounting for 15–20% of deaths in RA.

Gram-negative bacterial infections, including *Klebsiella pneumoniae*, *Escherichia coli*, and *Pseudomonas aeruginosa*, are more frequent in the CTDs, and infection with *Legionella* spp. is more frequent in the immunosuppressed patient. Fungal colonization, especially *Aspergillus fumigatus,* is common in fibrocavitary lung disease. Mycetoma are often asymptomatic and do not require specific therapy, but life-threatening haemoptysis may require bronchial artery embolization. Surgical resection is generally contraindicated, as the postoperative complication rate is very high. Mycobacterial infections are seen in patients with CTDs, and are characterized by lung infiltrates, multifocal nodularity, and small airways exudates on CT, and often require bronchoscopy for diagnosis. New widespread ground-glass opacification in an immunosuppressed patient should raise the possibility of *Pneumocystis jirovecii* or viral infection.

Aspiration pneumonia is seen most frequently in PM/DM and is associated with a marked increase in mortality. It occurs in 20% of patients and should always be suspected when pneumonia occurs in a patient with dysphagia due to pharyngeal muscle weakness.

The high prevalence of pneumothorax in MS of 5–10%, which are often recurrent and bilateral, is ascribable to the rupture of subpleural bullae; emphysema is evident on chest radiography in the majority of Marfan's patients with pneumothoraces.

Pulmonary nodules

Pulmonary nodules may be associated with underlying CTD, but malignant disease must always be considered. Pulmonary

rheumatoid nodules, present in over 20% of patients with RA, may be single or multiple, are often peripheral, are usually associated with extrapulmonary rheumatoid nodules, and vary in size depending on RA activity (sometimes simulating a malignant growth pattern). Complications include nodule cavitation and pneumothorax. In Caplan's syndrome, single or multiple variably cavitating nodules are associated with coal miner's pneumoconiosis.

DM is associated with an increased prevalence of malignancy, with systemic disease rsometimes representing a paraneoplastic phenomenon; recent studies have indicate that the prevalence of lung malignancy was previously overstated.[10] However, there is undoubtedly an increased risk of lung malignancy in association with PF, first described in idiopathic ILD, independent of the risk conferred by smoking. The likelihood of malignancy is increased if nodule diameter is greater than 10 mm.

Pseudolymphoma masses may arise in primary SS patients with prominent lymphocytic infiltration and often responds well to corticosteroid therapy; however, progression to pulmonary lymphoma occurs with a prevalence of 1–2%.

Wegener's granulomatosis is often associated with pulmonary nodules, which may be multiple, rapidly enlarge, and cavitate. The differential diagnosis for cavitating pulmonary nodules includes malignancy and pulmonary abscesses.

Bronchiectasis and large-airway disease

Bronchiectasis, characterized by bronchial wall inflammation and dilatation, is most prevalent in RA (and unusual in other CTDs), and may precede the development of systemic disease. It is often clinically silent, and usually less disabling than idiopathic bronchiectasis. However, in a minority of RA patients, bronchiectasis is associated with progressive airflow obstruction and recurrent infective exacerbations. The prescription of immunomodulatory drugs for systemic disease further complicates management.

Xerotrachea occurs in 25–50% of patients with primary SS and consists of atrophy of tracheobronchial mucous glands in association with a lymphoplasmocytic infiltrate, manifesting clinically as a relentless dry cough, and may be associated with bronchial hyper-responsiveness, to be differentiated from asthma. Relapsing polychondritis is associated with thickening of the tracheal rings and tracheal or airway collapse on inspiration, best appreciated on a flow–volume loop or dynamic CT. Approximately 10% of deaths are respiratory, generally resulting from airway stricture, collapse and distal infection.

Bronchiolitis

Bronchiolitis may be classified as obliterative (OB) or follicular (FB). The cardinal features of OB are infiltration of the bronchiolar wall by granulation tissue, effacement of the lumen, and eventual replacement of the bronchiole by fibrous tissue. Most cases of OB in CTDs occur in RA, although the prevalence of OB in RA is low. Small-airway disease tends to be clinically silent until advanced, and is often admixed with interstitial lung disease. OB may be associated with rapidly progressive airflow obstruction which is often unresponsive to corticosteroid treatment.

FB is a rare disorder, characterized by external compression of bronchioles by hyperplastic lymphoid follicles, and variable lymphocytic infiltration of the bronchiolar wall, occurring most frequently in SS. Clinically significant isolated FB is rare in RA but

its recognition is important because a response to corticosteroid therapy is more likely than in other forms of bronchiolitis.

Pleural disease

Pleural disease is common in RA and SLE. Pleural effusions (representing a serositis) are the most common pulmonary complication in RA, and are often asymptomatic, although pleuritic pain is present at some time in at least 20% of patients.[11] Aspiration is often required to exclude infection or malignancy. The pleural fluid is exudative, with reduced glucose levels and pH and a lymphocytosis, therefore if empyema is clinically suspected, management often relies upon microbiology as traditional fluid markers are less discriminatory for infection.

Overt pleural involvement is present in 20% of patients with newly diagnosed SLE; pleural abnormalities are found at autopsy in 50–100%. The fluid is usually serosanguinous, exudative, and neutrophilic during acute pleurisy, and lymphocytic in chronic effusions. The histological appearance of fibrinous pleuritis is non-specific.

Chest wall disease

In SLE, the 'shrinking lung' syndrome, characterized by elevation of the hemidiaphragms and basal atelectasis, results from extrapulmonic restriction,[12] with exertional dyspnoea and a restrictive ventilatory defect associated with relative preservation of DL_{CO} and elevation of the transfer coefficient (K_{CO}). The shrinking lung syndrome is usually self-limited. By contrast, respiratory muscle weakness resulting from myositis may progress to hypercapnic respiratory failure, although this is seen in less than 5% of PM/DM patients. Immobilization of the chest wall is common in AS, but is often clinically silent, with surprisingly preserved pulmonary function. Chest wall deformities may be striking in MS, although isolated pectus excavatum is usually asymptomatic. Extrapulmonic restriction in SSc may be due to severe scleroderma of the chest wall, leading to respiratory failure.

Pulmonary vascular disease

Pulmonary vascular disease in the CTDs may take the form of isolated pulmonary arterial disease, pulmonary vasculitis, thromboembolism, or pulmonary artery aneurysms (in Beçhet's syndrome) and may also result from vascular ablation due to extensive interstitial lung disease.

Pulmonary arteriolar hypertension occurs most commonly in SSc, with concentric arteriolar fibrosis with ablation of the intima and media, and clusters with limited cutaneous SSc and the ACA antibody. It is associated with a high mortality, accounting for a 5 year survival of less than 10% in patients with DL_{CO} levels of less than 40% of predicted.

Pulmonary hypertension was once regarded as rare in SLE but is now increasingly recognized. Vasoconstriction is likely to play a greater pathogenetic role than pulmonary vasculitis, together with recurrent thromboembolism in patients with anti-phospholipid antibodies.

Pulmonary capillaritis resulting in diffuse alveolar haemorrhage (DAH) is seen much more frequently in SLE than in other CTDs; it occurs in only 2% of SLE patients, but is responsible for over 20% of SLE hospital admissions, and is often life-threatening, with a mortality of over 50%.

Drug-induced pulmonary toxicity

Methotrexate-induced interstitial pneumonitis is the most frequently encountered drug-induced pulmonopathy encountered in the CTDs, with a prevalence of approximately 5%, in treated RA patients.[13] Methotrexate pneumonitis is potentially life-threatening with a mortality of 15–20%, presenting with cough, dyspnoea, fever, widespread crackles, a restrictive functional defect, and pulmonary infiltrates, and should always be suspected in the treated patient presenting with progressive lung disease. Peripheral eosinophilia is seen in 50%. Although sometimes explosive, the onset is more often subacute over many weeks, and the majority of cases are diagnosed within 4 months of starting methotrexate. The clinical, radiological, and histological findings are not diagnostic, although features of a hypersensitivity pneumonitis with lymphocytic infiltration are common. Whether pre-existing lung disease predisposes to methotrexate lung is uncertain; conflicting published data suggests that functional impairment is a relative but not an absolute contraindication to the use of methotrexate. Particular caution is warranted when pulmonary reserve is grossly compromised, and patients with previous methotrexate toxicity should not be rechallenged.

Pulmonary toxicity has also been documented with non-steroidal anti-inflammatory agents (NSAIDs), sulfasalazine, gold therapy, penicillamine, and anti-TNF agents. OP associated with sulfasalazine is rare and occurs most commonly in the upper lobes. Lung infiltrates induced by gold are often associated with fever or skin rash, and a bronchoalveolar lavage (BAL) lymphocytosis. Penicillamine has been implicated in the development of OB in RA, and has also induced hypersensitivity pneumonitis as well as a pulmonary–renal syndrome manifesting most commonly as DAH. Most patients with pulmonary toxicity respond well to withdrawal of the agent and corticosteroid therapy.

Investigation of lung disease

Pulmonary function tests

Spirometric measures of FEV_1 (forced expiratory volume in 1s) and FVC (forced vital capacity) are simple screening tools; an FEV_1/FVC ratio of less than 70% reflects obstructive airways disease, whereas a ratio of more than 80% reflects restrictive lung pathology including interstitial and chest wall disorders. The carbon monoxide gas transfer (DL_{CO}) is reduced in disorders that impede the efficacy of transfer of soluble gases from alveolus to capillary, including interstitial fibrosis, pulmonary hypertension, pulmonary embolic disease, emphysema, and anaemia. The most typical patterns of functional impairment in unselected patients with connective tissue disease are an isolated depression of gas transfer (reflecting subclinical interstitial involvement or pulmonary vascular disease) and, less frequently, a restrictive defect, due to overt PF.

ILD is characterized by a restrictive ventilatory defect and a reduction in DL_{CO}; in SSc, baseline DL_{CO} of less than 50% or FVC of less than 55% is unequivocally significant in the ILDs.[14] DL_{CO} alone does not discriminate between ILD severity and the presence of pulmonary hypertension, but the combined assessment of DL_{CO} and FVC can discriminate: in isolated pulmonary hypertension, a very low DL_{CO} is often associated with a normal FVC.

Airflow obstruction may denote smoking-related lung damage, bronchiectasis, or bronchiolitis. Extrapulmonic restriction, due to pleural or chest wall disease, often mimics the functional consequences of ILD, but there is relative preservation of DL_{CO}. Respiratory muscle weakness may be assessed by lying and standing FVC, although mouth pressures are more sensitive. Marked elevation of both DL_{CO} and K_{CO} is a pathognomonic finding in DAH if measured within 36 hours.

Serial pulmonary function tests are central to monitoring progression of disease, defined as a fall of more than 10% in predicted FVC or more than 15% in DL_{CO} from baseline values. In SSc-associated ILD, serial DL_{CO} assessment over 3 years appears to be predictive of survival.[7]

Chest radiology

Plain chest radiograph (CXR) confidently diagnoses consolidation, large pulmonary nodules, and pleural effusions, but often underestimates the ILD severity. An apparently normal chest radiograph should not inhibit the further investigation of symptomatic patients.

High-resolution CT (HRCT) has revolutionized the approach to ILD, owing to its high sensitivity and good correlation with the underlying histological appearance.[15] In fibrotic NSIP (common in SSc and PM/DM; Figure 20.1A), lower zone ground-glass
Fig. 20.1 CT images in CTD associated interstitial lung disease: (A) A fibrosing non-specific interstitial pneumonia (NSIP) pattern is commonly seen in SSc, with evidence of ground-glass and traction bronchiolar dilatation. (B) A usual interstitial pneumonia (UIP) pattern is more prevalent in RA, with basal subpleural honeycombing on CT.

attenuation is associated with reticulation and traction bronchiectasis, indicating fine intralobular fibrosis. In a minority of patients with cellular NSIP, ground-glass attenuation without traction bronchiectasis may predominate. A UIP pattern, common in RA, is characterized by peripheral, basal reticulation and honeycombing, without substantial ground-glass attenuation (Figure 20.1B). An admixture of OP and fibrosis is commonly seen in PM/DM, and other disease processes are often evident, especially bronchiolitis and bronchiectasis (in RA) and pleural disease (in RA and SLE).[16] The cardinal CT feature of OP is patchy bilateral airspace consolidation, which is often subpleural but occasionally bronchovascular. By contrast, OB is characterized by areas of mosaic attenuation, due to both bronchiolitis and regional hypoxic vasoconstriction. In SS, subclinical abnormalities are commonly evident on CT, including airways disease, ground-glass attenuation, reticular abnormalities, and patchy consolidation.

A simple CT staging system for ILD in SSc determines the overall disease extent as greater or less than 20%, and this is highly discriminatory of outcome, with extensive disease (>20%) predictive of mortality. When HRCT findings are difficult to classify using this approach, an FVC threshold of 70% of predicted normal values is used to classify disease as extensive or mild. This simple system aids the selection of a higher-risk patient for potentially toxic therapies.[17]

Nuclear medicine techniques

The clearance of radiolabelled diethylene triamine pentacetate clearance($^{99\,m}$ Tc-DTPA) detects subclinical ILD and may be used to evaluate prognosis in SSc, but it is not available in many centres. In SSc, rapid $^{99\,m}$ Tc-DTPA clearance denotes loss of epithelial cell integrity; persistently rapid clearance identifies an increased risk of subsequent deterioration.[18]

Bronchoalveolar lavage

BAL is invaluable in the exclusion of infection, particularly opportunistic pathogens, in an immunosuppressed patient with lung infiltrates. However, recent data have failed to validate the historical observation that a BAL neutrophilia in SSc is associated with a much worse outcome. Thus, BAL has only a limited role in routine prognostic evaluation.[19]

Lung biopsy

Transbronchial lung biopsy is often used to confirm the presence of OP but cannot reliably discriminate between fibrotic patterns of disease. CT guided biopsy is often used to sample peripheral lung nodules, particularly to exclude malignancy. Surgical lung biopsy is seldom required in the investigation of ILD in the CTDs, as distinctions between patterns of fibrotic disease carry little prognostic significance in SSc[7]—although there are inconclusive data suggesting that UIP may have a worse outcome than NSIP in RA. In general, surgical biopsy should be considered only when disease is clinically significant and HRCT appearances are atypical.

Vascular studies

Doppler echocardiography is often used to detect pulmonary hypertension; estimated pressures correlate with measurements of pulmonary artery pressures made at right heart catheterization, and right ventricular dilatation or hypertrophy may suggest pulmonary hypertension in the absence of a tricuspid regurgitant jet.

Screening for pulmonary disease

Screening for lung disease has an important role in the CTDs, both to identify early disease, and to assess the impact of potentially pneumotoxic immunosuppression. In general, those CTDs with a high prevalence of PF (SSc, PM/DM) should be screened with lung function and CXR at diagnosis, with a low threshold for CT if abnormalities are detected. Screening with PFTs in CTDs with a low prevalence of ILD (SLE, SS, AS) should probably be reserved for those with respiratory symptoms or CXR abnormalities. Screening in RA is more difficult to define, as there is a relatively low prevalence of clinically significant ILD. However, many therapies used in RA cause pulmonary toxicity and we therefore advocate a screening regimen akin to that of SSc. Knowledge of baseline PFT levels allows earlier detection of significant functional decline due to drug-induced lung disease.

Treatment decisions in relation to prognostic evaluation

The prediction of likely natural history is particularly relevant in ILD associated with CTDs. Many patients with ILD have limited disease with minor functional impairment, and remain stable without treatment, whereas a smaller group deteriorate more rapidly and should be treated as early as possible. Predictors of decline are often extrapolated from studies of SSc-associated ILD, where extensive disease on CT or pulmonary function tests, deteriorating pulmonary function tests, and a short duration of systemic disease are major indicators for treatment.[20] The extent of cutaneous disease, the pattern of fibrotic abnormalities on HRCT and biopsy, and BAL cell counts are less useful in determining prognosis or in treatment selection. Pending disease specific analyses, these principles can be applied to treatment decisions in lung disease associated with other CTDs.

Treatment options

Interstitial lung disease in the connective tissue diseases

There is limited trial evidence in the treatment of ILD in the CTDs; trial recruitment has been particularly problematic, because of disease heterogeneity, and variations in the severity and progressiveness of disease. In many studies, there is no clear distinction between regression of disease and prevention of progression, now accepted to be a positive outcome in predominantly fibrotic disease. The treatment of ILD in SSc has been most widely evaluated. High-dose corticosteroid therapy is not efficacious and may trigger scleroderma renal crisis.[21] Daily treatment with oral cyclophosphamide(2 mg/kg per day) for 1 year was associated with a small statistically significant benefit in FVC in a placebo-controlled randomized controlled trial (RCT),[22] but this effect was short-lived, suggesting that prolonged treatment is required.[23] In a smaller RCT, intravenous cyclophosphamide (600 mg/m^2 monthly), followed by oral azathioprine (2.5 mg/kg per day), in combination with low-dose prednisolone (e.g. 10 mg/day), conferred marginal FVC benefits at 1 year.[24] Taken together, these studies provide conceptual support for the widespread use of immunosuppressive therapy in clinically significant SSc-associated ILD, despite the relatively small effect on FVC levels. However, the low average magnitude of effect in these RCTs underlines the need to validate other treatment approaches, including the use of novel antifibrotic agents. Small retrospective studies of mycophenolate mofetil suggest a possible role but prospective

evaluation is required.[25] Autologous haematopoietic cell transplantation following immunoablative high-dose immunosuppression is being evaluated in European and US trials.[26] CD20-positive B-cell depletion with rituximab had a positive impact on lung function in an open-label RCT,[27] and our experience suggests that it is useful in rapidly progressive lung disease in CTD. A recent RCT evaluation established that endothelin antagonism did not influence the likelihood of clinically significant worsening.[28]

Interstitial lung disease associated with polymyositis/dermatomyositis

Uncontrolled reports suggest that high-dose corticosteroid therapy is more efficacious in PM/DM-associated ILD, reflecting the greater prevalence of OP, even when fibrotic disease is present. If the ILD is of moderate severity, a second-line agent (usually azathioprine, mycophenolate mofetil, or methotrexate) is often added to steroid therapy. However, disease is fulminant in a minority of cases with a mixture of OP and diffuse alveolar damage and high-dose intravenous methylprednisolone (1 g/day for 3 days) and cyclophosphamide may be required, with variable efficacy.[29] Retrospective studies have suggested a favourable outcome with rituximab in the anti-synthetase syndrome.[30]

Interstitial lung disease in rheumatoid arthritis

The treatment of ILD in RA suffers from an extreme paucity of outcome data. Historically, high doses of oral corticosteroids have been used, with the addition of an immunosuppressive agent (in particular azathioprine) as steroid therapy is reduced in selected patients, based upon disease severity and progressiveness.[31] The impact of T- and B-cell modifying therapies on rheumatoid-associated ILD is currently unclear.

Organizing pneumonia and drug-induced lung disease

High-dose corticosteroid therapy is usual in OP and drug-induced lung disease. However, especially in patients with OP, supervening fibrotic disease is not uncommon, with second line agents not infrequently required to prevent disease progression. Similarly, in LIP with SS, a good response to corticosteroid therapy is frequent but not invariable and there are no definitive therapeutic trials. In explosive ILD (diffuse alveolar damage, acute lupus pneumonitis, DAH, severe non-haemorrhagic vasculitis), there is no option but to intervene aggressively after infection has been rigorously excluded, usually with intravenous methylprednisolone and early use of cyclophosphamide; however, this empirical approach is based solely upon anecdotal responses. Pneumonitis due to drug toxicity generally responds well to withdrawal of the offending agent and corticosteroids, provided that fibrosis has not supervened.

Bronchiolitis

Regression of disease rarely occurs in OB with corticosteroid or immunosuppressive therapy; whereas disease stabilization or regression with therapy is seen in FB. A trial of corticosteroids is warranted in symptomatic pleural disease in RA or SLE: some patients with rheumatoid effusions respond well and a good outcome is seen in SLE, although prolonged treatment may be required. Somewhat surprisingly, steroid responsiveness has been documented in the shrinking lung syndrome of SLE.

Pulmonary vascular disease

Intervention in pulmonary vascular disease is complicated by the multiplicity of possible pathogenetic mechanisms. Treatment of SSc-associated pulmonary arteriolar hypertension includes anticoagulants, diuretics, supplemental oxygen, synthetic prostacyclins, endothelin-1 antagonism, and phosphodiesterase inhibitors, and is reviewed elsewhere.[32] In other CTDs, especially in SLE and mixed connective tissue disease, PAH may respond to corticosteroid or immunosuppressive therapy.

Bronchiectasis

The management of bronchiectasis mirrors that in the general population, namely regular sputum clearance with physiotherapy, and aggressive (microbiology guided) treatment of infective exacerbations (10–14 days). Inhaled bronchodilators and corticosteroids may be useful in alleviating airflow obstruction in bronchiectasis.

Lung transplantation in endstage interstitial lung disease

In endstage ILD, lung transplantation for systemic disease remains controversial. A recent series reports transplant outcomes to be similar in SSc and idiopathic ILD, although increased acute rejection rates were seen in SSc.[33] In many centres, aggressive connective tissue disease is regarded as an absolute contraindication to transplantation. In terminal disease, the need for regular oxygen therapy and treatment of supervening heart failure and infection are the primary therapeutic considerations.

In summary, the decision to treat many pulmonary complications of the CTDs is multifaceted and difficult, and requires a multidisciplinary approach with close interaction between the rheumatologist and respiratory physician.

Conclusion

Lung involvement occurs frequently in the CTDs, but in many patients pathological processes are self-limited and subclinical. Clinically significant lung disease often consists of an admixture of interstitial, airway-centred, vascular, or pleural processes. Careful evaluation allows the clinician to identify the predominant pathophysiological process, stage disease severity, estimate the likely prognosis, select treatments most likely to be efficacious, and choose the most appropriate investigations to monitor disease progression.

CHAPTER 21

Gastrointestinal system

Gerhard Rogler

Intestinal mucosa as an immune organ

The gastrointestinal (GI) tract represents the largest barrier between the human body and the environment, with a surface area of up to 400 m^2. Its lining is an epithelial monolayer, representing a very thin physical barrier. Below this epithelial layer, separated by a basal membrane, the lamina propria contains antigen-presenting cells (APCs) as well as lymphocytes.[1] The lamina propria substantially contributes to the barrier function of the intestinal mucosa.[2] APCs from the lamina propria form podocytes reaching through the basal membrane to the epithelial cells and even into the gut lumen.[3]

Under normal conditions the intestinal immune system mediates tolerance to our commensal flora. In inflammatory bowel disease (IBD), this tolerance is broken.[4] Genetic factors have been identified in 30–40% of IBD patients causing susceptibility for these diseases. Many of the susceptibility factors play an important role in the recognition of bacterial antigens (pattern recognition receptors, PRRs) and have functions in innate immune defence.[5]

The adaptive immunity in the GI tract is mediated by gut-associated lymphoid tissue (GALT). Morphologically this is composed of the Peyer's patches (PP), the lymphoid aggregates and lymph follicles of the intestinal wall and the mesenteric lymph nodes. In addition, B and T cells are scattered throughout the mucosa.[6] The mucosa-associated lymphoid cells can be divided into two phenotypic and functionally different cell populations: lamina propria lymphocytes (LPL) and intraepithelial lymphocytes (IEL).

The LPL constitute the largest portion of lymphocytes in the intestinal mucosa. In the lamina propria T lymphocytes clearly outweigh B lymphocytes and plasma cells. They consist to 95% of αβ T cells, which can be subdivided into CD4+ and CD8+ T cells. CD4 cells are two to four times as frequent as CD8 cells.[6] In contrast, IEL consist mainly of γδ CD8+ T cells, which differ morphologically and functionally from the LPL. They suppress inflammatory reactions and are tolerogenic.

In mouse models it is possible to discriminate clearly between Th1 cells, secreting proinflammatory cytokines such as IL-12, and Th2 cells, secreting a more anti-inflammatory pattern such as IL-4 or IL-10, but this much harder in human mucosa. None of the human inflammatory intestinal diseases can be described as a pure Th1- or Th2-mediated inflammation.

Regulatory T cells can also be found in the intestinal mucosa. The anti-inflammatory, 'regulatory' effect of those cells is attributed to the high production of IL-10. Regulatory T cells are in principle able to control or prevent intestinal inflammation, due to their immunosuppressive characteristics.[7]

Since its discovery, the Th17 cell population has attracted the attention of gastroenterologists.[8] This subgroup of T cells, which expresses the cytokine IL-17 in large amounts, plays an important role for the chronification of intestinal inflammation. Th17 cells may induce and maintain a chronic colitis independent of Th1 cells.[8] In animal models IL-17 secretion in the intestine is followed by production and secretion of chemokines, which recruit further inflammatory cells. The induction of Th17 cells is induced by several recently described interleukins such as IL-23, which therefore also can be regarded as pathophysiological relevant factors. IL-23 is secreted by APCs in the mucosa.[8] Interestingly, polymorphisms in the IL-23 receptor are associated with the risk of developing IBD.[9]

The GI tract contains three times as much immunoglobulin-producing plasma as the spleen, lymph nodes, and bone marrow combined.[10] In addition, mucosal mast cells have been shown to play an important role in chronic intestinal inflammation.

IEL are normally found in the epithelial layer, in a ratio of 5 lymphocytes to 100 enterocytes. They have regulatory functions. However, in coeliac disease IEL are a histological hallmark of inflammation and a diagnostic marker; they contribute to disease pathogenesis and epithelial damage.

T-cell-mediated and humoral immunity are controlled and regulated by GI hormones and the innate immune system. In turn, they affect physiological GI functions such as transport, permeability, and contractility. APCs in the GI mucosa activate the lymphatic cells via the secretion of cytokines such as tumor necrosis factor (TNF), tissue growth factor beta (TGFβ), interferon gamma (IFNγ), IL-23, and IL-10.[11]

In the intestine IgA is the dominant immunoglobulin secreted into the gut lumen. The secretory IgA differs from serum IgA.[10] The oral uptake of soluble antigens may induce an inability to produce systemic antibody or a T-cell-mediated reaction to parenteral stimulation with the same antigen, a phenomenon called oral tolerance.[7] An important aspect of oral tolerance is the suppression of immunological reactions against food antigens.[7] Secretory IgA and IgM are bound via cysteine residues to the mucus secreted on the apical side by epithelial cells to form a so-called 'unstirred layer' which is a part of the GI barrier. The penetration of potentially dangerous antigens into the organism is prevented by binding them on the surface of the mucus layer.

Immunomediated gastrointestinal diseases with rheumatological manifestations

Inflammatory bowel diseases

The IBDs can be divided into Crohn's disease (CD) and ulcerative colitis (UC) as well as a non-classifiable colitis (indeterminate colitis or 'colitis not classified'). Other forms of chronic mucosal inflammation such as lymphocytic, eosinophilic, and collagenous colitis are relatively rare but with increasing incidence in recent years. IBD is most frequently diagnosed between 20 and 30 years of age.[12]

CD may affect the entire intestinal tract, with a clear preference for the terminal ileum and/or the large intestine. CD is a transmural, partially granulomatous inflammation, which may involve the serosa and regional lymph nodes. Affected gut segments are discontinuous, and distant parts of the mucosa may be involved. UC is limited to the mucosa of the large intestine. It always involves the rectum and shows variable extension to the left-sided or entire colon. If only the rectum is involved the disease is called ulcerative proctitis; if the whole colon is involved, it is termed pancolitis. Typical histological changes may be found, but are not obligatory for diagnosis. For both types of IBD the diagnosis is made by clinical criteria integrating histological, biochemical, clinical, endoscopic, and radiological findings.

The prevalence of IBD in Europe is around 40–50 cases per 100 000 inhabitants; the incidence is 4–6 new cases per year per 100 000 inhabitants.[12] In most epidemiological studies UC is found more frequently than CD.[12] Gender distribution is largely balanced. In Europe a north–south gradient has been reported; both diseases are more frequent in northern Europe than in southern Europe.[13] IBD is clearly more frequent in countries with a 'Western' lifestyle than in other regions of the world.[12]

The aetiology of IBD is still only partially understood. There is no doubt that genetic susceptibility is an important factor. About 20–30% of IBD patients have a positive family history, and monozygotic twins more frequently develop IBD than heterozygotes.[12] The pathogenesis of CD and UC involves a complex interaction of genetic risk factors (polygenic aetiology) with immunological and environmental factors. In 2001 the first risk gene for CD was identified: 20–30% of all patients with CD carry one of three single nucleotide polymorphisms (SNPs) in a CAspase Recruitment Domain (CARD)-containing protein called NOD2. Muramyl dipeptide (MDP), a component of the bacterial cell wall, is the ligand for Nod2. Many genome-wide association studies (GWAS) have been performed, increasing the number of further genetic susceptibility factors to up more than 70 in CD and more than 30 in UC.[14] Relevant genetic risk factors were identified in components of the autophagosome, which processes intracellular bacteria and contributes to their recognition and destruction by the proteins ATG16L1 and IRGM.[14] A number of risk genes are shared between IBD and rheumatologic diseases, such as *PTPN2* or *PTPN22*.[15]

Epidemiological data support an important pathogenic role of environmental factors. People with a higher socio-economic status are at higher risk of developing IBD. A number of studies point to the fact that an increased risk of suffering from IBD is associated with higher hygiene standards.[16] An increased risk for CD and a worse disease course is found in smokers. In contrast, smoking appears to be 'protective' for UC.[16]

Genetic and environmental factors induce a defect of the mucosal barrier function.[7] In the phase of chronification of the inflammation, excessive activation of the intestinal immune system occurs.[7] In a cascade-like reaction, via secretion of cytokines as well as chemotactic factors, migration of neutrophils, monocytes/macrophages, and T cells into the mucosa is induced.

The most important symptoms of CD are chronic diarrhoea with or without bloody bowel movements, weight loss, abdominal pain, fever, fatigue, and perianal fistula.[17] They vary according to the extent and site of intestinal involvement. CD is characterized by a fluctuating natural disease activity; the frequency of flares and recurrence is unpredictable and varies markedly in different patients.[17]

The main symptom of UC is bloody diarrhea, frequently associated with abdominal pain. 70% of the UC patients exhibit only a proctitis/proctosigmoiditis or left-sided colitis, and only 30% will have extended disease.[17] Fever and weight loss are less frequent as compared to CD, and are always a sign of severe disease.

Extraintestinal manifestations are frequent in both CD and UC. Rheumatological manifestations are joint involvement (arthralgia or arthritis in up to one-third of patients), oligoarthritis, spondylarthritis, erythema nodosum, pyoderma gangraenosum, uveitis, and iritis.[18] The frequency of peripheral arthritis in IBD has been reported to range between 17% and 20%. Enthesitis has been reported in up to 7% of patients.[19] Two types of peripheral arthritis associated with IBD are discriminated: The type I or pauciarticular form usually is acute and associated with intestinal IBD activity.[20] The joint involvement is asymmetric and both large and small joints may be affected. The arthropathy may even appear before the diagnosis of IBD is made. On the other hand the type II or polyarticular form has a more chronic course, is independent of intestinal IBD activity, and involves mainly small joints in a more symmetric pattern.[20]

Ankylosing spondylitis (AS) and other forms of axial involvement also are frequently found in patients with IBD. AS it is more common in CD (5%–22%) as compared to UC (2%–6%).[19] The prevalence is 10%–20% for sacroiliitis and 7%–12% for AS.[19] Up to 30% of the patients with IBD have inflammatory low back pain, 33% have abnormal Schober index, and 30% have unilateral or bilateral grade I or II sacroiliitis.[19] Axial symptoms may precede gut symptoms. The clinical course of the extraintestinal IBD manifestation is independent of the intestinal disease activity. AS associated with IBD can develop at any age.[19]

In UC patients there is an increased risk for the development of a colorectal carcinoma which depends on the long-term activity and extent of the disease. UC may also be associated with the occurrence of primary sclerosing cholangitis—an autoimmune inflammation of small and large bile ducts which puts patients at a risk of cholangiocarcinoma and increases colonic carcinoma risk.

Investigation and diagnosis

A detailed medical history and physical examinations are of high value for the diagnosis of IBD. The most important diagnostic tool, however, is ileocolonoscopy. In UC it will always result in pathological findings, and a diagnosis can also be made in CD with involvement of the colon and/or the terminal ileum. Usually biopsies are taken during endoscopy, and may reveal typical histological results.

In CD patients, if only the jejunum or the proximal ileum is affected diagnosis may only be possible by MRI, CT, or capsule endoscopy. Ultrasound is a very valuable diagnostic tool; bowel wall thickening is an objective sign of inflammatory activity.

Treatment

During mild or moderate flares of UC, 5-aminosalicylic acid (5-ASA) is the treatment of choice.[21] In distal and left-sided UC topical treatment with suppositories, foam preparations, or enemas has been shown to be more effective than oral (systemic) treatment. If left-sided colitis does not respond to 5-ASA application, steroid therapy should be used.[21] In more extended disease, oral therapy with 5-ASA is the treatment of choice. Sulfasalazine, which is well known in rheumatology and also useful in the presence of joint manifestations, is used less frequently these days mainly because of its side effects such as fatigue, abdominal pain, and gastroesophageal reflux disease (GERD).

In more severe disease courses, or in case of a lack of response to first line therapy, oral or intravenous administration of steroids, e.g. 40–100 mg prednisolone equivalent, with consecutive dose tapering is necessary.[21] In steroid-refractory cases the administration of ciclosporin or anti-TNF antibodies has been proven to be effective. Thus colectomy can be avoided in the long term in approximately 50% of these severely ill patients.[21] Long-term immunosuppression with azathioprine or anti-TNF antibodies must be discussed with respect to the option of colectomy, which in many centres can be done laparoscopically.

After remission is achieved it can be maintained by administration of 5-ASA. In more severe cases, and after induction of remission by steroids, azathioprine may be useful (2–2.5 mg/kg bw).

Several studies have confirmed that administration of oral steroids during acute flares of CD can induce remission. The response rate to steroid therapy is around 70–80%.[22] In chronically active and steroid-refractory patients, azathioprine (2–2.5 mg/kg per day) is effective. The administration of methotrexate induces remission in more than 40% of patients. Anti-TNF antibodies are very effective in refractory and more severe CD.[22] Infliximab, adalimumab, and certolizumab pegol have similar efficacy.[22] Azathioprine is also able to maintain remission.

Gluten-sensitive enteropathy (coeliac disease)

Gluten-sensitive enteropathy or coeliac disease is characterized by an atrophy of the duodenal and small intestinal villi, which is accompanied by the typical symptoms of malabsorption.[23] Characteristically the clinical and histological changes disappear under a gluten-free diet and typically recur within 2 years of re-exposure to gluten.[23] An important pathogenic factor for this disease is a 31-amino-acid peptide of gluten that cannot be digested or degraded by the proteases of the human GI tract. It is presented to T cells via a specific MHC II molecule (HLA-DQ 2/8); this HLA type is present in a quarter to a third of the European population. The prevalence of coeliac disease is up to 1% of the population in European countries.

Coeliac disease is frequently found in familial clusters. An IgA deficiency predisposes for its occurrence.[23] Very different prevalence and incidence rates have been reported, with the highest incidence in northern Europe (e.g. Finland). With the help of serum markers, which may be more sensitive than the clinical activity, a prevalence ranging from 1:250 to 1:100 was found in Europe.[23]

Although there is a clear familial predisposition for coeliac disease, the inheritance pattern does not follow a mendelian pattern, so multigenetic or multifactorial pathogenesis has been assumed.[23] The concordance in monozygotic twins is 75%, and in HLA-identical siblings it is 30%. Genetic risk factors induce an increased susceptibility for sensitization by gliadin. In a next step the formation of auto-antibodies against the enzyme tissue transglutaminase (tTG2) occurs.[23] tTG2 deaminates certain gluten peptides, increasing their affinity for HLA-DQ2 and HLA-DQ8 is. This leads to CD4 Th1 activation, which then initiates mucosal inflammation. Gluten can also activate the innate immune system. γδ T-cell-receptor positive lymphocytes are found in increased number in the periphery.[23]

Coeliac disease and dermatitis herpetiformis are parts of the spectrum of gluten-sensitive enteropathy. The symptoms often begin between the first and third year of life, when the child's nutrition is changed. A second peak of incidence is found in the third decade. The most prominent clinical symptoms are diarrhoea, meteorism, weight loss, fatigue, and symptoms due to deficiency of vitamins or minerals. Several diseases may be associated, such as IgA nephropathy, primary biliary cirrhosis, and sclerosing cholangitis.[23]

Connective tissue diseases are found in 7.2% of patients with coeliac disease, Sjögren's syndrome in 3.3%. Autoimmune thyroid diseases are also reported to be associated.[23]

Because the clinical presentation is frequently uncharacteristic, the histology of duodenal biopsies is important for diagnosis. In several guidelines the determination of IgA antibodies against human tissue transglutaminase is recommended as initial screening test.[24] It is important to quantify total IgA in parallel, as coeliac disease is more frequent in IgA deficiency syndrome.

A completely gluten-free diet is the only and most important therapeutic measure; this means a diet free of wheat, rye, and barley. On such a diet clinical complaints improve within days, and histological normalization occurs within weeks or months.

Chronic atrophic gastritis type A and pernicious anaemia

Chronic atrophic gastritis type A, which involves the gastric corpus and fundus, is followed by a complete atrophy of the gastric glands. Basal neuroendocrine cell complexes and an increase of glandular endocrine cells may be found, as well as autoantibodies against parietal cells and intrinsic factor.[25] A lack of intrinsic factor finally results in vitamin B_{12} malabsorption (pernicious anaemia).[25] Both genetic influences and environmental factors have been found to play a role in the pathogenesis: familiar accumulation and associations with HLA A-3, B-7 and also DR-2 and DR-4 were observed. A discordance in monozygotic twins indicates additional environmental factors.

Gastritis is one of the most frequent diseases of the human stomach: signs of chronic gastritis can be found in 60–70% of the adult population. However, mild forms are usually found and a progression to atrophic gastritis is unlikely.[25] The prevalence of pernicious anaemia in the Western world is about 0.1%.

In chronic atrophic gastritis there is no general disturbance of humoral or cellular immune functions. Circulating autoantibodies against intrinsic factor, parietal cells, and gastrin receptor are detected only if pernicious anaemia develops.[25] Chronic atrophic gastritis type A is not associated with serious symptoms, but associated vitamin B_{12} deficiency as consequence may lead to haematological (macrocytic anaemia) and neurological symptoms (funicular myelosis). Diagnosis is only possible by endoscopy and subsequent histology. Reduced vitamin B_{12} levels add to the diagnosis. The detection of autoantibodies is not sufficient

for the diagnosis, as they can also be found in type 1 diabetes, Hashimoto's thyroiditis, and Addison's disease. Cytotoxic autoantibodies against cell surface antigens of parietal cells have a high disease specificity, but they are not part of routine diagnostics. The therapy of pernicious anaemia consists of parenteral vitamin B_{12} substitution.

Collagenous colitis and lymphocytic colitis

In both forms of microscopic colitis, collagenous colitis and lymphocytic colitis, endoscopic appearance of the colonic mucosa is normal. The diagnosis is based on histological findings and clinical symptoms. In specimens from patients with collagenous colitis a linear layer of collagen is found beneath the epithelium, which consists of type 1 and type 3 collagen.[26] The standard treatment of collagenous colitis is the administration of 5-ASA (3 g/day) or budesonide (3 × 3 mg/day). The time interval from start of therapy to symptom improvement may vary markedly.[26]

In patients with lymphocytic colitis, usually in the entire large bowel, an increased number of intraepithelial lymphocytes in a somewhat flattened epithelial surface can be found histologically, as well as an infiltration with neutrophils and other inflammatory cells.[27] The first line therapy also is based on 5-ASA, but it may be necessary to apply topical or systemic steroids or immunosuppressants if the disease appears to be refractory to steroids.[27] The annual incidence of microscopic colitis seems to be higher than was assumed in the past: incidence rates have been found that are similar to those of Crohn's disease (CD).

The pathogenesis of both forms of microscopic colitis is unknown.[27] Clinically, both forms present with watery diarrhoea in all patients, and more than 80% also have arthritis. The prognosis in general is good. A transformation to ulcerative pancolitis has been reported.

Autoimmune pancreatic diseases

Autoantibodies against antigens of the exocrine pancreas are found in patients with IBD and in patients with Sjögren's syndrome as well as in primary sclerosing pancreatitis (which is very rare).

In addition, a new pancreatitis entity has been described recently: autoimmune pancreatitis.[28] The clinical symptoms are very variable. Severe abdominal or other signs of acute pancreatitis are rare. In two-thirds of cases a 'painless jaundice' occurs. An exocrine dysfunction may be found as well as secondary diabetes. The exocrine dysfunction usually improves or resolves completely after the start of adequate therapy. Imaging may support the diagnosis and can include CT, MRI, endoscopic retrograde cholangiopancreatography (ERCP), and endosonography.[28]

In autoimmune pancreatitis, segmental or relatively long strictures of the pancreatic duct with prestenotic dilatations are typical. Strictures of the common bile duct may also occur. Hypergammaglobulinemia and elevated IgG4 immunoglobulins are very characteristic, although cases without IgG4 elevation have also been described.[28] Symptoms usually rapidly improve upon systemic steroid therapy. Almost all pancreatic changes of can completely resolve under this therapy. A IgG4-associated cholangitis has also been described. An overlap with autoimmune pancreatitis can occur and the two diseases may be hard to discriminate in certain cases.

Rheumatic diseases with intestinal manifestations

Behçet's disease

In 1937 Behçet first described a syndrome with repeated occurrence of oral and genital aphthous lesions together with eye inflammation and occasionally intestinal ulcerations.[29] A familiar accumulation pattern can be found, and an association with certain HLA antigens and with specific unusual immune reactions. Behçet's syndrome is more frequently found in the Mediterranean area.

Therapy includes administration of steroids or, thalidomide (2 × 100–200 mg/day). Colchicine (1 × 0.6 mg/day) and ciclosporin A (5 mg/kg per day) have also been reported to be effective.

The involvement of the gastrointestinal tract is frequently not obvious and only rarely important for diagnosis; only 10% of all patients with Behçet's syndrome are severely affected by gastrointestinal manifestations.[29]

Vasculitis and intestinal inflammation

During the course of vasculitis or rheumatoid arthritis (RA), involvement of the intestinal tract is frequently reported. Ileitis and colitis have been described in the context of SLE, polyarteriitis nodosa, or Henoch–Schönlein purpura, and are occasionally observed with Churg–Strauss syndrome.

Abdominal pain is the most common symptom of gastrointestinal involvement during Henoch–Schönlein purpura. Other symptoms may include nausea or melena. These symptoms are secondary to vasculitis involving the splanchnic circulation (mesenteric vasculitis),[30] and may be confused with typical IBD symptoms. Usually, skin manifestations precede gastrointestinal manifestations, but in one-fourth of cases skin lesions occur after gastrointestinal manifestations.[30] Endoscopic findings are not typical and only histology is diagnostic. Joint involvement is found in about two-thirds of patients. Typically, non-migratory, non-destructive polyarthralgias occur which are symmetrical in distribution and mostly involve the knees and ankles.[30]

Gastrointestinal and hepatic manifestations of rheumatoid arthritis

An enteric origin for various arthritides has frequently been discussed. Similar molecular signatures have been found in intestinal bacteria and synovium or cartilage. Intestinal infections caused by typical pathogens such as *Salmonella* and *Campylobacter jejuni* may be accompanied by joint involvement such as arthritis or arthralgia. However, a clear pathophysiological link has never been established and generally acknowledged.

Non-steroidal anti-inflammatory drugs (NSAIDs), frequently used for the treatment of joint pain in arthritis, may impair the intestinal barrier function. NSAIDS are well known to cause damage to the intestinal mucosa. Diclofenac, ibuprofen, or naproxen may cause flares of IBD within 2 weeks of therapy in up to 25% of treated patients.

In patients with RA undergoing colonoscopy, an inflammation of the terminal ileum is found in up to 11% of cases. When 54 patients with RA underwent ileocolonoscopy and biopsies were taken, 15% of the RA patients had histological signs of inflammation.[31] 20–25%

of RA patients have increased levels of serum IgA correlating with extra-articular symptoms and intestinal abnormalities.[32]

Rheumatoid vasculitis occurs in about 1–5% of patients with RA and up to one-third of those patients will suffer from intestinal involvement.[33] In severe cases patients may suffer from multiple ischemic ulcers and perforations or segmental extensive bowel infarction, sometimes complicated by intraperitoneal haemorrhage.[33]

Gastrointestinal and hepatic manifestations of systemic lupus erythematous

SLE can involve the entire GI tract and the liver. GI symptoms may occur in up to 50% of patients with SLE; they are usually mild.[34] Intestinal pseudo-obstruction is a rare complication and only found with active lupus serology. It preferentially involves the small bowel.[34] Another rare condition, protein-losing enteropathy, characterized by diarrhoea, oedema, and hypoalbuminaemia, may even be the initial presentation of SLE. Associated with coeliac disease, a malabsorption may occur in 9.5%. Pancreatitis appears with an annual incidence of 0.4–1 in 1000. About 10% of patients with autoimmune hepatitis have SLE. On the other hand, 4.7% of patients with SLE have chronic active hepatitis correlating with the presence of antibody to ribosomal P protein.[34]

CHAPTER 22

Neuroendocrine system

Rainer H. Straub

Introduction

Endocrine abnormalities in chronic autoimmune rheumatic diseases (CARDs) are based on an altered systemic neuroendocrine response stimulated by inflammatory stimuli or by direct autoimmune involvement of endocrine glands (the latter is not considered in this chapter). The neuroendocrine–immune interplay serves regulation of energy homeostasis and metabolism. These programmes have not been positively selected for CARDs due to negative selection pressure or lack of selection pressure (Box 22.1).[1]

Evolutionary theory says that genes, signalling pathways, and networks have been positively selected for normal physiology or

<div style="border:1px solid">

Box 22.1 Three major reasons for missing positive selection of disease-modifying genes after outbreak of a chronic autoimmune rheumatic disease (CARD)

- **High negative selection pressure**: CARDs lead to loss of reproducibility because affected individuals are at a disadvantage: excluded or impaired in the competition for food, positions in the group, and sexual partners. In addition, the long-term high inflammatory activity inhibits the hypothalamic–pituitary–gonadal (HPG) axis, leading to impairment of fertility (see below).

- **Absence of selection pressure**. At present, many CARDs only become manifest in patients at older ages. Due to the short life expectancy in the past, our ancestors did not suffer from the CARDs we know today.

- **There has been no time for natural selection**. This situation would occur if various CARDs did not exist some 100–200 years ago. Indeed, there is a suggestion that RA, for example, is a relatively new disease.

Genes whose products operate in the symptomatic phase of CARDs will not be positively selected, because of the negative influence of the disease. Nevertheless, genes can be transmitted before the outbreak of a CARD and persist among descendants. Transmitted genes may confer an increased risk for a CARD, but most probably, these genes were positively selected for fitness in reproduction and survival at younger ages independent of the CARD (antagonistic pleiotropy[2]). A perfect example is HLA DR4 (DRB1*04) because this genetic variant protects from dengue haemorrhagic fever. This has been summarized elsewhere.[1]

</div>

transient serious, albeit non-life-threatening, inflammatory episodes such as infection, foreign body reactions, wound healing, or similar.[1] Likewise, mechanisms for energy regulation have been positively selected for normal physiology and transient inflammatory episodes but not for CARDs.[3] Energy regulation involves many endocrine and neuronal pathways, which are summarized in Figure 22.1. In short-lived inflammatory episodes, there is a transient reallocation programme that redirects energy-rich fuels like glucose, amino acids (alanine, glutamine), and free fatty acids from classical stores such as liver, muscle, and fat tissue to the activated immune system (Figure 22.1).[3] This adaptive redirection programme is active as long as inflammation persists. In CARDs, the continuous use of these programmes leads to a permanent energy appeal reaction that leads to multiple systemic neuroendocrine abnormalities, as discussed in this chapter (Box 22.2).

Mild activation of the hypothalamic–pituitary–adrenal axis

Altered cortisol regulation in patients with CARDs has been intensively discussed for years. To summarize:

- Cortisol serum levels are somewhat elevated in untreated patients with CARDs.

- The hypothalamic–pituitary–adrenal (HPA) axis is visibly disturbed when subtle stress tests are applied.[4]

- Cortisol levels are low in relation to inflammation (see next section).

In addition, the HPA-axis-related adrenal androgen production is almost switched off at the expense of cortisol production.[5]

As a result of the allocation of energy-rich fuels to the immune system, mildly elevated levels of cortisol and severely downregulated anabolic androgens support gluconeogenesis by stimulating glucogenic enzymes in the liver and, concomitantly, muscle protein breakdown (provision of glucogenic amino acids). The cortisol-to-androgen preponderance supports cachectic obesity.[6] As cortisol and adrenaline support each other's signalling pathways, the concomitant increase in both hormones potentiates gluconeogenesis (sympathetic activation, see 'Mild activation of the sympathetic nervous system'). Growth hormone stimulates lipolysis by cortisol at physiological levels, and in this way provides the
Fig. 22.1 Energy regulation involves many endocrine and neuronal pathways. Energy-rich fuels are taken up and stored if there is no actual need for higher energy resources. During systemic inflammation, cytokines induce an energy appeal reaction in order to redirect fuels to the activated immune system. Under normal conditions, a circadian rhythm of allocation of energy-rich substrates exists to serve daytime and night-time consumers. Factors shown in green are typically storage factors, while factorsin red release energy-rich substrates from storage sites. ASD, androstenedione; DHEA, dehydroepiandrosterone; IGF-1, insulin-like growth factor 1.

Box 22.2 Systemic neuroendocrine abnormalities linked to a continuous energy appeal reaction of the activated immune system

- Endocrine abnormality
- Mild activation of the HPA axis
- Inadequate secretion of ACTH and cortisol relative to inflammation (disproportion principle)
- Mild activation of the SNS
- High serum levels of oestrogens relative to androgens (androgen drain)
- Inhibition of the HPG axis and consequences for fertility
- Fat deposits adjacent to inflamed tissue
- Increase of serum prolactin and immunostimulation
- Hyperinsulinemia, insulin resistance, and the metabolic syndrome
- Circadian rhythms of hormones, cytokines, and symptoms

immune system with energy-rich fuels. However, mild hypercortisolemia is not high enough to suppress the inflammatory process.

Inadequate secretion of ACTH and cortisol relative to inflammation—the disproportion principle

In humans, severe HPA axis alterations have not been found; only smaller changes were observed.[7] There are no big differences in basal blood levels of ACTH and cortisol in CARDs compared to healthy controls. Even with strong stimulation such as insulin hypoglycaemia these hormone levels showed no significant alterations.[7] This outcome was expected, because life-threatening situations need counteraction, which is obviously possible in medically treated CARD patients. Similarly, injection of corticotropin-releasing hormone (CRH) or adrenocorticotropin (ACTH) did not reveal marked alterations of the HPA axis, as summarized earlier.[7] It seems that some patients with CARDs demonstrate an escape in the dexamethasone/CRH test as substantiated in rheumatoid arthritis (RA) and multiple sclerosis.[7]

Under mild stimulation of the HPA axis during stress tests or mild exercise some altered function can be observed, as demonstrated in RA[4,8] and in systemic lupus erythematosus (SLE).[8] These are minor alterations, but given an increased proinflammatory load the HPA axis response is not adequate. This is particularly true because stress in patients with CARDs increases circulating cytokines compared to controls.[9] If stress induces an increase of cytokine levels but cortisol or ACTH levels remain normal or somewhat elevated, the imbalance of cytokines and HPA axis hormones becomes evident.

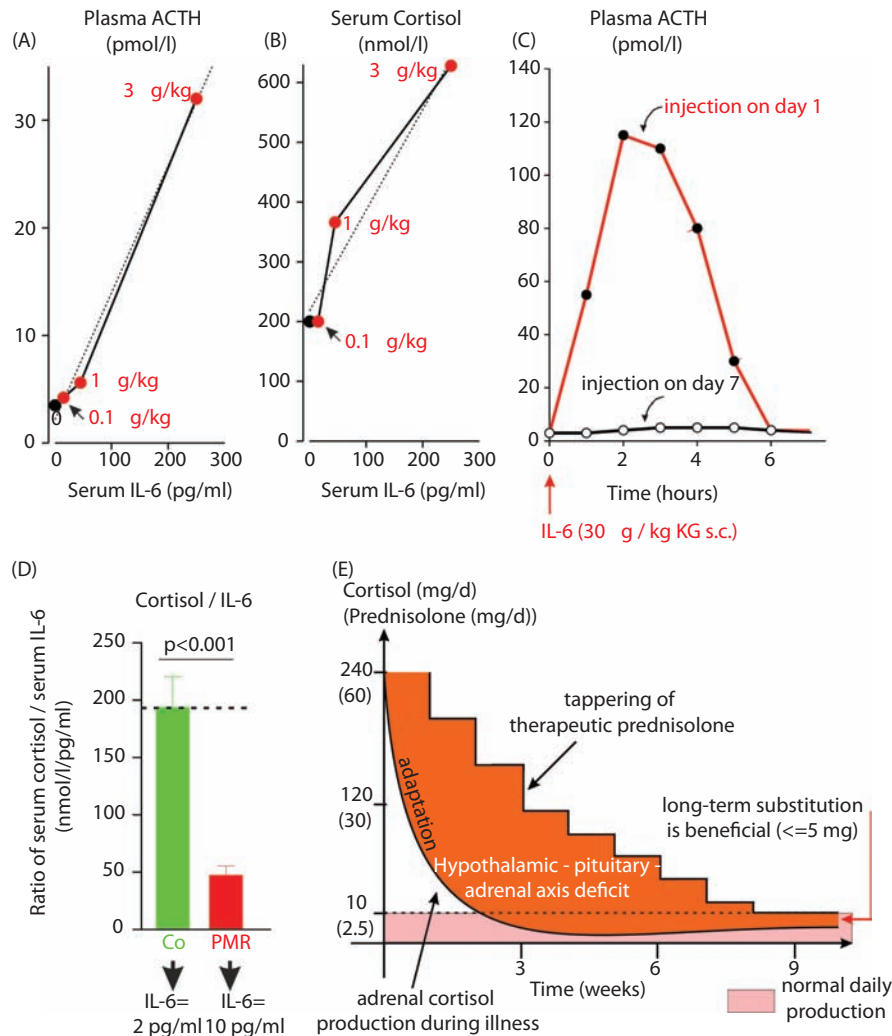
The human HPA axis response is activated by single cytokines such as tumour necrosis factor (TNF), interferon (IFN)-α, IFN-γ, and interleukin (IL)-6.[10] A fivefold elevation is observed in human volunteers treated with IL-6.[10] A dose–response relationship was demonstrated with a high linearity between serum IL-6 levels and cortisol/ACTH levels in a range of 3 to 300 pg IL-6 per mL serum/plasma (Figure 22.2).[10] Since patients with CARDs have between 3 and 300 pg/mL of IL-6, one would expect them to have similar levels of serum cortisol or plasma ACTH as found in this study in healthy volunteers. If patients have cytokine levels in this range, the


Fig. 22.2 Disproportion principle. (A-C): Adaptive downregulation of hypothalamic–pituitary–adrenal (HPA) axis activity upon repeated inflammatory stimuli. (A) Positive correlation between serum IL-6 levels and plasma ACTH after injection of indicated doses of IL-6 (red numbers) to healthy volunteers.[10] (B) Positive correlation between serum IL-6 levels and serum cortisol after injection of IL-6.[10] (C) Blunted ACTH response after repeated daily injection of IL-6 (red: day 1; black: day 7).[49] Panel C demonstrates the adaptive downregulation of HPA axis activity (here ACTH) during long-term elevation of serum IL-6. Adaptive downregulation is a cause for inadequate secretion of HPA axis hormones relative to inflammation. (D–E): Inadequate cortisol secretion in relation to inflammation. (D) Relatively low levels of cortisol in relation to IL-6 in patients with polymyalgia rheumatica (PMR). The original raw data were taken from a previous study.[50] In the given range of 2–10 pg IL-6/mL, the ratio of serum cortisol divided by serum IL-6 should be constant according to panel B. Controls show approximately 180 nmol/L cortisol in relation to 1 pg/mL of serum cytokine. This is different in patients with PMR who demonstrated approximately 50 nmol/L cortisol per 1 pg IL-6/mL. (E) The HPA axis deficit. An immediate increase of cortisol production can be observed after acute inflammatory stimulation such as an outbreak of an inflammatory disease (up to 240 mg/day), but this production rate is not maintained for a long period of time due to rapid adaptation of the HPA axis (see panel C). To control the disease a higher amount of daily glucocorticoids is needed, and the physician is providing high-dose prednisolone therapy starting at 60 mg/day (tapering down regimen). The orange area between the adrenal production rate and the exogenous prednisolone amount per day demonstrates the HPA axis deficit. The HPA axis is not able to produce the necessary amount. Importantly, the adrenal production rate can arrive at lower production rates compared to baseline, requiring long-standing substitution, e.g. in patients with PMR. The substitution therapy of 2.5 mg prednisolone per day reflects the basal adrenal production rate of cortisol.

hormone/cytokine ratio should be similar in healthy controls and in patients with CARDs (Figure 22.2). However, in patients with polymyalgia rheumatica, RA, and reactive arthritis, hormone levels were much lower in relation to IL-6 (Figure 22.2D).[11] This is known as the **disproportion principle**: inadequately low secretion of cortisol/ACTH in relation to stimulating cytokines such as IL-6 and TNF (Figure 22.2).

But what is the teleological significance of this? Persistently elevated glucocorticoid levels would lead to aggravation of systemic infectious illness, because cortisol inhibits essential defence reactions of the body. A brisk rise and fall of ACTH/cortisol has been positively selected by evolution in order to support an immediate response, thus preventing inhibitory influence on the immune system.[1] In short, the HPA axis response is defective precisely because it is normal.[7] One can hypothesize that such an inadequate response can even lead to disease perpetuation in CARDs, because secretion is somewhat elevated, supporting gluconeogenesis and lipolysis, but anti-inflammatory effects are absent.

High serum levels of oestrogens relative to androgens—the androgen drain

An increased conversion of androgen precursors to downstream oestrogens (independent of gender) was found in inflamed tissue and inflammatory cells of patients with CARDs.[12] It can be observed in immune cells by directly studying the conversion of androgen to oestrogen.[13] TNF is able to activate the aromatase in peripheral cells, thus leading to high local oestrogen levels.[14] This proinflammatory cytokine blocks the activation of biologically inactive androgen precursors in synovial cells of RA patients, such as the conversion of dehydroepiandrosterone sulphate (DHEAS) to bioactive dehydroepiandrosterone (DHEA).[14] In consequence, TNF leads to androgen loss by stopping supplies and by increasing the downstream drainage to oestrogens. This is supported by the inhibition of adrenal production of DHEAS and DHEA, as observed in CARDs.[15] A cytokine-induced block of androgen production in the adrenal and gonadal glands leads to low serum levels of androgens,[14] which in older subjects is responsible for the decline of adrenal androgen secretion also.

Another important proinflammatory pathway of steroid hormone conversion exists for DHEA. Stimulated by TNF, this hormone is converted into 7α-DHEA in synovial fibroblasts of patients with RA and in experimental arthritis in mice.[16] Since 7α-DHEA has proinflammatory activities, this steroid hormone conversion is unfavourable. Downstream of androgens, 17β-oestradiol is converted to proinflammatory and proproliferative 16α-hydroxylated oestrogens but not to anti-inflammatory 2- or 4-hydroxylated oestrogens.[17] The 16α-hydroxylated estrogens can stimulate the female type of subcutaneous lipid accumulation.[18] Increased levels of oestrogens (also in men) relative to androgens can support female-type fat distribution, cachectic obesity, and even generation of regional fat depots in the proximity of inflamed tissue (see 'Fat deposits adjacent to inflamed tissue'). In addition, the increase of oestrogens relative to androgens aggravates muscle wasting, as seen in transsexuals.[18]

Those alterations of the homeostatic steroid axes evolved to cope with short-lasting inflammatory episodes, but their long-term occurrence in CARDs is deleterious because they support allocation of energy-rich fuels to the immune system and lead to disease sequelae such as cachectic obesity and muscle wasting.

Inhibition of the hypothalamic–pituitary–gonadal axis and consequences for fertility

Inflammation-induced alteration of the hypothalamic–pituitary–gonadal (HPG) axis has been extensively studied in animals.[19] In humans, similar overall HPG axis abnormalities appear, especially in male RA patients, in whom follicle-stimulating hormone (FSH) and luteinizing hormone (LH) are elevated compared to controls.[20] This was confirmed in postpubertal boys and girls with SLE,[21] in male patients with ankylosing spondylitis and SLE,[22] in juvenile dermatomyositis,[23] and by a luteinizing hormone releasing hormone (LHRH) function test in patients with Sjögren's syndrome.[24] Elevated FSH and LH imply peripheral gonadal dysfunction, whereas lower levels of these hormones are an indicator of central abnormalities. Lower levels of LH were also found in patients with RA and SLE, probably demonstrating central involvement.[25]

Because of these alterations of the HPG axis and peripheral sex hormones, one would expect fertility problems in patients with CARDs. Indeed, the testicular Sertoli cell function and testicular volume are markedly altered in male SLE patients,[22,26] and patients with ankylosing spondylitis demonstrate sperm abnormalities that are ameliorated by anti-TNF therapy.[27] Similarly, women with SLE often demonstrate amenorrhea and abnormalities of FSH and LH,[25] and patients with juvenile dermatomyositis presented delayed menarche.[23] A recent population-based study demonstrated that RA patients were more often nulliparous compared to a control group.[28] Although, rheumatologists try to treat their patients to the best of current knowledge, these studies clearly demonstrate the negative impact of inflammation (not only of disease-modifying anti-rheumatic drugs, DMARDs) on HPG axis function in CARDs, leading to negative selection pressure.

Aberrant function of the HPG axis is not restricted to rheumatic diseases; it has been described in patients with filarial infections, leprosy, urinary bilharziasis, and HIV infection. Acute hantavirus infections or toxoplasmosis can induce acute hypogonadism. Keeping this in mind, the question arises why these alterations appear with such a uniform expression in many systemic inflammatory diseases.

With regard to energy regulation, inflammation leads to a diversion of energy-rich substrates to the activated immune system. Since courtship behaviour and reproduction are extremely energy-consuming, HPG axis activities and reproduction are switched off at the expense of the HPA axis stress response. This adaptive programme is highly favourable for short-lived inflammatory disease, to supply the immune system with energy-rich substrates.

Fat deposits adjacent to inflamed tissue

Nearly all lymph nodes are embedded in adipose tissue,[29] and most smaller adipose depots enclose one or more lymph nodes. Lipolysis and release of glycerol from perinodal fat depots was increased through activation of lymph nodes by proinflammatory stimuli.[29] As fatty acids can be used by immune cells, it is obvious that lymph node-associated adipose tissue is needed as a local source of energy-rich fuels.[29]

Selective hypertrophy of adipose depots in the proximity of inflammatory lesions is common in several CARDs including RA, osteoarthritis, Crohn's disease, mesenteric panniculitis, and Graves' ophthalmopathy.[30] Along with energy-rich fuels (fatty acids),

adipocytes produce proinflammatory adipokines, such as leptin, high-molecular weight isoforms of adiponectin, TNF, IL-1β, monocyte chemotactic protein-1 (MCP-1), or IL-6, as well as anti-inflammatory factors such as trimeric adiponectin.[30,31] Thus, the finely tuned balance of pro- and anti-inflammatory factors supports processes in neighbouring lymph nodes such as clonal expansion of antigen-specific lymphocytes.

It is very likely that fat tissue in the proximity of inflamed tissue keeps the local inflammation going. Adipocytes differentiate from pluripotent mesenchymal stem cells, which readily enter chronically inflamed tissue.[30] If stimuli for adipocyte differentiation are available, adipose tissue adjacent to inflammatory lesions can develop locally. Regional adipose tissue is a store of energy-rich substrates fuelling the neighbouring inflammatory process.

Increase of serum prolactin

Prolactin levels typically increase with the start of sleep, and this has been linked to the night-time increase in proinflammatory cytokines.[32] In this respect, it has a similar role to that of melatonin and growth hormone. In addition, prolactin is a classical stress hormone that increases during inflammatory episodes.[10]

In CARDs, serum levels of prolactin were found to be normal or slightly elevated (by a factor of 2) reaching serum levels of approximately 15–25 ng/mL.[33,34] Increased values were demonstrated in RA, SLE, multiple sclerosis, Sjögren's syndrome, Hashimoto's thyroiditis, polymyalgia rheumatica, systemic sclerosis, and others.[33,34] A further link between CARDs and prolactin has recently been discovered: The PRL-1149 G/T polymorphism (rs1341239) in the prolactin gene decreases prolactin expression, and this is associated with a decreased risk of developing RA.[35]

Prolactin has many immunostimulatory (T helper type 1 favouring) and proinflammatory activities.[33,34] Therapeutic inhibition of pituitary prolactin secretion has been studied using bromocriptine or other dopamine agonists in some small studies.[33,34] The therapeutic effect was not strong, but some patients might profit.[33,34] No randomized placebo-controlled clinical trials have been performed with these agents. In addition, since prolactin can be secreted from immune cells and other local tissue cells such as lymphocytes and fibroblasts,[33] the modulation of pituitary prolactin secretion seems to be a doubtful strategy because it would only block the dopamine-dependent pituitary production of this hormone.

In the context of energy regulation in systemic inflammation, prolactin has three major roles:

- It decreases lipogenesis in white adipose tissue by inhibiting important lipogenic enzymes (inhibition of triglyceride storage, thus, provision to the immune system).[36]

- It increases insulin secretion from pancreatic β-cells, leading to higher insulin levels (support of immune cells, see 'Hyperinsulinaemia and insulin resistance').[36]

- It stimulates immune cells.

All three effects support the reallocation of energy-rich substrates to the immune system and activation of inflammatory cells.

Hyperinsulinaemia and insulin resistance

Using an early version of the glucose tolerance test, endocrine imbalances with unresponsiveness to hyperglycaemia, insulin

resistance, and increased gluconeogenesis in patients with RA and ankylosing spondylitis were demonstrated about 60 years ago.[37] These results were supported by the finding that basal serum insulin levels and the maximum insulin response to glucose loading were significantly higher in patients with RA than in control subjects.[38] It was concluded that impaired glucose handling in RA is due to peripheral insulin resistance mediated by the inflammatory process.[38] This was supported by the euglycaemic hyperinsulinaemic glucose clamp technique.[38] In other studies it was shown that serum levels of C-reactive protein (CRP) and disease activity negatively correlated with insulin sensitivity in RA.[39] Insulin resistance is not a phenomenon of RA alone but is a general principle in CARDs.

Energy-rich fuels are needed to feed the immune system (mainly glucose and glutamine, other glucogenic amino acids, ketone bodies, and free fatty acids; see Figure 22.1). During activation of the immune system, muscle proteins are degraded and glucogenic amino acids are used for gluconeogenesis. In the presence of elevated activity of the sympathetic nervous system (SNS; see 'Mild activation of the sympathetic nervous system') and slightly increased activity of the HPA axis (albeit relatively low in relation to inflammation, see 'Mild activation of the hypothalamic–pituitary–adrenal axis'), gluconeogenesis results in somewhat higher circulating glucose levels (as tested by increased fructosamine and pentosidine levels in CARDs), and increased levels of free fatty acids (such as the 20:3ω6 and 20:4ω6 fatty acids). Free fatty acids induce insulin resistance and, in parallel, proinflammatory cytokines such as TNF can disturb insulin receptor signalling.[40] This has been shown by the improvement of insulin resistance and IGF-1 resistance associated with TNF neutralizing therapies.[14,41] Most probably, the increased proinflammatory load with elevated circulating cytokines is the main contributor to insulin resistance in CARDs. The important question appears to be whether immune cells become insulin resistant.

Immune cells take up glucose via the GLUT1, GLUT3, and GLUT4 transporters that are activated by specific immune stimuli such as lipopolysaccharides, anti-CD3 antibodies, cytokines (e.g. IL-7, IL-4), hormones (e.g. leptin), and also by insulin.[42] In addition, glycolysis and pentose phosphate pathways are switched on in activated immune cells[42] and they do not become insulin resistant. In contrast, insulin is important for glucose uptake, cytokine synthesis, and activation of immune cells.

In summary, the energy appeal reaction increases the insulin resistance of liver, muscle, and adipose tissue in order to deflect energy-rich fuels to the activated immune system. The activated immune cells themselves do not become insulin resistant.

Circadian rhythms of hormones and cytokines and pathophysiology link to symptoms

In CARDs, symptoms follow a circadian rhythm leading to an early morning peak in symptoms such as stiffness, functional disability, and pain.[32] These symptoms are a consequence of the nightly increase of proinflammatory cytokines such as IL-6 and TNF whose function is tightly linked to plasma extravasation, stimulation of sensory nerve fibres, and activation of central nervous microglia. The increase of TNF and IL-6 stimulates the morning rise of endogenous ACTH, cortisol, adrenaline, and noradrenaline

showing a lag phase of 30–60 minutes between cytokine and later hormone increase.[43] When hormones reach the peak level in the early morning they are able to suppress cytokines, leading to spontaneous reduction of cytokine serum levels and symptoms during the later morning.

With the start of sleep, proinflammatory hormones such as prolactin, melatonin, and growth hormone activate the nocturnal immune system. In parallel, a decrease in catecholamines and cortisol leads to the rise of cytokines until the next morning. This self-regulating interacting fluctuation of hormones and cytokines serves energy regulation.[3]

The allocation of energy-rich fuels follows circadian rhythms because the uptake of energy resources is limited (the upper threshold of uptake is approximately 20 000 kJ). Energy-rich substrates need to be partitioned between brain, muscles, and immune system (and body growth).[3] Since brain and muscle need these fuels during the day (daytime consumers) and the immune system and growth-associated pathways request energetic substrates during the night (night-time consumers), circadian rhythms are a positively selected adaptive programme to overcome possible fuel shortage.[3] These circadian rhythms are controlled by higher-order neuroendocrine centres in the brain that regulate peripheral immune function and, hence, disease outcome.

Recent therapeutic developments are based on an understanding of the circadian rhythm because night-time release of therapeutic glucocorticoids has intriguing advantages over classical morning glucocorticoids.[44]

Mild activation of the sympathetic nervous system

An increased activity of the SNS can be found in different diseases.[45] Decreased levels of serum cortisol lead to increased basal sympathetic tone in relation to the degree of inflammation since there is a certain cooperativity of cortisol and noradrenaline on a molecular level via the β-adrenergic receptor signalling cascade. Functional loss of one factor (mainly cortisol in relation to inflammation) probably upregulates the other factor in order to maintain common functions such as blood glucose homeostasis (glycogenolysis, gluconeogenesis), lipolysis, blood pressure control, and regulation of the bronchial lumen. Such anti-inflammatory cooperativity of cortisol and noradrenaline can be found in synovial inflammation in RA.[46]

The SNS with its two effector arms, the adrenal medulla and peripheral sympathetic nerve fibres, is the main regulator of glycogenolysis, gluconeogenesis, and lipolysis. Although the adrenal medulla generally stimulates the splanchnic organs, sympathetic nerve fibres can stimulate distinct adipose tissue regions in the body. Provision of energy-rich fuels by the SNS depends on β_2-adrenergic receptor signalling. For example, catecholamines via β_2-adrenoceptors activate hormone-sensitive lipase in order to breakdown triglycerides into glycerol and fatty acids. The α_2-adrenergic receptor exerts antilipolytic, so-called lipogenic, effects.[47] Thus, elevated systemic SNS activity supports lipolysis, gluconeogenesis, and glycogenolysis. In addition, a high firing rate of sympathetic nerve fibres to adipose tissue supports local lipolysis.

Many CARDs are accompanied by increased levels of circulating proinflammatory cytokines and elevated SNS activity, which can be a substantial risk factor for cardiovascular disease. The circulating cytokines directly stimulate the SNS in the hypothalamus but also the local proinflammatory process in vascular lesions. In addition, hyperinsulinaemia accompanying CARDs is related to increased SNS activity because insulin stimulates the SNS.

From an energy regulation perspective, somewhat higher SNS activity is important to sustain allocation of energy-rich fuels to the immune system and, at the same time, maintain systemic circulation. Indeed, denervation of the SNS largely decreased early inflammation in animal models.[48] In conclusion, we can postulate that elevated systemic SNS activity as a consequence of an energy appeal reaction and local retraction of sympathetic nerve fibres are important for the activated immune system.

Conclusion

Neuroendocrine abnormalities are manifold and are a consequence of systemic inflammation. Systemic inflammation induces a neuroendocrine immune energy appeal reaction that redirects energy-rich substrates from stores such as liver (glucose, triglycerides), adipose tissue (triglycerides), or muscle (amino acids) to activated immune cells in primary/secondary lymphoid organs or locally inflamed tissue. Orchestrated energy regulation on the systemic and local cellular level has been positively selected for normal physiology and for transient serious, albeit non-life-threatening, inflammatory episodes, but these mechanisms have not been positively selected for CARDs. In transient inflammatory processes, the increase and decrease of immune responses (e.g. in infection) are part of a coordinated and highly regulated process. In CARDs, due to the chronic course of the disease, a similar coordinated regulation does not exist. Rather, the long-standing energy appeal reaction induces many neuroendocrine abnormalities, which are perpetuating and aggravating the course of CARDs. Hopefully, recognition of the importance of energy fluxes and related neuroendocrine alterations during both acute and chronic inflammation can provide a new perspective of disease pathogenesis and lead to better approaches for diagnosis and treatment.

CHAPTER 23

Malignancy

Jennifer Hamilton and Clive Kelly

Rheumatic disorders with an increased risk of malignancy

Rheumatoid arthritis

Although the overall incidence of malignancy in rheumatoid arthritis (RA) is not increased, an association between RA and lymphoma was suspected nearly 50 years ago[1] and confirmed 20 years later.[2] Duration rather than severity of RA was initially felt to be the main risk factor.[3] One year later, a large cohort study reported an increased incidence of myeloma in patients with RA.[4] The presence of a paraprotein was found to increase the probability of developing myeloma or lymphoma in RA.[5] More recent work has confirmed a twofold increase in both the prevalence and the incidence of lymphoma in RA.[6] The risk of leukaemia is similarly doubled, but no association of myeloma was found. This appears to be a consequence of the chronic inflammatory nature of RA and associated immunosuppression, rather than the consequence of treatment.[7] The risk of lymphoma in patients treated with anti-tumour necrosis factor (TNF) was also similar when corrected for disease duration.[6] Similar data from the British Society for Rheumatology Register (BSRBR) has also been reported recently.[8]

The standardized incidence ratio (SIR) of cancers at certain other sites are also influenced by the presence of RA. Colon and rectal cancer is reduced (SIR 0.77), probably as a result of the use of non-steroidal anti-inflammatory drugs (NSAIDs), while lung cancer is increased (SIR 1.63), perhaps due to smoking and the increased prevalence of interstitial lung disease.[9] Skin and prostate cancers are also reportedly more common in RA.[10] Age-adjusted mortality from cancer has been shown to be increased in patients with RA,[11] perhaps as a result of later detection, with patients hospitalized as a result of RA having a hazard ratio for overall survival of 1.31.[12]

Sjögren's syndrome

Lymphoma is strongly associated with primary Sjögren's syndrome (pSS) with a SIR of around 40.[13] Diffuse large B-cell lymphoma and salivary marginal zone B-cell lymphomas (MALTomas) are seen in up to 5% of pSS patients,[14] and relate to disease activity and severity.[15] The incidence of second malignancy is increased in patients with pSS and lymphoma.[16] Other malignancies are not significantly associated with pSS.[16]

Scleroderma

Population-based studies initially gave conflicting results on the association of scleroderma with malignancy.[17,18] There is now good evidence that lung cancer (especially alveolar cell and adenocarcinoma) is increased in diffuse disease, and is often associated with pulmonary fibrosis.[19] Breast cancer, B-cell lymphoma, and tongue cancer are also commoner in scleroderma.[20,21] There is now evidence to show that some patients develop scleroderma as a consequence of RNA polymerase antibodies expressed by cancer,[22] suggesting that scleroderma may sometimes be a paraneoplastic phenomenon.

Dermatomyositis

Myositis is associated with an increased risk of malignancy, and this is much greater in patients with dermatomyositis, where up to 25% of patients may develop a malignancy.[23] It is associated with severe skin and/or muscle involvement, but less likely in those with renal or lung disease. Careful investigation of all new or recurrent presentations with myositis is recommended. This should include a chest radiograph and often an upper gastrointestinal endoscopy and pelvic ultrasound. Malignancies of the lung, oesophagus, and ovary are most frequently associated with dermatomyositis.[23,24] Anti-p 155/140 antibodies appear to predict malignancy, and the skin and muscle inflammation may result from an immune response to antigenic material expressed by the underlying neoplasm.[24]

Systemic lupus erythematosus

There is a small overall increase in cancer (SIR 1.15) in patients with systemic lupus erythematosus (SLE).[25] The incidence of cancer is especially increased in patients under the age of 40. There is a three-fold increased risk of non-Hodgkin's lymphoma (NHL), and it is unclear whether this relates to the disease or its treatment. The risk of lung cancer and other lymphomas are increased to a lesser degree. Vulvovaginal and cervical cancers are also increased in SLE,[26] possibly as a result of delayed clearance of human papillomavirus. Table 23.1 summarizes the SIRs of specific cancers associated with rheumatic disorders.

Cancer associated with therapy of rheumatic disease

Immunosuppressive drugs used in the treatment of rheumatic disease increase the likelihood of certain types of neoplasia. It can be

Table 23.1 Standardized incidence ratios (SIR) of specific cancers associated with rheumatic disorders

Disease	Cancer	SIR	References
Rheumatoid arthritis	NHL	2.1	6–8
	Leukaemia	2.0	6
	Lung cancer	1.63	9

Systemic lupus erythematosus	NHL	3.0	25
	Lung	N/A	25
	Vulvovaginal	N/A	25
	Cervical	N/A	25

NHL, non-Hodgkin's lymphoma.

difficult to assess the degree of risk from clinical studies as many of the rheumatic diseases also carry an increased risk of cancer.

Methotrexate

Methotrexate is most commonly used disease-modifying antirheumatic drug (DMARD). A 3 year prospective French study suggested that overall the risk of NHL was not significantly increased in RA patients treated with methotrexate. However the incidence of Hodgkin's disease (HD) was significantly increased in comparison to the French population (SMR 7.4 [3.0–15.3; $p < 0.001$]). Of the 7 cases of HD, 5 were associated with Epstein–Barr virus (EBV).[27] Another study demonstrated the presence of latent EBV in 7/13 lymphomas arising during methotrexate treatment, versus only 2 out of 11 in patients not treated with methotrexate. This suggests that EBV-related transformation is important in the pathogenesis of lymphomas in patients on methotrexate treatment.[28] This is important, as some tumours will regress within 4 weeks of methotrexate cessation.[29]

Cyclophosphamide and azathioprine

High-dose cyclophosphamide and azathioprine have also been linked with an increased risk of haematological malignancy. Overall the relative risk for all types of cancer when azathioprine is used in RA is 1.4–8.7. Up to 16% of patients with Wegener's granulomatosis will have bladder cancer by 15 years when treated with prolonged courses of cyclophosphamide. Use of drugs such as cyclophosphamide has led to a significant reduction in mortality from diseases such as SLE and granulomatosis with polyangiitis (Wegener's). Recent studies have shown that lower total doses of

cyclophosphamide are as effective as the old high-dose regimens, but carry with them improved morbidity.[30] The decision to treat with immunosuppressive drugs is always a balance of risk versus potential benefit. High levels of vigilance for development of cancer must be maintained, often for many years after the drug is discontinued. The commonest types of cancer in this cohort of patients are skin, haematological, and bladder cancer in cyclophosphamide-treated patients. It therefore makes sense to advise patients to wear high-factor sun block, ensure GPs have a low threshold for investigating persistent lymphadenopathy and B-cell symptoms in patients with rheumatic disease, and continuing to regularly dip urine of patients treated with cyclophosphamide for many years after discontinuation of treatment. In the future more tailored use of biologics such as rituximab in patients with connective tissue disease will decrease this risk still further.

Ciclosporin and mycophenolate

Both these agents carry an increased risk of inducing malignancy, especially skin cancer and lymphoma. Most of the available data is derived from the transplantation literature.[31,32] The risk increases with increased dose and duration of use.[33]

Biologic agents

Theoretically the inhibition of anti-TNF may potentiate the risk of malignancy in humans as a result of the activity of anti-TNF against tumours in laboratory models. Although results from biologic registries have been reassuring, this conflicts with reports from metanalyses. Data from the South Swedish Arthritis Treatment Group showed that although the SIR for all types of malignancy was no different between patients treated with etanercept or infliximab and patients treated with conventional DMARDs, the relative risk of lymphoma in the TNF inhibitor group was 11.5 (95% CI 3.7–26.9) compared with 1.3 (95% CK 0.2–4.5) for the DMARD group. However, other studies have shown no increase in risk. There is more evidence to support a link between biologic agents and non-melanoma skin cancer in patients treated with TNF inhibitors. It should be remembered that biologics are contraindicated in patients with a history of cancer within the preceding 10 years.[34–37]

Cancer drugs causing rheumatic symptoms

Many of the drugs used to treat cancer have been associated with rheumatological side effects (Table 22.2). The agents associated with the most significant joint and muscle symptoms are those that inhibit microtubular function, and these side effects are often dose related. In general the symptoms will develop within 48–72 hours of chemotherapy and will last for 4–7 days. Risk factors for acute musculoskeletal side effects include antecedent peripheral neuropathy, diabetes, alcohol use, age, prior neurotoxic chemotherapy, and history of arthritis or neuromuscular disorder. Where rest, simple analgesics and NSAIDs fail to improve symptoms, corticosteroids and opiates may be tried.[38]

Taxanes are widely used in female pelvic, breast, respiratory, and genitourinary malignancy. Up to 75% of patients will experience significant joint or muscle morbidity. This usually develops within 24–48 hours and may persist for 3–5 days. Premedication with dexamethasone may decrease this.

In addition, a 'postchemotherapy rheumatism syndrome' may occur in patients receiving adjuvant chemotherapy for breast cancer.

Table 23.2 Rheumatological side effects of anti-cancer drugs

Drug	Rheumatic complaint
Aromatase inhibitors, interferon, topotecan, bryostatin, fludarabine, dacarbazine, altretamine, vinorelbine, gemcitabine, procarbazine, isotretenoin	Arthralgia Osteoporosis
Bleomycin	Scleroderma Raynaud's
Taxanes	Myalgia and arthritis
Glucocorticoids	Osteonecrosis
Bisphosphonates	Musculoskeletal pain and osteonecrosis
Radiotherapy	Myalgia and stiffness
Taxols	Scleroderma like syndrome Joint pain, acute myalgia and arthralgia
Intravesical BCG	Reactive arthritis, septic arthritis
High-dose methotrexate	Increased bone resorption and inhibition of bone formation leading to osteoporosis and fracture

BCG, bacille Calmette–Guérin.

Serological tests, autoimmune markers, and imaging are all unremarkable although patients may have mild periarticular swelling. NSAIDs are usually ineffective but some patients may respond to low-dose steroids.

Additionally, aromatase inhibitors are associated with an increased risk of osteoporosis as a result of accelerated bone loss.[39] This is particularly accelerated in premenopausal females and has led to recent guidelines on the use of prophylactic bisphosphonates and regular surveillance of bone density in such patients.[40]

Intravesical bacillus Calmette–Guérin (BCG)

Intravesical BCG is used for prophylaxis and treatment of superficial bladder cancer. Arthritis or arthralgia occur in approximately 0.5–1% of patients.[41]

A reactive arthritis may develop in the lower limbs within 2 weeks of BCG instillation. Up to 53% may be HLA B27 positive and a small proportion of these may go on to develop chronic symptoms. The majority will settle with discontinuation of treatment and NSAIDs. If symptoms fail to settle after a couple of weeks, glucocorticoids may be appropriate. Septic arthritis is rare but must be considered in patients presenting with an effusion especially if it only affects one joint.[42–43]

Gout

In addition to polyarthritis patients undergoing treatment for malignancy, especially lymphoproliferative disorders, can develop acute gout as a result of release of nucleic acids from killed tumour cells and formation of uric acid. Patients at risk from the tumour lysis syndrome should receive aggressive rehydration and urate-lowering agents prior to receiving chemotherapy.

Rheumatological presentations of malignancy

The first manifestation of malignancy may be rheumatological. Skeletal metastases may present as either bone pain or a vertebral crush fracture. Patients can however present with polyarthritis, features suggestive of polymyalgia rheumatica, vasculitis, regional limb pain and symptoms suggestive of connective tissue disease. In one retrospective study 23.1% of patients admitted to a general medical ward with previously unclarified rheumatic disorders were found to have an occult malignancy.[4,44] In 9 of the 25 cases long term remission of neoplasia was achieved, and this was associated with an improvement in rheumatic symptoms.

In the majority of patients evidence of malignancy will be found on routine examination or laboratory tests. However, rheumatologists should maintain a high level of suspicion and consider more extensive investigation for malignancy in patients presenting with seronegative disease, abrupt onset of symptoms, atypical features, significant weight loss or other systemic symptoms, and where either degree of symptoms or inflammatory markers are disproportionate to the physical signs. Breast examination should always be

Table 23.3 Conditions that may present to rheumatologists and could suggest malignancy

Condition	Associated cancer	Features that should raise suspicion
Erythema nodosum	Hodgkin's lymphoma T-cell lymphoma with direct skin infiltration	Recurrent rashes Atypical mediastinal lymphadenopathy
Sweet's syndrome (20–25% have associated malignancy)	Mainly acute myelogenous leukaemia, other lymphoproliferative disorders. 15% of tumours are solid affecting GU tract, breast and GI tract	Should be considered in all patients presenting with Sweet's syndrome
Pyoderma gangrenosum	Usually lymphoproliferative. Most commonly associated with IBD	Should be considered in all patients especially where no underlying IBD
Cancer-associated fasciitis panniculitis syndrome	May present with symptoms suggestive of scleroderma	Should be considered in autoantibody-negative scleroderma especially if atypical or systemic features
Pancreatic panniculitis	Pancreatic; presents with tender erythematosus nodules which may ulcerate	
Vasculitis	Usually haematological malignancy	Risk of underlying cancer small; further investigations should be guided by other features in history and examination

GI, gastrointestinal; GU, genitourinary; IBD, inflammatory bowel disease.

considered in patients who do not regularly self-examine or attend for screening. Pancoast tumours should enter the differential diagnosis in patients presenting with shoulder pain. Shoulder pain is present in up to 96% of patients and treatment for other disorders may lead to a delay in diagnosis. The tumour may not always be apparent on plain film so a CT scan of chest should be considered where there is marked muscle wasting, extreme pain, and/or night waking. Because of the location of the tumour, respiratory features may not present until later in the disease.[45–47]

There are certain rheumatological presentations that are strongly suggestive of malignancy, e.g. hypertrophic pulmonary osteoarthropathy (HPOA). In one Japanesese study of 2625 patients with lung cancer, HPOA was present in 0.7% of patients and was strongly associated with adenocarcinoma of the lung. It is characterized by abnormal proliferation of skin and osseous tissue at the distal extremities and leads to digital clubbing and periostosis in the long bones, and can also be associated with joint effusion. Arthropathy can sometimes develop before the finger clubbing. Treatment of the lung cancer normally causes the clinical manifestations to regress but is not always effective. If NSAIDs or other analgesics fail to relieve symptoms, treatment with IV bisphosphonates has been found to be effective in case reports.[48,49]

Other rheumatic presentations of malignancy are shown in Table 23.3.

CHAPTER 24

The eye

Harry Petrushkin and Miles Stanford

Introduction

Most rheumatological diseases have ocular complications, many of which are specific to the disease, and consequently the ophthalmologist has an important diagnostic role. Many ophthalmic complications require specific therapy and in some cases may actually dictate the systemic therapy for the disease. Furthermore, rheumatological diseases require a wide range of drugs and several of these have important ocular side effects; the ophthalmologist therefore has a role in monitoring the eye and preventing complications.

In general, diseases that involve the uvea, sclera, or cornea cause painful red eyes with preserved vision, whereas involvement of the retina or optic nerve causes profound visual loss without pain or redness. Fortunately, with the particular exception of juvenile idiopathic arthritis (JIA), most of the ocular complications that affect sight are symptomatic, so the rheumatologist can easily notice these when taking a focused history.

The more common eye symptoms encountered in patients with rheumatological diseases are dry, gritty eyes; photophobia; watering; redness; pain; floaters; and, most importantly, blurring or actual loss of vision. The differential diagnosis of the painful red eye and of sudden loss of vision is outlined in Tables 24.1 and 24.2.

Common eye disorders encountered in rheumatological disease

Dry eyes

Patients with dry eyes may complain of a foreign-body sensation, redness, grittiness, and excessive mucus secretion. Keratoconjunctivitis sicca occurs when the secretory function of the lacrimal and accessory lacrimal glands are of insufficient quality or quantity to maintain an adequate tear film and stable ocular surface.

Reduction in secretion, usually secondary to destruction of the lacrimal gland is associated primarily with autoimmune diseases such as Sjögren's syndrome,[1] systemic lupus erythematosus (SLE),[2] rheumatoid arthritis (RA),[3] and systemic sclerosis.[4] Infiltrative conditions such as lymphoma, sarcoidosis,[5] and amyloidosis[6] can also cause a reduction in lacrimal gland secretion.

Staining the cornea with fluorescein can help diagnose a dry eye. In early cases of keratoconjunctivitis sicca the stain may be limited to the conjunctiva and in severe cases can be seen all over the cornea.

Frequent ocular lubricants are the mainstay of treatments and these range from thin, watery preparations, which need to be instilled regularly, to more viscous gels and ointments which last longer, but tend to cause more blurring of vision. Occasionally

Table 24.1 Differential diagnosis of the painful red eye

Ocular pathology	Vision	Pain	Distribution of redness	Extra signs	Likely systemic disease
Conjunctivitis	Good	Mild	Diffuse	Purulent, sticky exudate	Reiter's syndrome
Dry eyes	Good	Gritty	Mild diffuse	Schirmer's test Reduced tear film break-up time	Rheumatoid arthritis Systemic vasculitis Sjögren's syndrome (primary and secondary)
Episcleritis	Good	Irritation or 'bruised' sensation	Diffuse or nodular	Mobile nodules	Rheumatoid arthtitis Systemic vasculitis
Scleritis	May be reduced	Very severe	Diffuse or nodular	Keratitis	Rheumatoid arthritis
Anterior uveitis	Reduced	Mild to severe	Circumcorneal or diffuse	Small or irregular pupil Photophobia	Seronegative spondyloarthropathies Sarcoidosis Behçet's disease

Table 24.2 Differential diagnosis of sudden loss of vision

Cause of visual loss	History of visual loss	Field	Pupil reaction	Media	Fundus	Likely systemic disease
Vitreous haemorrhage	Sudden	Generalized constriction	Normal	Hazy	Not usually visible New vessels or venous occlusion may be visible	Systemic vasculitis Behçet's disease Diabetes Trauma
Macular oedema	Gradual, with distortion	Small, relatively central scotoma	Normal	Hazy	Swollen disc	Behçet's disease Sarcoidosis Seronegative arthropathies Intermediate uveitis
Central retinal artery occlusion	Sudden	Dense, large, central scotoma	Afferent pupillary defect	Clear	Normal or pale optic disc Pale retina Cherry red spot	Systemic vasculitis Polyarteritis nodosa Cardiovascular disease
Ischaemic optic neuropathy	Sudden	Dense, altitudinal scotoma	Afferent pupillary defect	Clear	Pale or swollen optic disc	Systemic vasculitis Giant cell arteritis Cardiovascular disease
Inflammatory optic neuropathy	Progressive	Central, or centro-caecal scotoma	Afferent pupillary defect	Clear or hazy	Pale or swollen optic disc	Sarcoidosis Wegener's granulomatosis Demyelinating disease

punctal plugs can be inserted into the lacrimal punctae to block the drainage of what few tears there are.

Episcleritis

The episclera is a thin layer of transparent tissue lying between the conjunctiva and the sclera. Episcleritis is a benign, self-limiting condition, reported to be associated with systemic inflammatory disease in 3–5% of patients; it can also be the presenting feature of gout.[7]

Scleritis

Scleritis is a serious, potentially sight-threatening condition which, in contrast to episcleritis, is almost always painful and does not subside spontaneously. Pain is often described as 'deep or boring' and may be excruciating. Characteristically, patients report that the pain wakes them from sleep. The inflamed area is red and can be in a nodular, diffuse, or necrotizing in its pattern (Figure 24.1). Spread to the cornea produces peripheral ulceration, keratitis, and photophobia, whereas involvement of the posterior sclera causes retinal folds, serous retinal detachment, and optic disc swelling.

An unusual variant of scleritis is scleromalacia perforans (Figure 24.2), which occurs in elderly women with severe RA. This is characteristically painless and the affected sclera becomes chalky-white because of the underlying arteritic infarction.[8] Eventually the sclera becomes atrophic and the blue of the underlying choroid can be seen bulging through it. Actual perforation of the globe is very rare, despite the name.

Autoimmune diseases are present in up to 50% of patients with scleritis,[9] and include RA, systemic vasculitis (particularly Wegener's granulomatosis), SLE, inflammatory bowel disease (IBD), and relapsing polychondritis. Patients with scleritis tend to have more aggressive systemic disease than those without scleritis.

Fig. 24.1 Scleritis. A 35 year old man presents with severe pain in his left eye. He is unable to sleep as the pain is so severe. The eye is tender to touch and the sclera is a dusky red colour, typical of scleritis.

Scleritis can also occur in SLE and is most common when the disease is poorly controlled.[10] These patients usually require aggressive medical treatment. A recent case series found that 5% of patients with scleritis had IBD, although the most common ocular manifestation of IBD is uveitis.[11] Relapsing polychondritis can often present with scleritis, which is characterized by recurrent inflammation of type II collagen fibres present in the sclera.[12]

Acute anterior uveitis

Acute anterior uveitis (AAU) is inflammation within the anterior chamber of the eye. The patient complains of an acutely painful, red
Fig. 24.2 Scleromalacia perforans. A 50 year old woman with severe rheumatoid arthritis has suffered from relapsing scleritis for over 20 years. She now has a very thin superior sclera with underlying choroid bulging through.
Fig. 24.3 Granulomatous uveitis. A 40 year old woman presented with photophobia and decreased visual acuity. She has had symptoms for 3 weeks and has developed keratic precipitates and Koeppe nodules on her iris.

eye with photophobia, sometimes associated with blurred vision. The condition is generally unilateral and frequently recurrent. The ophthalmological signs consist of circumcorneal redness and keratic precipitates on the endothelial surface of the cornea. Flare (protein) and cells (white blood cells) in the anterior chamber resemble 'a shaft of light with specks of dust' when viewed through the slit lamp. Koeppe and Busacca nodules can form on the iris in cases of granulomatous uveitis (Figure 24.3) and cells can gravitate to form a fluid level called a hypopyon. The pupil is small and poorly reactive and the intraocular pressure can be either low, due to ciliary body inflammation, or high, due to blockage or inflammation of the trabecular meshwork.

The lifetime cumulative incidence of AAU in the general population has been calculated to be about 0.2%, which increases to 1% in HLA B27-positive subjects.[13] Patients who are HLA B27 positive tend to be younger at the time of their first attack, have more severe ocular inflammation, and a longer recovery period than those who are HLA B27 negative.[14]

Retinal vasculitis and posterior uveitis

In patients with seronegative arthropathies and Behçet's disease there may be inflammation in the posterior chamber of the eye. Patients may complain of floaters and blurred or distorted central vision secondary to macular oedema. In mild to moderate cases, fundoscopy reveals focal or diffuse white sheathing of the retinal veins; in severe cases there are also scattered haemorrhages. Occlusion of the retinal veins leading to neovascularization of the optic disc or peripheral retina may also develop. The new vessels, similar to those in diabetes mellitus, generally develop as a consequence of retinal ischaemia, but may also appear as a reaction to the intraocular inflammatory process. Their walls are fragile and they frequently bleed, leading to vitreous haemorrhages, which are an important cause of visual morbidity in these patients.

In contrast, patients with systemic vasculitis do not usually develop inflammation within the eye but the vasculitic process affects the retinal capillaries and arterioles to produce retinal or choroidal ischaemia.

Optic neuropathy

Diseases of the optic nerve invariably cause profound visual loss. Symptoms range from blurred central vision and difficulty differentiating colours to complete blindness. The cardinal ophthalmological signs of optic nerve disease are reduced visual acuity, impaired or absent colour vision, a central or altitudinal visual field defect and a relative afferent pupillary defect (RAPD). The optic disc may look swollen, pale, or even normal depending on where the inflammation has occurred along the optic nerve.

The pattern of visual loss can vary from sudden and complete to slow and progressive. This depends on whether the optic nerve has undergone infarction, such as in giant cell arteritis, or slow compression from a granuloma. All patients who develop disease of the optic nerve require urgent investigation.

Specific ocular manifestations of systemic inflammatory diseases

The ocular manifestations of systemic inflammatory disease varies according to the size and type of vessel predominantly affected by the disease process. As a general rule, diseases that affect arterioles involve the cornea, episclera, sclera, and retinal arterioles, whereas those affecting the venules produce uveitis, macular oedema, and retinal venous disease.

Giant cell arteritis

Giant cell arteritis is an ophthalmic emergency and an important cause of preventable blindness in elderly people. Twenty-five per cent of patients develop ocular disease and the majority experience sudden loss of vision in one eye, with a dense, central field defect.[15] The cause of blindness is usually infarction of the optic nerve, causing an ischaemic optic neuropathy and/or occlusion of the central retinal artery (Figure 24.4). About 12% of patients may also present with a cranial nerve palsy, giving rise to diplopia. Treatment is with immediate, high-dose systemic steroids (e.g. intravenous methylprednisolone 1–2 mg/kg daily or oral prednisolone 60–80 mg daily) to produce symptomatic relief of the headache and, most importantly, to prevent blindness in the other eye. Recovery of vision in the affected eye is rare.
Fig. 24.4 Giant cell arteritis. An 80 year old man with scalp tenderness, weight loss, and jaw claudication presents to casualty with recent loss of vision in his left eye. The optic disc is swollen and pale, indicating an anterior ischaemic optic neuropathy (AION). There is also a secondary central retinal artery occlusion.

Unusual neuro-ophthalmological complications of giant, cell arteritis include Horner's syndrome, cortical blindness (due to embolization from affected vertebral arteries), internuclear ophthalmoplegia, and visual hallucinations.[16]

Systemic lupus erythematosus

Eye symptoms are common in patients with SLE and range from minor external problems to severe retinopathy.[17] Five per cent of patients will develop scleritis at some time during the course of their disease, and this is occasionally seen at presentation. Scleritis indicates active systemic disease and may require adjustment of systemic therapy. Uveitis is very rare in SLE and only occurs in association with severe scleritis.[18]

The most important ophthalmic manifestation is retinopathy consisting of cotton-wool spots, retinal haemorrhages, and central or branch retinal artery occlusions.[19] Retinal vascular occlusion in SLE is due to deposition of immune complexes within the vessels, rather than vasculitis; however, vasculitis can occur in the choroid, leading to choroidal infarcts (Figure 24.5).[20] The presence of anti-cardiolipin antibodies may be a marker for the development of retinal vascular occlusion (Figure 24.6).[21]
Fig. 24.5 Choroidal infarcts in systemic lupus erythematosus.
Fig. 24.6 Central retinal vein occlusion in a woman who suffers from systemic lupus erythematosus.

Polyarteritis nodosa

Ocular involvement is present in 10–20% of patients with polyarteritis nodosa.[22] The most common manifestation is choroidal and retinal vasculitis, which is secondary to accelerated hypertension. It can be characterized by arteriovenous nipping, cotton-wool spots, and flame shaped haemorrhages.

Patients can also develop conjunctival infarction, keratoconjunctivitis sicca, episcleritis, scleritis, and necrotizing scleritis associated with peripheral ulcerative keratitis. Choroidal infarcts and exudative serous retinal detachments can occur due to involvement of the posterior ciliary arteries and choroidal vessels.

The development of scleritis or retinal vascular disease in the absence of hypertension warrants investigation of the systemic disease.

Wegener's granulomatosis

Eye problems develop in 29–52% of patients with Wegener's granulomatosis, with 8% of patients suffering disease-related vision loss.[23,24] It is the only systemic inflammatory disease that commonly presents with orbital disease due to infiltration of the orbit with granulomatous tissue. Patients may complain of proptosis, caused by the orbital mass; red eyes caused by scleritis; or blurred vision from compression of the optic nerve by the granulomatous tissue (Figure 24.7). They may also develop swollen optic discs and choroidal folds. Many patients also suffer from epiphora (watering eyes) due to destruction of the nasolacrimal duct in sinus disease. Of these conditions, scleritis usually occurs first, with nasolacrimal and orbital disease occurring after years of disease activity. A similar disease pattern can be seen in eosinophilic granulomatosis with polyangiitis (Churg–Strauss) and IgG4 disease.

Systemic sclerosis

The most common eye complaint in systemic sclerosis is dry eye, a loss of eyelid elasticity, and eyelid telangiectasia, which can occur in approximately 50% of patients.[25] Lid changes are thought to be due to sclerosis of the eyelid connective tissue, resulting in a 'woody' feeling and leading to difficulty everting the upper eyelids during examination. These changes tend to occur most commonly in patients who have more extensive skin involvement (i.e. diffuse cutaneous systemic sclerosis).
Fig 24.7 Orbital disease in Wegener's Granulomatosis.

Fig. 24.8 Hypopyon in Behçet's disease. A 20 year old man with known Behçet's disease presented with a red eye, decreased visual acuity, and a visible hypopyon associated with a fibrinous uveitis.

A minority of patients develop retinopathy similar to that seen in the other systemic vasculitides, with cotton-wool spots, haemorrhages and occlusion of retinal arteries.

Recent studies have suggested that patients with systemic sclerosis have an increased incidence of normal-tension glaucoma (NTG).[26] There is also evidence that the disease can lead to increased central corneal thickness, an important factor in the interpretation of intraocular pressure.[27]

Rheumatoid arthritis

A third of patients with RA suffer from dry eyes and in 10% this is combined with a dry mouth (Sjögren's syndrome). Five per cent of patients presenting with episcleritis and 30% presenting with isolated scleritis have RA. Bilateral scleritis, while still rare, is more common when associated with RA.[28]

Scleromalacia perforans (see Figure 24.2) affects elderly women predominantly. Advancing scleral disease in these patients almost always heralds a flare-up of their systemic disease (particularly the vasculitic complications).

Ankylosing spondylitis and the seronegative arthropathies

AAU is the most important ocular disease in this group of patients. It occurs in 33% of patients with ankylosing spondylitis and in 10–15% of patients with other associated seronegative arthropathies.[29] The clinical symptoms and signs are similar, regardless of the accompanying disease. Attacks are usually unilateral but both eyes can become affected during the course of the disease. Severe cases can develop a fibrinous uveitis with posterior synechiae (adhesions between the iris and the lens capsule) and raised intraocular pressure.[30]

Posterior segment disease is less common in this group of diseases. Ten per cent of these patients develop vitritis and a retinal vasculitis affecting predominantly the capillaries and postcapillary venules.

Behçet's disease

Ocular manifestations in Behçet's disease occur in up to 60% of patients.[31] Severe anterior uveitis, often in a painless eye, is common and a hypopyon may form (Figure 24.8). The anterior uveitis is typically recurrent but can resolve spontaneously.

Internationally, approximately a quarter of patients with Behçet's disease go blind as a result of their uveitis.[32,33] The pathognomonic features are sequential occlusions of branch retinal veins and retinal infiltrates. The nature of the venous occlusions results in progressive ischaemia and eventually the entire retinal vasculature is obliterated and results in optic disc atrophy.

Ocular involvement in rheumatic conditions of childhood

Uveitis occurring before the age of 16 years is approximately three times less common than uveitis in the general population.[34] In two reviews of uveitis in childhood, systemic illnesses such as sarcoidosis, Behçet's disease, and vasculitis accounted for less than 8% of patients.[35]

The most common associated disorder is seronegative JIA.

Juvenile idiopathic arthritis

The chronic anterior uveitis that occurs in association with JIA deserves special mention, particularly as it does not occur in adults. Affected children are mostly girls, and are usually young at onset of arthritis (mean age 3 years). Joint involvement is usually pauciarticular, although it may spread to become polyarticular.[36] Most patients have associated anti-nuclear antibodies (ANA) in their serum. Arthritis generally predates the eye involvement by 1–3 years or sometimes much longer, but 5–10% of cases present with uveitis and the ophthalmologist should therefore ask for a rheumatological opinion in any young child with chronic anterior uveitis. Similarly, because the eye disease is usually asymptomatic

until complications occur, the rheumatologist must arrange for an early slit lamp examination on all children. Regular follow up will be arranged by the ophthalmologist depending on the age of the child, their ANA status, and their age (Box 24.1).

The non-granulomatous iridocyclitis runs an uncomplicated course in one-third of affected children. The majority of untreated cases develop numerous complications such as band keratopathy, posterior synechiae, cataracts, or glaucoma. Early onset of uveitis, either symptomatic or when picked up in routine screening within the first year of arthritis, and particularly if associated with posterior synechiae at this first examination, are associated with a significantly worse prognosis for vision. Most eye involvement develops for the first time 4–5 years after of the onset of arthritis, and after this the risk is much lower. This is unlike the acute symptomatic anterior uveitis in ankylosing spondylitis, which may occur for the first time very many years later than the original musculoskeletal symptoms.

Treatment of ocular manifestations of systemic disease

Mild anterior segment inflammation such as dry eye, conjunctivitis, and episcleritis will invariably respond to local treatment. This can often be with simple ocular lubricants, but occasionally a mild topical steroid may be indicated.

Scleritis

Scleritis is an indication for systemic treatment. Adequate doses of non-steroidal anti-inflammatory drugs (NSAIDs) can often control pain and help reduce ocular inflammation (e.g. flurbiprofen 50 mg three times a day). If NSAIDs do not help to control symptoms,

systemic steroids are indicated. Occasionally, steroid-sparing agents are necessary (e.g. cyclophosphamide, azathioprine, ciclosporin, or mycophenolate mofetil).

Biological agents have been used successfully in the management of scleritis. Rituximab, an anti-CD20 B-cell monoclonal antibody, has been shown to be of use in scleritis refractory to multiple other agents.

Uveitis

The treatment for uveitis depends primarily on the site of the inflammatory process. In most cases, anterior uveitis can be treated topically with steroid eye drops to reduce the inflammation and a dilating agent such as cyclopentolate 1% to prevent posterior synechiae.

If the vision drops due to occlusion of the retinal vasculature, or involvement of the optic nerve, systemic immunosuppressants are indicated. Corticosteroids are usually sufficient in the first instance, but they may also be used in conjunction with ciclosporin, azathioprine, mycophenolate mofetil, or methotrexate.

Recently trials of biologic agents such the tumour necrosis factor alpha (TNF-α) inhibitor infliximab[37–39] and interferon alpha[40–42] have been used with good results, particularly in Behçet's disease and JIA.

Other biologic agents have been used to treat the ocular complications of various rheumatological diseases. Etanercept[43] and adalimumab[44] have been used successfully to treat JIA and Behçet's disease uveitis as well as macular oedema associated with uveitis. Rituximab has had good responses in JIA patients who have failed to respond to corticosteroids, methotrexate, etanercept, or infliximab.[45]

Daclizumab is a monoclonal antibody that targets interleukin 2 (IL-2), it has had promising results in patients with JIA, non-infective intermediate, posterior, and panuveitis.[46]

Small trials have used intravenous immunoglobulin (IVIG) to treat uveitis. The use of this has been limited due to the severe side effects (thromboembolism, aseptic uveitis) and high cost.[47]

Antirheumatic therapy with ocular side effects

Hydroxychloroquine is a commonly used drug in the treatment of RA and SLE. It has a high affinity for melanin-containing tissue in the eye, such as the retinal pigment epithelium. The pathophysiology of retinal damage is related to a malfunction of phagolysosomes, resulting in faulty clearance of ageing photoreceptor membranes.[48,49] Hydroxychloroquine has a better ocular side-effect profile than chloroquine, possibly because it does not cross the blood–retina barrier as easily.

Corneal deposits occasionally occur in patients taking quinolones, as the drug is deposited within the epithelium. The deposits, which can appear as punctate changes or whorl-like patterns, usually resolve on discontinuation of the drug.

The features of hydroxychloroquine retinopathy begin with a fine stippling of the macula and loss of the foveal light reflex. This can then produce a 'bull's eye' maculopathy made up of pigmented and depigmented rings centred on the fovea, resulting in loss of visual acuity and visual field loss. Even if treatment is stopped, atrophy of the retinal pigment epithelium can continue for a time before stabilizing.

Box 24.1 Current UK screening guidelines for anterior uveitis in juvenile idiopathic arthritis

The first screening visit should be carried out within 6 weeks of referral. This should be followed by a review every 2 months **from onset of arthritis** for 6 months, then 3–4 monthly screening for time outlined below:

Age at onset	Screening period
Oligoarticular involvement irrespective of ANA status and onset <11 years of age	
<3 years	8 years
3–4 years	6 years
5–8 years	3 years
9–10 years	1 year
Polyarticular involvement, ANA positive, onset <10 years of age	
<6 years	5 years
6–9 years	2 years
Polyarticular involvement, ANA negative, onset <7 years of age	
All children need 5 years screening	

Royal College of Ophthalmologists. *Guidelines for screening for uveitis in juvenile idiopathic arthritis,* 2009.

The most recent (2009) guidelines from the Royal College of Ophthalmologists[50] recommend that regular screening for hydroxychloroquine toxicity is **not** carried out. This is a significant change from the previous guidelines and is based on the following:

- The incidence of clinically significant hydroxychloroquine retinopathy is very low—in a large prospective study of patients taking the maximum dose of hydroxychloroquine (6.5 mg/kg) only 2 of the 400 patients developed irreversible toxicity and both of the patients affected had been taking the drug for over 6 years.

- There is no reliable method for detecting retinal toxicity at a reversible stage—visual fields, Amsler charts, distance and near visual acuity, autofluorescence, and multifocal electroretinography are all used to detect macular changes, but none provides a definite endpoint at which the toxicity level becomes irreversible.

Recommendations for rheumatologists are given in Box 24.2.

Corticosteroids

Both oral and topical corticosteroids may cause a variety of ophthalmic side effects[51]:

- Cataracts commonly develop after high doses of systemic steroids, but these can usually be easily dealt with surgically when the patients become symptomatic.

- Raised intraocular pressure. Five per cent of the population are termed 'steroid responders' because of a significant, but asymptomatic increase in pressure. The frequency, duration, and strength of oral or topical steroid all influence this effect. Where possible, steroid-sparing agents should ideally be used in these patients.

- Patients on steroids are more prone to infections and their use can also worsen underlying ocular infections such as herpes simplex. A full slit lamp examination should be carried out on all patients with a red eye before starting topical steroids to rule out an infectious cause.

Immunosuppressives

Patients on long-term immunosuppressives are at risk of developing opportunistic infections such as cytomegalovirus retinitis or
Fig. 24.10 Cytomegalovirus retinitis.

acute retinal necrosis (herpes simplex and zoster) (Figure 24.10). Any patient presenting with a new onset of floaters, red eye, visual field defect, or decreased visual acuity should have a dilated slit lamp examination.

Box 24.2 Hydroxychloroquine: recommendations for rheumatologists

- Do not exceed the maximum dose of 6.5 mg/kg (200–400 mg/day) of hydroxychloroquine.

- Establish renal and liver function before starting treatment.

- Enquire about any visual impairment not correctable with glasses before starting treatment and at yearly review.

- Before starting treatment, test the patient's reading vision with their reading glasses, (using a near vision chart or newspaper).

- If visual impairment is suspected the patient should be advised to consult an optometrist in the first instance. Any abnormality would then be referred to an ophthalmologist in the usual way.

CHAPTER 25

The kidney

Mark Little and Alan Salama

Introduction

Kidney involvement in the setting of rheumatology practice is frequently associated with increased mortality and considerable morbidity.[1] It may arise as part of the underlying rheumatic disease or may be a complication of its treatment. As with many other causes of kidney disease, early diagnosis allows timely intervention which is associated with an increased chance of recovery and prevention of chronic renal dysfunction. It is therefore of considerable importance that rheumatologists have a clear understanding of the causes and signs of renal disease. Relying solely on serum creatinine as a measure of renal dysfunction will result in a late appreciation of established kidney disease, and represents a missed opportunity for early detection of renal abnormalities.

The kidney is a complex organ that can be affected by abnormalities predominantly affecting its vasculature (such as in scleroderma), its filtration compartment (in glomerulonephritis secondary to systemic conditions such as systemic lupus erythematosus, SLE) or its concentrating and reabsorptive compartment (in tubulointerstitial nephritis secondary to non-steroidal anti-inflammatory drugs, NSAIDs). Although all three compartments may be affected simultaneously, particular disease patterns may arise due to individual compartments being predominantly affected. This can often be deduced from basic investigations, which may provide strong clues as to the likely aetiology of the renal dysfunction. Moreover, some changes may precede the elevation in serum creatinine, or decline in glomerular filtration rate (GFR), making them important early markers of kidney involvement.

Assessment of renal function

The serum creatinine is a reliable marker of changes in GFR if its limitations are understood. The urea level is a less reliable marker of changes in renal function, primarily because it may be elevated in several conditions where renal function is stable, such as gastrointestinal bleeding and steroid administration. As a result, rises in urea are best interpreted in relation to changes in the serum creatinine.

Approximately 20% of urinary creatinine excretion under physiological conditions is due to tubular secretion. Therefore, as glomerular filtration declines and tubular secretion of creatinine contributes a greater fraction of creatinine excretion, increases in the serum creatinine and a fall in the creatinine clearance tend to underestimate the true decrease in GFR that has occurred.[2]

Some medications, such as trimethoprim, competitively inhibit tubular creatinine secretion, leading to an increase in serum creatinine in the absence of any changes in GFR.

It is important to note that one can only infer GFR from a relatively stable creatinine level as the creatinine rise in acute kidney injury (AKI), which is dependent on the ongoing production of creatinine by muscle, lags behind the abrupt decline in GFR. For example, it is quite possible to have a GFR of 1 mL/min with a creatinine level of, say, 140 µmol/L if the GFR reduction occurred within the previous 24 hours. In this setting of zero or near-zero excretory kidney function the creatinine level will usually rise by about 80–100 µmol/L per day.

Finally, because the serum creatinine is roughly inversely proportional to creatinine clearance or GFR at relatively normal levels of renal function, changes in the serum creatinine tend to be a relatively insensitive biomarker of falling GFR. For example, an increase in the serum creatinine from 80 µmol/L to 160 µmol/L would represent a 50% decline in GFR. Once such a change has occurred, substantial renal function has been lost, despite what appears to be only a modest increase in the serum creatinine. An increase in the serum creatinine from 80 µmol/L to 90 µmol/L, if real, represents a 9% decline in GFR, also potentially significant. However, the standard laboratory assay for serum creatinine has a variation of about 10%, meaning that any change of 10 µmol/L in the serum creatinine level could (correctly or incorrectly) be attributed to laboratory variation. Therefore, it is important that even seemingly small changes in the serum creatinine should not be discounted and that particular attention should be made to temporal changes. If a major doubt persists, GFR should be measured by radionuclide methods. Novel biomarkers, such as neutrophil gelatinase-associated lipocalin (NGAL) and kidney injury molecule-1 (KIM-1),[3–5] show promise as sensitive early markers of renal injury but are not yet in general clinical practice. To overcome the problems of using serum creatinine alone to estimate renal GFR, physicians have used estimated GFRs based on equations which take into account the variables of production by including age, sex, and ethnicity in their derivations (see www.renal.org/eGFRcalc/GFR.pl and [6]). Some form of estimated GFR is now frequently provided by biochemistry laboratories and reported with the patients' serum creatinine. However, these equations are not intended for use when the renal function is normal or changing rapidly (as in AKI), or in patients with non-standard body morphology who may have greater or lesser muscle mass than average for their age.

Other important biomarkers of kidney disease are to be found in the urine, in particular in the form of proteinuria and haematuria. Proteinuria is a marker of renal inflammation and of irreversible injury. It may develop much earlier in the course of renal dysfunction than elevation in serum creatinine or decline in estimated GFR and in those patients with persistent protein leaks, is generally regarded as one of the most important predictors of future decline in renal function. Identification of proteinuria is generally by means of a dipstick test, but its quantification is also important in helping predict the source of leak and potential underlying disease process as well as monitoring response to treatment.

Proteinuria

Following validation of the technique, protein estimations on spot urine corrected for urine creatinine have become more commonplace and in many centres have replaced the 24 hour collections. When both protein and creatinine are quantified in mg/dL the urine protein:creatinine ratio is equivalent to the daily rate of protein excretion in grams.[7] These spot assessments are more convenient for patients, are processed more rapidly, and are reported in the form of a spot protein:creatinine ratio.

It is important to consider the nature of the protein excreted as this varies depending on the renal compartment affected. In health, urine has a low protein content, up to 80 mg/day, consisting of roughly half glomerular (filtered plasma) proteins and half tubular proteins. Glomerular protein loss (seen in active or chronic glomerulonephritis) consists mostly of albumin which is actively excluded in the urine by the glomerular filtration barrier, while tubular protein loss (seen in tubulointerstitial disease) is due to the failure of tubular resorption of filtered or secreted proteins, and consists of low molecular weight proteins such as retinol binding protein and β_2-microglobulin (Table 25.1). Under certain circumstances it is therefore important to measure both the albumin:creatinine and protein:creatinine ratio (which will pick up both albumin and low molecular weight proteins).

Haematuria

Haematuria is defined by the abnormal finding of red blood cells in the urine. It may be of renal origin or arise from lower down in the urinary tract (Table 25.2); it may be detected only on dipstick or microscopy (microhaematuria) or be visible to the naked eye (macrohaematuria). False-positive haematuria may arise when certain drugs, dyes, or pigments discolour the urine, giving the impression of blood, or when myoglobin or haemoglobin is present due to processes such as rhabdomyolysis or intravascular haemolysis, respectively. It is therefore important to confirm all dipstick positive haematuria with urine microscopy. In health, only a few red cells

Table 25.1 Glomerular and tubular proteinuria

Glomerular proteinuria	Tubular proteinuria
Albumin	Low molecular weight proteins
Microalbuminuria (>2.5–3.5<30 mg/mmol)	Usually about 1 g/day or PCR 100 mg/mmol
Macroalbuminuria (>30 mg/mmol)	
Nephrotic range (>3 g/day or PCR >300 mg/mmol): nephrotic syndrome	

PCR, protein/creatinine ratio.

Table 25.2 Causes of haematuria

Intrinsic renal bleeding	Lower tract bleeding
Glomerulonephritis	Infection
Thrombotic microangiopathy	Prostatic hypertrophy/malignancy
Tubulointerstitial nephritis	Ureteric/bladder malignancy
Pyelonephritis	Haemorrhagic cystitis
Structural abnormalities, e.g. thin glomerular basement membrane lesion, Alport's syndrome, Fabry's disease	Renal/bladder stones
Renal tumour	Anticoagulant therapy
Renal vein/arterial thrombosis	Trauma
Papillary necrosis	Vascular malformations
Polycystic kidneys	Factitious
Trauma	

(up to 3 per high power field) are found in the urine, the majority being excluded by the glomerular basement membrane. Under pathological conditions those red cells that traverse the glomerulus may become deformed and dysmorphic, while any bleeding from the lower urinary tract leaves the cells intact. Therefore urine microscopy can, in experienced hands, provide clues as to the origin of the haematuria, by careful examination for dysmorphic red cells. Haematuria always needs investigation and whether this starts with renal or lower tract investigation will depend on the age of the patient and the clinical setting. Urine cytology may provide important clues as to the nature of the red cells and other diagnostic cells in the sample. Examination of the lower urinary tract with cystoscopy, and imaging with ultrasound or CT, are important tools in investigating haematuria.

Urine dipstick testing

The urine dipstick is one of the most useful tools available to detect renal disease. Not only does it detect proteinuria and haematuria, it also allows detection of leucocyturia (suggesting inflammation or infection), and can provide important information regarding tubular dysfunction causing changes in concentrating ability, glucose leak, and acidification abnormalities. These are often overlooked but represent an early and sensitive marker of renal dysfunction. The main protein detected by urine dipsticks is albumin and it is important to remember that dipsticks are insensitive to globulins, including Bence Jones protein, making them an inadequate tool for assessing renal involvement in plasma cell dyscrasias.

Tubular damage occurs consequent to interstitial inflammation leading to a number of functional tubular defects, the pattern of which is dependent on the predominant region of the tubule affected (Table 25.2). Urine dipstick testing may also reveal glycosuria which, if the blood glucose level is normal, suggests a renal glucose leak; a low urine specific gravity (indicating a potential concentrating defect); and an alkaline pH (suggesting a defect in urine acidification).

Renal failure: acute

Definitions

Acute renal failure is defined as a sudden decline in renal function, usually measured by an increase in serum creatinine and blood

urea, or a decrease in GFR. For most of the first part of the 21st century, an acute decline in kidney function was defined according to the Acute Dialysis Quality Initiative (ADQI) 'RIFLE' criteria. These definitions had many limitations, leading to the introduction of the Acute Kidney Injury Network (AKIN) criteria:

◆ an abrupt (within 48 hours) absolute increase in the serum creatinine concentration of ≥0.3 mg/dL (26.4 μmol/L) from baseline, or

◆ a percentage increase in the serum creatinine concentration of ≥50%, or

◆ oliguria of <0.5 mL/kg per hour for more than 6 hours.[8]

The term 'acute kidney injury (AKI)' is now used in place of 'acute renal failure'. It remains controversial as to whether prerenal and postrenal acute declines in GFR should be included in the AKI definition; for the purposes of this discussion, we shall assume that they are included and that AKI refers to any abrupt rise in creatinine level.

Diagnostic approach to the patient with acute kidney injury

The commonest cause of an acute rise in serum creatinine level is a prerenal insult, and the initial assessment should focus on assessment and correction of the extracellular fluid volume status (assessed clinically: dependent oedema, status of neck vein filling, and postural blood pressure), use of NSAIDs, angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs), or other factors that could reduce effective renal perfusion.

Once prerenal issues have been addressed, the key questions that one should consider when faced with persisting AKI are:

1. Is this truly acute, or is there an element of chronic (presumed irreversible) kidney disease (CKD) at play?

2. Are the kidneys obstructed (hydronephrotic)?

3. Is there a severe immunologically mediated intrinsic renal disease present?

An estimate of the disease duration and tempo (acute, subacute, or chronic) can be derived from the history, an early telephone call to the patient's family doctor for information on historic creatinine values, and urgent imaging of the kidneys. A recent clinical syndrome of defined onset, such as general malaise, joint pains, rash, or change in urine colour, suggests that there is at least an acute element to the decline in GFR, although it does not exclude the possibility that this is occurring on a background of CKD. This is an important issue as it determines what will be achievable in terms of renal function recovery. Therefore, the most important piece of data to obtain in a patient with an elevated serum creatinine level is a recent creatinine value in the normal range; all efforts should thus be made to identify a clinical scenario within the previous 6 months where a creatinine level may have been measured.

The key investigation that will help one decide whether the kidneys are acutely injured (and therefore potentially recoverable) or obstructed is a renal ultrasound scan, which should be performed as soon as possible in AKI. This will provide reliable information on the presence or absence of lower urinary tract obstruction (in which case hydronephrosis will be present), and on renal size and asymmetry. In the setting of established CKD the kidneys are usually, but not always, reduced in size and echogenic. A skilled ultrasonographer will comment on the thickness of the renal cortex, which is also reduced in CKD. The presence of normal-sized kidneys with a normal cortical thickness in the context of AKI is often the start of a pathway towards diagnostic renal biopsy. The kidneys may occasionally be large (>13 cm) on ultrasound; in the setting of AKI this usually indicates an infiltrative process, such as amyloidosis or lymphoma. If one kidney is more than1.5 cm smaller than the other, this suggests longstanding severe renal artery stenosis to the small kidney (and by inference possible renal artery stenosis to the larger kidney also), which is of particular relevance in the setting of ACE inhibitor and ARB use. One should also note that, while unilateral hydronephrosis generally does not cause a significant rise in serum creatinine, if the other kidney is atrophic then urinary tract obstruction can be implicated as the sole cause of AKI, as the small kidney may not be providing any excretory renal function.

In the rheumatology setting, the next major question that needs to be considered is whether the kidneys are severely injured by an intrarenal process that would respond to a specific therapy, such as rapidly progressive glomerulonephritis (RPGN), haemolytic uraemic syndrome (HUS), acute interstitial nephritis, or myeloma cast nephropathy. These conditions are discussed in more detail below (see 'Diagnostic approach to the patient with acute kidney injury'). If the creatinine level is rising day by day and the ultrasound demonstrates normal-sized unobstructed kidneys, the diagnosis will most often be acute tubular necrosis (ATN), especially in the hospital setting, but one must always consider whether an acute glomerular or other tubulointerstitial process is present. Most helpful in this setting is careful urinalysis of urine which is freshly obtained and not catheter derived. If there is blood and protein present on dipstick testing, and especially if red cell casts are seen on urine microscopy, it is likely that the patient has RPGN. It must be emphasized that appropriate immunosuppressive treatment of RPGN often results in marked improvement in renal function and that, without it, glomerular destruction progresses relentlessly to the point where the patient develops irreversible dialysis-dependent renal failure. Therefore, urgent appropriate serological testing and early referral to a nephrologist for consideration of kidney biopsy are essential. The probability of RPGN being the cause of AKI is highest if certain underlying rheumatological conditions are present, in particular ANCA vasculitis, SLE, Henoch–Schönlein purpura (HSP), and cryoglobulinemia, and/or if there is a coexistent pulmonary syndrome, such as lung haemorrhage or a new lung infiltrate.

If the kidneys are unobstructed and of normal size, and the patient has AKI with a normal urine dipstick test, important diagnoses to consider are HUS[9] and other causes of thrombotic microangiopathy, and myeloma cast nephropathy.[10] In the former there is reduction in glomerular blood flow because of intraglomerular capillary thrombosis; in the latter there is tubular obstruction and damage by complexed Tamm–Horsfall protein and light chains. The focus in this clinical scenario should be on looking for features of the systemic disease: hypertension, thrombocytopenia, and microangiopathic haemolytic anaemia in HUS; hypercalcaemia, anaemia, lytic bone lesions, serum paraprotein/free light chains, and urine Bence Jones protein in multiple myeloma. If the AKI occurs in the setting of systemic sclerosis (SSc), early consideration must be given to scleroderma renal crisis, which is also associated with a relatively normal urinalysis. The key feature of scleroderma renal crisis is severe and progressive hypertension which may be characterized

by features of malignant hypertension, such as papilloedema. Note that occasionally there may be minimal skin changes of scleroderma and that a renal crisis may be the presenting feature of SSc.

If there is persisting AKI, but no evidence of RPGN, HUS, or myeloma, and the urine dipstick demonstrates proteinuria and leucocytes, the diagnosis may be acute interstitial nephritis, an often overlooked condition. Traditionally, if interstitial nephritis is suspected, one is taught to look for systemic evidence of hypersensitivity, such as rash, eosinophilia, and eosinophiluria. In practice these findings are rarely helpful and the diagnosis can only be made on renal biopsy.

The next step in the assessment of the patient with AKI is diagnostic blood testing. The priority here is to liaise with the laboratory to ensure that serological tests are run urgently if RPGN is suspected. Of the serological tests available, the ANCA test has greatest utility in this setting. When ethanol-fixed neutrophils are exposed to patient serum and antibody binding is detected using fluorescently labelled antibodies, two patterns of indirect immunofluorescent staining may be identified: fine granular cytoplasmic (c-ANCA) and perinuclear (p-ANCA). Proteinase 3 (PR3) and myeloperoxidase (MPO) are the most commonly identified autoantigens leading to the c-ANCA and p-ANCA appearances, respectively, and therefore the terms PR3-ANCA and MPO-ANCA are frequently used. A positive PR3-ANCA ELISA test, when combined with a positive immunofluorescence test, is highly sensitive and specific for active granulomatosis with polyangiitis (GPA; previously Wegener's). Of note, immunofluorescence testing alone is not sufficiently specific and should always be combined with an ELISA looking for the specific antibody.[11,12] The overall sensitivity is estimated to be 66%, those with limited upper airway disease often being ANCA negative, and the overall specificity for the combined test is 99%.[12,13] One potential pitfall to bear in mind is chronic cocaine use, which may mimic the nasal and sinus features of GPA, and is occasionally associated with anti-PR3 antibodies; in addition, there is strong evidence to support an association between levamisole-tainted cocaine and ANCA- vasculitis.[14] During active GPA, the pooled sensitivity increases to 91% and the pooled specificity rises to 99%. Whether titres of ANCA correlate directly with disease activity remains controversial.[15,16]

It is worth mentioning that a positive ANA test may be confused with a positive p-ANCA staining pattern, reinforcing the importance of combining the immunofluorescence test with the ELISA. The sensitivity of a positive p-ANCA plus anti-MPO antibody test for MPA is 67%, and the allied specificity (when the test is performed in the appropriate clinical context) is 99%.[12,13] Among those with positive ANCA serologies (both immunofluorescence and ELISA) and a clinical presentation of RPGN, the positive predictive value of finding a pauci-immune crescentic glomerulonephritis on renal biopsy is at least 98% in all age groups.[17,18] Of note, classical polyarteritis nodosa (which is not characterized by crescentic glomerulonephritis) is not associated with the presence of ANCA.

In rheumatological settings other than systemic vasculitis, the following antibody tests also have specific utility:

- In patients with SLE, anti-C1q antibodies are associated with renal involvement and may be associated with renal flares.[19]

- In patients with SSc, fibrillarin (U3-RNP) and anti-RNA polymerases (I and III) are associated with the development of scleroderma renal crisis.[20,21]

In addition to antibody testing, it is useful in the setting of AKI to measure serum levels of complement components C3 and C4. If depressed, this strongly suggests a renal disorder characterized by glomerular deposition or serum consumption of complement: lupus nephritis, cryoglobulinemic glomerulonephritis (C4 is often depressed in isolation), or HUS.

Potential causes of acute kidney injury in rheumatological practice

Prerenal acute kidney injury

Probably the most frequently encountered cause of acute prerenal AKI in rheumatological practice is an NSAID-induced reduction in renal perfusion by diversion of eicosanoid synthesis away from prostacyclin (these agents are also instrumental in causing acute interstitial nephritis, discussed below; see 'Acute interstitial nephritis'). Volume depletion, hepatic disease, and lupus nephritis predispose to the adverse renal haemodynamic changes associated with the NSAIDs. The alterations in renal function are reversed upon discontinuation of the offending drug. The ACE inhibitors and ARBs can also induce decreased renal perfusion and an acute decline in renal function through dilatation of intrarenal efferent arterioles. Such alterations in renal function are enhanced when there is underlying volume depletion, renal vascular disease, or pre-existing glomerular disease.[22–24] In addition to being the preferred treatment for kidney disease characterized by proteinuria, these antihypertensives have been particularly efficacious in the treatment of malignant hypertension associated with scleroderma renal crisis and the microangiopathies. When using these medications, renal function and serum electrolytes must be monitored closely because of the risk of AKI and electrolyte abnormalities, such as hyperkalaemia. Having said that, most nephrologists would expect (and tolerate) a 10% rise in creatinine level after starting an ACE inhibitor or ARB.

Postrenal acute kidney injury

Postrenal AKI is characterized by oliguria caused by an intrarenal or extrarenal obstruction to urine flow. Intrarenal obstruction may be due to crystallization of a substance within the renal tubules. This might be endogenous, such as uric acid or a calcium salt, or exogenous, such as crystals of methotrexate or aciclovir. However, the most important cause of intrarenal postrenal AKI is obstruction and destruction of tubules by casts composed of light chains and Tamm–Horsfall mucoprotein in the context of multiple myeloma. Light chains have a molecular weight of approximately 22 000 and are freely filtered by the glomerulus. Normally, the daily filtered quantity of 30 mg/day is reabsorbed in the proximal tubule; with vastly excessive overproduction (up to 20 g/day) by a malignant plasma cell clone, this reabsorptive capacity is overwhelmed with consequent precipitation in complex with Tamm–Horsfall mucoprotein in the loop of Henle. Any patient with AKI and a negative urine dipstick test should undergo formal quantification of urine protein excretion rate and a screen for multiple myeloma. Volume depletion (especially when induced by loop diuretics), radiocontrast administration, and increased urinary calcium excretion (e.g. in hypercalcemia) greatly increase the risk of AKI in multiple myeloma. Traditionally, advanced renal insufficiency caused by myeloma cast nephropathy was considered largely irreversible. However, recent advances in myeloma therapy (e.g. bortezomib therapy) and serum light chain removal (with high-flux,

extended-hours dialysis) may allow recovery of kidney function.[25] Therefore, early referral is essential for patients with AKI in the context of myeloma, even if the creatinine level is only mildly elevated.

Clinically apparent extrarenal obstruction to urinary flow most commonly involves the lower urinary tract because the obstruction of only one of two functioning kidneys will allow the non-affected kidney to continue to make urine, so oliguria and a reduction in GFR will not result. The characteristic feature of AKI secondary to extrarenal obstruction is marked reduction in urine output, often to the extent of anuria: acute anuria should be considered due to obstructive uropathy until proven otherwise by ultrasound scanning; if the ultrasound scan is normal, consideration should be given to whether there is bilateral renal infarction due to an acute occlusion of arterial blood supply.

By far the commonest causes of extrarenal obstruction causing AKI are prostatic disease (in which case the bladder will be markedly distended clinically) and locally advanced pelvic cancer (in particular, cervical and bladder). Bilateral papillary necrosis could lead to obstruction of the upper urinary tract through occlusion of both ureters, but this would be a most unusual event. Postrenal failure can be reversed if the obstruction is relieved before onset of renal parenchymal damage.

Intrinsic acute kidney injury: key relevant pathologies

Rapidly progressive glomerulonephritis

The pathological hallmark of RPGN is the glomerular crescent, which is a non-specific pathophysiological response to severe glomerular injury, and is observed as the result of a variety of insults which are classified according to the presence or absence of glomerular deposition of immunoproteins:

- Linear deposition of IgG along the glomerular basement membrane (GBM) is seen in conjunction with circulating anti-GBM antibodies in Goodpasture's disease. This is the rarest form of RPGN, but tends to be the most severe. It is relatively unusual for patients with this condition to recover kidney function if they present requiring dialysis.

- Widespread deposition of immunoproteins (immunoglobulins, complement components) throughout the glomerulus. In a rheumatological setting this is most often seen in SLE, but may also be a feature of severe HSP (IgA deposits), postinfectious glomerulonephritis and cryoglobulinaemia.

- Relative absence of immunoprotein deposition: so-called pauci-immune crescentic glomerulonephritis. In this case the glomerular injury occurs secondary to inflammatory necrosis of the glomerular tuft due to vasculitis of the afferent arteriole, and is pathognomonic of systemic small-vessel vasculitis, usually in association with circulating anti-PR3 or anti-MPO antibodies. The clinical term applied to this condition is determined by the nature of the extrarenal manifestations. If necrotizing granulomatous inflammation of the nasal passages, sinuses, and upper airways is present, or there are granulomata evident on chest imaging, this is termed GPA. If the there is no granulomatous inflammation and the predominant extrarenal manifestation is 'vasculitic' (i.e. alveolar haemorrhage, leukocytoclastic skin vasculitis, iritis, mononeuritis multiplex), this is termed MPA. Of note, small-vessel vasculitis limited to the kidney is now

considered 'single organ vasculitis'. The renal lesion of MPA and GPA is pathologically indistinguishable and is generally treated in the same way, although patients with MPA tend to have more chronic lesions and more extensive glomerular scarring at diagnosis.

Crescentic glomerulonephritis is usually treated with high-dose corticosteroids and cyclophosphamide and, when sufficient immunosuppression is given, appreciable recovery of renal function often follows (except in cases of advanced anti-GBM disease). A delicate balance needs to be struck between the adverse effects of such intense immunosuppression and the consequences of advanced irreversible renal failure. It is worth appreciating in this regard that chronic dialysis therapy is tolerated poorly in elderly people and that the equation usually falls on the side of giving immunosuppression if the kidney biopsy shows acute, potentially reversible, glomerular lesions. In ANCA vasculitis there is now strong clinical trial evidence to support the use of the anti-CD20 monoclonal antibody rituximab in place of cyclophosphamide in severe glomerular disease, especially when there is a perceived risk of infection or desire to preserve fertility.[26,27] In addition, plasma exchange is often used in anti-GBM disease and in severe ANCA-associated vasculitis (creatinine level >500 μm).[28]

Thrombotic microangiopathy

In some cases of intrinsic AKI the lesion is confined to the microvessels of the glomerulus, with evidence of acute thrombosis but no inflammatory infiltrate or glomerulonephritis. In these cases of thrombotic microangiopathy, two important diagnoses must be considered and differentiated:

Scleroderma renal crisis

The presence of microscopic renal lesions in patients with systemic sclerosis may occur in up to 80% of individuals, although only 40–50% will present with clinical renal involvement, including hypertension, proteinuria, or renal impairment. In 15–20% of patients who develop hypertension in the setting of diffuse cutaneous SSc, the onset is abrupt with severe elevation of diastolic blood pressure, often associated with cardiac failure, retinopathy and rapid deterioration of renal function: so-called scleroderma renal crisis. This severe complication of SSc almost invariably occurs within 5 years of diagnosis, and usually within 2 years. Prior use of high-dose glucocorticoids appears to be a risk factor. In some patients, scleroderma renal crisis may be the presenting feature of SSc, with little involvement of skin, peripheral vessels, or joints, in which case differentiation from thrombotic thrombocytopaenic purpura (TTP) and HUS may become difficult. Histologically, the small arterioles of the kidney in patients with the malignant form of hypertension in SSc show extensive fibrinoid necrosis and microthrombus formation, with 'onion-skin' intimal hypertrophy. Glomerular changes show varying degrees of thrombosis and necrosis secondary to ischaemia. The accelerated hypertension and rapidly progressive renal failure are life threatening and demand prompt, intensive intervention. The initial priority is to bring the blood pressure under control, and ACE inhibitors are the mainstay of therapy in this regard. Even if oliguria and progressive renal failure supervene despite control of blood pressure, antihypertensive therapy should be continued because it will protect other organs from the damaging effects of severe hypertension and renal function may return after months of dialysis support.[20,29]

Thrombotic thrombocytopenic purpura and haemolytic uraemic syndrome

TTP and HUS are classical examples of microangiopathic haemolytic anaemia and have many features in common, including anaemia, thrombocytopenia, and renal involvement. The two syndromes are similar in most of their clinical and laboratory findings, although patients with prominent neurological features are generally considered as having classical TTP, and those with dominant renal features are considered as having HUS. Many cases of HUS are associated with a diarrhoeal illness; those that are not are termed 'atypical' or 'D-' HUS. Mutations in the genes for complement proteins including C3, factors H, B, and I, and CD46 are associated with approximately 50% of cases of atypical HUS. Recent work has sought to classify TTP based on the level of ADAMTS13 (**A D**isintegrin-like **A**nd **M**etalloprotease with **T**hrombo**S**pondin type 1 repeats), deficiency of which leads to accumulation of unusually large Von Willebrand factor multimers, which in turn promote platelet aggregation.[30] Although useful, the exact link with TTP remains controversial, and reduced levels of this protease are also observed in other conditions such as sepsis.[31] The classical pathological finding in the kidney in both syndromes is occlusive lesions of arterioles and glomerular capillaries with fibrin, platelets, and red blood cells. The features of TTP and HUS may be seen in patients with SLE, and it is also seen in the setting of severe disseminated intravascular coagulation, sepsis, quinine therapy, allogeneic bone marrow transplantation and systemic vasculitides. Plasma exchange has become the mainstay of therapy in TTP and HUS.

Acute interstitial nephritis

Tubulointerstitial nephritis (TIN) is an inflammatory renal condition in which the damage is focused on the tubules and interstitium. It is of considerable importance, since tubulointerstitial damage correlates more closely with impairment of renal function than the degree of glomerular damage. Interstitial inflammation may be secondary to glomerular injury, renovascular or metabolic disease, or may be initiated primarily within the interstitial compartment. The commoner causes of TIN are drug reactions, but infections and certain rheumatological diseases may have predominant impact on the tubulointerstitium (Box 25.1). Many drugs commonly used in rheumatological practice, such as NSAIDs, proton pump inhibitors, or antibiotics, may induce TIN, and these do not always manifest with other allergic manifestations, making the diagnosis difficult unless a renal biopsy is obtained.

TIN may result in AKI, accounting for up to 27% of cases presenting with renal failure and normal-sized kidneys on ultrasound.[32,33] Many clinical features are common to TIN irrespective of its

---

Box 25.1 Rheumatological conditions associated with tubulointerstitial nephritis

- Systemic lupus erythematosus
- Mixed connective tissue disease
- Sjögren's syndrome
- Sarcoidosis
- Tubulointerstitial nephritis and uveitis (TINU)
- Primary systemic vasculitis
- Relapsing polychondritis

Table 25.3 Sites of injury and patterns of tubular dysfunction in tubulointerstitial nephritis

Site of injury	Tubular dysfunction	Clinical features
Proximal tubule	Decreased reabsorption of Na^+, glucose, HCO_3^-, urate, PO_4^-, amino acids	Glycosuria, hypouricaemia, hypophosphataemia, aminoaciduria, alkaline urine, acidaemia[a]
Distal tubule	Decreased secretion of Na^+, H^+	Alkaline urine, acidaemia,[b] hyperkalaemia, inability to preserve Na^+
Medulla and papilla	Decreased reabsorption of Na^+ Decreased concentrating ability	Polyuria, nocturia, inability to preserve free water[c]

[a]Proximal renal tubular acidosis.
[b]Distal renal tubular acidosis.
[c]Nephrogenic diabetes insipidus.

aetiology (Table 25.3). However, since suggestive clinical features can be absent or the diagnosis may not be suspected, renal biopsy is required to confirm the diagnosis. There may be evidence of systemic acidaemia, hypo- or hyper-kalaemia, hypophosphatemia, or hypouricaemia. Immunological tests should be performed in all cases and may be helpful in the diagnosis of systemic disorders associated with TIN.

Interstitial nephritis induced by NSAIDs appears to be unique among the drug-induced tubular interstitial nephritides in its association with heavy proteinuria. The propionic acid derivatives—fenoprofen, ibuprofen, and naproxen—have accounted for three-quarters of the cases reported, with fenoprofen alone accounting for over one-half of the incidence of tubulo-interstitial disease induced by NSAIDs.[34] The lesions have also been found after the self-administration of over-the-counter ibuprofen and may recur after exposure to different NSAIDs of the same group or upon re-exposure to the same agent. Renal function improves within days of discontinuing the offending agent, although proteinuria may persist for weeks to months and the GFR may remain permanently reduced in 40% of cases.[35] Alternative agents infrequently associated with nephrotoxicity include meclofenamate and sulindac. The issue of corticosteroid treatment of TIN remains controversial and there are no trial data to guide their use. However, most nephrologists would advocate treatment with up to 6 weeks of corticosteroids in patients who do not demonstrate improvement in kidney function within 1 week of withdrawal of the offending agent.

Drug-induced acute tubular injury

Nephrotoxic agents generally cause injury to the tubular components of the nephrons, particularly the highly metabolically active proximal tubule. A large range of agents can cause nephrotoxicity and AKI; we consider in detail several of relevance to rheumatological practice:

Radiocontrast agents

These agents, particularly older high-osmolality contrast agents, are a common cause of acute tubular injury, probably mediated by intrarenal vasoconstriction. By far the biggest risk factor is pre-existing renal dysfunction, with diabetes mellitus providing additive risk. Congestive cardiac failure and multiple myeloma also increase the risk. The induced renal dysfunction is generally mild,

non-oliguric, and reversible within 3–5 days, suggesting that overt tubular necrosis does not generally occur.

Aminoglycosides

Aminoglycosides cause non-oliguric AKI in approximately 10% of treated individuals, which is usually mild and reversible upon stopping the agent. The main injury is to the proximal tubule, where the drug is concentrated, giving very high intracellular levels; dysfunction of proximal tubular cells may give rise to a Fanconi-type syndrome, with glycosuria, aminoaciduria, and phosphate wasting. Distal tubular damage may also result and is manifested as polyuria and renal magnesium wasting. There is a close relationship between drug exposure and risk of injury, so long treatment courses with high trough drug levels are the main risk factor. Advanced age, sepsis, and pre-existing renal disease (mainly due to the increased

risk of overdosing) are the other main risk factors. Use of infrequent dosing schedules (every 24–48 hours) reduces the risk of toxicity.[36]

Calcineurin inhibitors

Calcineurin inhibitor (CNI, ciclosporin and tacrolimus) nephrotoxicity causes AKI (which is largely reversible after reducing the dose), or chronic progressive irreversible renal disease. The acute effect is dose dependent and mediated by endothelial injury resulting in intense vasoconstriction of intrarenal arterioles. Occasionally, thrombotic microangiopathy occurs with features of microangiopathic haemolytic anaemia. Because of the tight association of AKI with blood levels of the drug, it is important to measure levels at regular intervals in all patients treated with a CNI.

The clinical features of AKI are summarized in Table 25.4.

Table 25.4 Features of acute kidney injury

Type of acute kidney injury	Characteristic features
Prerenal acute kidney injury (reduced renal perfusion)	
Volume depletion (over-diuresis, vomiting, diarrhoea)	◆ Oliguria
Hypotension	◆ Concentrated urine
Congestive cardiac failure	◆ No intrinsic renal damage
Cirrhosis (hepatorenal syndrome)	◆ Reversible upon correction of underlying problem
ACE inhibitors/ARBs/NSAIDs	
Hypercalcaemia	
Postrenal acute kidney injury (obstructive uropathy)	
Prostate hypertrophy or cancer	◆ Anuria
Ureteric obstruction by tumour at the base of the bladder (cervical, bladder, ovarian)	◆ Obstruction must be bilateral to cause significant reduction in GFR
Ureteric obstruction by retroperitoneal fibrosis	◆ Hydronephrosis
Intraureteric obstruction (bilateral calculus, bilateral papillary necrosis, bilateral blood clot)	◆ Causes irreversible intrinsic renal damage if prolonged
Intrarenal tubular obstruction (myeloma casts, oxalate crystals (e.g. ethylene glycol ingestion, aciclovir crystals)	◆ Bland urine sediment
	◆ Elevated PCR with negative urine dipstick (Bence Jones proteinuria)
Intrinsic acute kidney injury	
Crescentic glomerulonephritis (ANCA-associated vasculitis, class III/IV lupus nephritis, anti-GBM disease, IgA nephropathy (HSP), cryoglobulinemia)	◆ Glomerular haematuria
	◆ Red cell casts
Glomerular microangiopathy (haemolytic uraemic syndrome)	◆ Bland urine
	◆ Red cell fragments on blood film
	◆ Hypertension
Vascular causes (scleroderma renal crisis, malignant hypertension, atheroemboli, renal vein thrombosis)	◆ Hypertension
	◆ Red cell fragments on blood film
	◆ Relatively bland urine sediment
Ischemic tubular injury (prolonged prerenal state, sepsis syndrome)	◆ Clear preceding factors
Toxic tubular injury (aminoglycosides, myoglobin, antiretrovirals)	◆ High urinary sodium excretion
	◆ Tubular dysfunction (renal glucose and phosphate wasting)
Tubulointerstitial nephritis (penicillins, NSAIDs, PPI, sacroidosis)	◆ Non-nephrotic range proteinuria
	◆ Preserved urine output
	◆ Leukocyturia

ACE, angiotensin-converting enzyme; ARBs, angiotensin receptor blockers; GFR, glomerular filtration rate; HSP, Henoch–Schönlein purpura; NSAIDs, non-steroidal anti-inflammatory drugs; PPI, proton pump inhibitor; PCR, protein/creatinine ratio.

Patient with Rheumatological disease (in particular: SLE, HSP, Sjogren's syndrome, SSc, systemic vasculitis, RA, sarcoidosis)

Scenario

| Red or "tea-coloured" urine | Incidentally discovered abnormal urine dipstick findings on ≥2 occasions | Progressive swelling, actue weight gain and pitting oedema | Declining GFR (chronic) | Declining GFR (actue) |

Specific findings

| Positive dipstick for **blood** >3 RBC per HPF May also be positive for protein | Positive dipstick for **blood** >3 RBC per HPF May also be positive for protein Normal eGFR | Dipstick positive for **protien (+1)** ACR 30–300mg/mmol PCR>45–400mg/mmol | Dipstick positive for **protien (+3)** ACR >300mg/mmol PCR>400mg/mmol | eGFR<60ml/min/1.73m^2 on 2 readings 3 months apart | >26mmol/L rise in creatinine level in <48hrs Urine output may be reduced (<0.5ml/kg/hr) |

Ensure GFR is not falling rapidly

Fig. 25.1 Algorithm depicting typical diagnostic pathways following various clinical scenarios. Acute kidney injury and nephrotic syndrome should lead to timely nephrology referral.

General principles of management of acute kidney injury

The prognosis of AKI is determined both by the underlying disease and by the quality of medical management. Individuals with renal dysfunction complicating a rheumatic disorder should be followed up jointly by a rheumatologist and a nephrologist (see Figure 25.1). Early consultation with a nephrologist is advisable in order to rapidly diagnose the underlying aetiology of AKI. In many situations, prompt resolution of the inciting factors can lead to a rapid return of renal function. In cases where deterioration cannot be halted, nephrologic support by means of renal replacement therapy can be initiated in a timely manner. The chief cause of complications in the setting of AKI is not azotaemia, but associated fluid and electrolyte abnormalities. In the acutely ill, highly catabolic patient with systemic illness, early and frequent dialysis may be required. The rheumatologist and nephrologist should review the prescribed medications critically as soon as AKI is recognized. The dosage schedule for potentially nephrotoxic agents such as NSAIDs, aminoglycosides, and amphotericin B should be adjusted for the level of renal failure or discontinued if possible. Intravascular radiocontrast procedures should be avoided during AKI. If it is necessary to use a diagnostic procedure requiring contrast, a minimal dose should be employed and the patient intensively hydrated before, during, and after the procedure to promote excretion of the radiocontrast agent. The presence of a highly catabolic state caused by corticosteroid therapy, gastrointestinal bleeding, parenteral nutrition, or septicaemia can induce a rise in the blood urea by as much as 30 mM/day in the setting of AKI. Such levels of azotaemia are detrimental to platelet and neutrophil function, and may potentiate a bleeding diathesis or further compromise host defences. Therefore, daily or continuous dialysis may be warranted.

Kidney failure: chronic

Definitions

Chronic kidney disease (CKD) is much commoner than AKI; it is estimated that approximately 8% of the population has renal disease resulting in a chronic reduction in eGFR to less than 60 mL/min. The internationally accepted definition of CKD consists of:

◆ the presence of markers of kidney damage for ≥3 months, as defined by structural or functional abnormalities of the kidney with or without decreased GFR, that can lead to decreased GFR, manifested by either pathological abnormalities or other markers of kidney damage (such as haematuria or proteinuria), or abnormalities in imaging tests, or

◆ the presence of GFR <60 mL/min/1.73 m^2 for ≥3 months, with or without other signs of kidney damage as described above.[37]

Irrespective of the cause, and even in those in whom the renal injury has been effectively treated, there is a tendency for ongoing loss of GFR over time, an observation related to hyperfiltration and overload of the remaining nephrons. The rate of progression is dependent on many factors, including persistence of the inciting renal disease, carriage of certain genetic polymorphisms, ethnicity, degree of hypertension, and presence of comorbid conditions. The strongest predictor of progressive loss of GFR is the degree of proteinuria (Table 25.5).

Diagnostic approach to the patient with chronic kidney disease

In rheumatological practice, the presence of CKD is usually suggested by the anecdotal finding of an elevated serum creatinine level or abnormal urine dipstick result. The reduction in GFR is well tolerated clinically until the patient reaches stage IV–V CKD and the GFR drops below 20 mL/min. The vast majority of patients with CKD are thus asymptomatic, although they may manifest features of the underlying disease. If the renal dysfunction is very severe (stage V CKD) the patient may display clinical features of the 'uraemic syndrome': mental dullness, anorexia, and vomiting, usually associated with progressive swelling, itching, and shortness of breath.

The principal causes of CKD 3 or greater in the United Kingdom are diabetic nephropathy, glomerulonephritis, hypertension, ischemic nephropathy (secondary to renovascular disease), reflux nephropathy, and monogenetic renal disease (particularly adult polycystic kidney disease). Diagnostic clues include the following:

◆ Diabetic nephropathy is typically associated with albuminuria, which may exceed protein/creatinine ratio (PCR) >300 mg/mmol. Indeed, diabetic nephropathy is the commonest cause of nephrotic syndrome.

◆ Chronic glomerulonephritis may be associated with dipstick haematuria or features of a systemic disease such as SLE, HSP, or SSc.

◆ Renovascular disease is characterized by hypertension, asymmetric kidneys on ultrasound, and a bland urine dipstick.

◆ Reflux nephropathy is a commoner cause of CKD in younger patients and is characterized by renal scarring on DMSA renography and low grade (non-nephrotic) proteinuria.

◆ The presence of bilateral enlarged kidneys with cysts on ultrasound is diagnostic of adult polycystic kidney disease and mandates nephrologist referral.

The initial priority is to identify and reverse superimposed AKI, as detailed above. Thereafter, most cases of mild–moderate CKD are managed in primary care. Indications for referral to a nephrologist include relatively rapid decline of GFR (>5 mL/min per year), associated proteinuria (PCR>100) or presence of CKD stage IV or greater (GFR<30 mL/min). Such cases of advanced CKD are generally managed in a dedicated clinic where the emphasis is on management of CKD complications (anaemia, volume overload, hypertension, hyperkalemia, acidosis, and renal bone disease) and preparation for dialysis or transplantation.

Table 25.5 Stages of chronic kidney disease (the numbers in parentheses indicate the prevalence in the general population)[38]

Stage 1	Normal GFR (>90 mL/min per 1.73 m^2) and persistent albuminuria (1.8%)
Stage 2	GFR 60–89 mL/min per 1.73 m^2 and persistent albuminuria (3.2%)
Stage 3	GFR 30–59 mL/min per 1.73 m^2 (7.7%)
Stage 4	GFR 15–29 mL/min per 1.73 m^2 (0.35%)
Stage 5	GFR <15 mL/min per 1.73 m^2 or endstage renal disease (0.24%)

and Stanton Newman

Impact of rheumatic disease on the individual

Symptoms

Pain

Arthritis is one of the most common causes of pain, and this is customarily ranked as the most important symptom by people with arthritis. The majority rate their pain as being severe and this can lead to limitations in daily activities and difficulties in leading a 'normal' life. The impact of pain also extends to more frequent use of medications and health services, and time off work.

Descriptions of pain vary between different rheumatic conditions. For example, people with fibromyalgia describe their pain as aching, exhausting, and nagging while those with rheumatoid arthritis (RA) use the word 'stiff' more frequently. Pain quality also appears to relate to activity, with pain at rest described as throbbing or aching, and pain on movement described as shooting and spreading.

Physiological models have been unable to explain variations in the reports of pain. Identical conditions or injuries do not predict the severity, intensity, or quality of self-reported pain, therefore other intervening psychological and social factors must play a role. In this chapter pain will be linked with a number of psychological outcomes including depression and anxiety as well as adaptive and maladaptive coping strategies and cognitions.

It is not surprising that pain, which can persist for months and years, will influence all aspects of a person's functioning and in particular psychological well-being. There is a vast amount of literature demonstrating a bidirectional relationship between pain and depression.[1] In addition feelings of anxiety, in particular fear in relation to completing tasks which may exacerbate pain, can lead a patient to avoid activities and situations that involve movement. Research suggests that it is this fear of movement and re-injury which better predicts disability than biological factors and even pain severity and duration.

Stiffness

Stiffness has been the subject of less research and although it has been described in the literature as a slowness and difficulty in moving the joints, its qualities are poorly understood. Because of its temporal nature, individuals who are able to adjust their timetable to accommodate early-morning stiffness and those who can be more flexible in their work patterns are often more able to deal with stiffness. But despite morning stiffness being a part of the classification criteria for RA and potentially leading to early withdrawal from work,[2] more research is needed to better understand and define this symptom.

Fatigue

Fatigue is a primary and debilitating symptom of rheumatic disease. The experience of fatigue is complex, comprising both physical and cognitive features with an associated impact on functional and emotional outcomes. The prevalence of significant fatigue varies from 41% in RA and osteoarthritis (OA)[3] to 90% in systemic lupus erythematosus (SLE).[4] Despite the prevalence of fatigue and the importance patients place on this symptom, the mechanisms which cause or exacerbate the condition are not well understood. Fatigue has been related not only to the arthritis itself but to the medications used to treat the condition. Arthritis-related fatigue has also been associated with sleep difficulties, reduced physical activity,[5] greater pain, anxiety,[6] greater functional disability,[7] and depression.[8]

Sleep difficulties

Poor sleep quality is a very common complaint in arthritis. Sleep complaints and related daytime symptoms are reported by up to 80% of patients with arthritis. Complaints include difficulties in falling asleep, poor quality sleep, non-restorative sleep, numerous awakenings during the night, early morning awakening, and excessive daytime sleepiness. Poor sleep and restlessness in SLE have been associated with pain, fatigue, and depressed mood.[5,9,10] Sleep disorders are also more common including, sleep apnoea, and restless leg syndrome.

Physical functioning

Disability

Epidemiological surveys of disability estimate that activity limitations affect approximately 8% of people with arthritis and this is set to grow as the population ages. Individuals with a rheumatic disease, despite appearing similar on clinical criteria, differ in self-reported physical function. Along with clinical variables, psychosocial factors appear to be important in predicting disability. An example of the importance of psychosocial variables is in a study examining 155 patients with RA.[11] Clinical and psychosocial variables combined accounted for 54% of the variance in disability at

baseline and 35% at a 12-month follow-up. Feelings of helplessness added significantly to the prediction of disability, independent of disease severity, suggesting that patients who feel powerless in their ability to control the course of their illness and its impact report greater limitations on their ability to perform day-to-day activities. The importance of mood has also been demonstrated, with depressed RA patients being more impaired in their daily functioning than non-depressed patients.[12] Levels of disability tend to increase over time and predictors of this increase include older age, female, of a lower socio-economic status, being rheumatoid factor (RF) positive, greater pain, fatigue, depression, and functional and radiological damage, particularly in late RA.[13]

Social functioning

Employment and work

Rheumatic diseases are often associated with an inability to work. Work disability (WD) can effect up to 50% of the arthritis population even in the early stages of the disease, and this only increases with disease duration. WD not only constitutes a financial burden for patients and their families and an economic burden for society but it has a negative impact on self-esteem and opportunities to socialize, and is associated with poorer quality of life (QoL).

Determinants of WD are relatively consistent between different conditions. Disease activity, pain, and physical functioning along with age, socio-economic status, and lower education are all associated with WD. The nature of work also appears to be an important predictor of retaining employment. The association between educational level and WD is often attributed to the type of work performed, with physically demanding jobs linked with increased WD.

Relationships

The challenges of rheumatic disease are thought to burden relationships, as they may lead to increased levels of irritability, bad temper, dependency and isolation, and decreasing interest in sexual activity. Sexual functioning has important implications on personal relationships, and overall QoL and 50% of arthritis patients report sexual dysfunction. Physical limitations due to rheumatic stiffness and limited mobility are the principal predictors of sexual disability, but diminished desire and satisfaction are also reported across rheumatic conditions with psychosocial variables such as depression, anxiety, and body image all playing a role.

In contrast to the above, it is important to note that a large number of patients with RA report experiencing interpersonal benefits after their diagnosis, such as an appreciation of the support offered by loved ones. Thus, interpersonal relationships can not only be negatively affected by a diagnosis of arthritis but can also be strengthened at a time of increased stress and uncertainly.

Social support

Social support is the process by which interpersonal relationships promote well-being by buffering stress and protecting people from a decline in health. Social support involves family, friends, healthcare professionals, and patient groups, who offer emotional as well as practical support. Social support has been conceptualised as structural (the number of people in a person's network) and functional (a person's evaluation of the quality of the support they receive). Research suggests it is the quality rather than quantity of social support which is important to well-being. The provision of support implies a shared understanding of need, what is required, when, and an ability to negotiate the provision of support at a time when the provider is ready to offer it.

Support can not only be positive but also potentially problematic, when it may be perceived as non-supportive. Problematic support has been linked with increased depression and when patients experience greater problematic support in association with low positive support they may report more arthritis-related symptoms. Problematic support has also been found to predict depression and is linked with lower family functioning and life satisfaction in RA.[14] In fact, spousal criticism in RA has been associated with both depression and anxiety. Conversely, satisfaction with social support has been associated with promoting adaptive coping strategies where greater use of cognitive reframing, emotional expression, and problem-solving in association with arthritis-related pain are used.

Psychosocial well-being

Quality of life

QoL refers to the physical, psychological, and social impact of a chronic illness on a patients' life. Recommendations now state that QoL should be systematically assessed within routine clinic time to establish the impact of the rheumatic disease on the patient's daily life. Impaired QoL in physical, mental, and social domains has been reported for those with arthritis when compared to both the general population and other chronic conditions.[15,16]

It is important to recognize that QoL is not associated with disease activity or damage but has been linked with age and gender as well as a number of psychosocial variables. Physical QoL has been associated consistently with symptoms such as pain and physical function, whereas mental health QoL has been linked with increased levels of depression, anxiety, and poor social support.[17] The measurement of QoL in clinical practice is important as it acknowledges the impact arthritis is having from the patient's perspective.

Mood

We have already noted the impact that arthritis symptoms, as well as the physical and social consequences of arthritis, can have on depressed mood. Depression is of particular concern in arthritis as research suggests that the presence of clinical depression increases the risk of mortality.[18] Depression affects 15–66% of the arthritis population and anxiety 13–70%. However, the occurrence of depression in SLE is more complex due to the presence of neurological symptoms in almost half of patients. This co-occurrence has led some to suggest that it is difficult to distinguish whether depression in SLE is indicative of central nervous system involvement or whether it reflects the psychological impact of a long-term condition.

The prevalence of depression in RA is greater than in the general population but similar to other chronic conditions, thus reflecting the general effects of living with a chronic illness. Research has shown that soon after diagnosis RA is characterized by more anxiety and established RA with depression.[19] This may be because early on patients are dealing with the shock of diagnosis and uncertainty about the future, while over time the increased levels of disability and pain provoke higher levels of depression.

Besides the impact physical and symptomatic changes have upon mood in arthritis, the beliefs and cognitions a patient holds about their disease also play a role. For example, those who see

more negative consequences to their arthritis tend to be more depressed.[20] Conversely, depression also appears to have an impact on beliefs. For example, those suffering from depression are less likely to believe in medication effectiveness and importance, thus suggesting that depression may impact upon medication adherence. Depressed mood is generally associated with dramatically reduced perceptions of QoL and physical functioning, and individuals with high levels of depression may restrict their social activities and become isolated as a result of this. Taken together, these findings illustrate the difficulty in establishing causal relations between mood and other measures in arthritis as the effects are likely to be bidirectional.

Impact of psychological variables on health status and well-being

Research suggests that the consequences of arthritis are dependent upon how individuals interpret their illness, how others respond to their needs, and aspects of their environment. A number of psychological concepts have been used in attempting to account for the mediation between disease and its consequences, and it is to these that we now turn (see Figure 26.1).

Coping

There are many stressors for someone with arthritis. These include accepting the diagnosis, adjusting to the medical treatment and consequences of the condition, and uncertainty about the future. People with arthritis use different coping strategies in an attempt to reduce the impact of these stressors. Research on the ways in

Fig. 26.1 Representation of the impact of clinical, social, and psychosocial factors on psychological well-being.

which individuals cope with arthritis has been growing in recent years and there are many classification systems and ways of measuring this concept.

One classification has been between active and passive coping strategies. Active coping involves taking action or exerting efforts to remove or circumvent the stressor. In contrast, passive strategies focus on withdrawing or passing control on to something or someone else. In RA the literature suggests that passive coping strategies are linked to increased levels of pain, depression, and anxiety. Similarly, avoidant coping—another maladaptive strategy—tends to have negative outcomes in both cross-sectional and longitudinal studies.[21] In contrast, active coping has been associated with increased social support[22] and less pain, disability, and depression.[23]

Taken together these studies suggest that coping strategies in arthritis are important determinants of health status. However, as with most chronic diseases, rheumatological conditions are not static and change over time. This requires a continual adjustment to new demands if coping is to remain successful.

Beliefs

Beliefs about the disease, its treatments, and what one can do about it also have an impact on outcomes. These beliefs act as a mediator between the disease and adaptation, and are important in the management of arthritis.

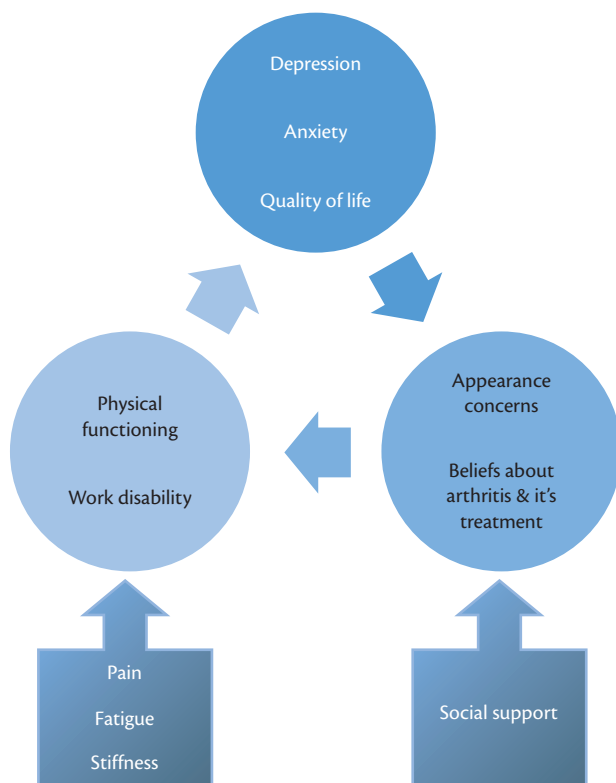
Self-efficacy

Self-efficacy is one such belief and concerns an individual's belief in their ability to undertake a task. In a condition such as arthritis, which involves the patient managing aspects of the disease and its treatment, this concept is fundamental to good health and well-being. Measures of self-efficacy can be general, as to how one behaves in the world, or specific to arthritis.

In a 2-year longitudinal study low self-efficacy was related to increased RA-related pain, fatigue, disability, and poor QoL. In fact high self-efficacy at the start of the study was related to improved health status at follow-up.[24] Patients who report greater self-efficacy also experience less depression, are more physically active, and adhere more closely to medication regimes.

Beliefs about arthritis

How people perceive their illness and the beliefs they hold in relation to their condition has been termed illness perceptions. As part of the self-regulation or common sense model,[25] cognitions are said to provide patients with a framework for coping with and understanding their illness. Overall the perceptions patients have about their arthritis tend not to be related to clinical measures but do correlate significantly with the impact of the condition on psychological well-being, disability, depression, and QoL.[26]

Viewing the consequences of arthritis as being more serious, feeling less control over the illness, and believing that it can be cured has been associated with increased levels of disability and poorer physical and social functioning[26,27] as well as future levels of depression, anxiety and pain.[20,28] Not only are the beliefs a patient holds important, but when they are in agreement with a partner this results in better adjustment in the future,[29] thus acknowledging the importance of the social environment as an influence on the impact of arthritis.


Appearance concerns

It is not surprising that patients with arthritis can have concerns about their appearance, as many rheumatic conditions are characterized by inflammation which can cause disability and disfigurement. Disfigurement of the hands and feet is common and these changes can impact upon not only psychological well-being but also social interactions. In fact, how a person perceives their appearance contributes to levels of depression in patients with RA and SLE.[30]

Patients with arthritis often speak of embarrassment, self-consciousness, and distress about their appearance and this tends to be in relation to their joints. The hands are of particular concern, with reports of anger, shyness, disgust, and shame, suggesting that feelings of stigmatization may be related to the visible and public nature of RA.[31] These feelings can often lead to the avoidance of social situations and an increased desire for surgical intervention.[32,33] Similarly, changes to the appearance of the feet are also of concern, particularly for women, who describe a loss of femininity and sexuality as a result of prescribed footwear. The choices available to these women, as well as the associated disfigurement, may force them to take on an altered body image and hence change their social behaviour by either covering themselves or avoiding social interaction.

Adherence and beliefs about treatment

Approximately 60% of patients with arthritis are at some point non-adherent to medications. Non-adherence is complex; it can be either unintentional (e.g. memory failure) or intentional (i.e. making a deliberate choice). The most frequently cited reasons tend to be unintentional and include changes in daily routines and not being able to obtain a refill. Intentional reasons for non-adherence are much more complicated and include the beliefs the patient holds about a specific medication and their overall attitude towards taking medications in general. Broadly speaking, lower adherence has been associated with negative beliefs about the potential side effects of medications such as non-steroidal anti-inflammatory drugs (NSAIDs) and disease-modifying anti-rheumatic drugs (DMARDs), lower perceived efficacy of the treatment,[34] a belief that the medication is unnecessary, that medications in general are overused,[35,36] and fear of addiction.[37]

Adherence to lifestyle recommendations such as changes to diet, exercise, physical therapy, clinic appointments, and the use of assistive devices makes the regimen complex for many patients. Adherence to these behaviours is also suboptimal. Patient beliefs about the causes of RA, flare-ups, and whether the treatment advice is compatible with the patient's coping system and feelings of self-efficacy have been shown to predict adherence to some of these behaviours.[38]

Psychosocial interventions

As there is clear evidence for the role of psychological variables in arthritis and because these factors are potentially modifiable, a number of psychosocial interventions have been developed. These attempt to modify the individuals' understanding, beliefs, coping style, and social support in order to influence psychological well-being and health status. Many of these interventions include disease information and a range of skills to help enhance their ability to manage the disease.

Providing information is a small but significant component that appears integral to most interventions. Education-based interventions have found to increase knowledge among participants,[39] and in some studies to produce small short-term effects on disability, joint count, patient global assessment, psychological status, and depression. There is, however, no evidence for long-term benefits in adults with RA.[40] The behavioural and cognitive techniques taught to participants are therefore vital.

Most psychosocial interventions are derived, at least in part, from theories and this will determine the components incorporated in the intervention. For example, those that are based on social learning theory aim to enhance patients' self-efficacy to manage their disease. Others attempt to influence beliefs about symptoms and disability and use a cognitive behavioural framework. Some focus on the social environment and aim to improve a patients' ability to enlist social support. These interventions may include training in cognitive pain management, joint protection, exercise, communication skills, and problem-solving, among other techniques.

Interventions can be delivered by healthcare professionals to either individuals or groups and usually take place in a hospital setting, although some have been delivered by telephone or using a self-instruction manual or computer program.

The best-known psychosocial intervention is the Arthritis Self-Management Programme (ASMP). The intervention, set within a self-efficacy framework, aims to enhance a patient's perceived ability to control various aspects of their arthritis through skills mastery, modelling, reinterpretation of symptoms, and persuasion. This programme differs from many others in that it is community based and delivered by trained lay leaders who themselves have arthritis. Groups can include people with different types of arthritis and it has broadened further to include people with a variety of chronic conditions. A 12-year review of the programme indicated improved behaviour, self-efficacy, and aspects of health status.[41] Subsequent research in the United Kingdom suggests benefits of up of 12 months post intervention in terms of mood, self-efficacy, and pain for both OA and RA patients.[42] Similar self-management interventions in other arthritic conditions have also been beneficial in enhancing self-efficacy and coping skills while decreasing depression and fatigue, and these improvements have also been sustained in the long-term.

A number of systematic reviews have also been undertaken looking at the use of non-pharmacological or psychosocial interventions, some of which have focused on specific aspects of arthritis such as pain and fatigue while others have been more general. A recent review of seven studies in RA fatigue reports significant reductions in fatigue for cognitive behavioural therapy (CBT).[43] CBT has also been the focus of many pain management interventions for patients with RA and OA, resulting in significant improvements in pain, active coping, anxiety, joint swelling, disability, depression, and self-efficacy.[44] Furthermore, interventions to improve adherence in RA which involve the teaching of coping strategies have been found to be more effective.[45]

In a general review of 25 psychological interventions a number of components were identified including relaxation, imagery, stress management, and the teaching of cognitive coping skills. Authors suggest that despite some methodological flaws, significant effects were found post intervention for pain, functional disability, psychological status, coping, and self-efficacy. Long-term benefits for tender joints, psychological status, and coping were also found. However, no clear or consistent patterns emerged as to which types

of interventions were more beneficial. Findings do however, suggest that these psychological interventions may be more effective for patients who have had the illness for a shorter period of time.[46]

Conclusion

Research on the psychological factors associated with rheumatic disease has shown that attempts to predict disability and psychological well-being need to incorporate how individuals perceive their disease, how they try to deal with the stresses it creates, and factors in their social environments. This has spawned a number of non-pharmacological interventions where there now exists some evidence for efficacy.

CHAPTER 27

Epidemiology and the rheumatic diseases

Deborah P. M. Symmons

Introduction

Epidemiology is the study of the distribution and determinants of disease in populations. Clinical epidemiology is the study of the distribution and determinants of outcomes in populations with a specific disease. Understanding the epidemiology of disease is important from a number of perspectives. First, it is important for those planning and paying for health services at any level to know the likely burden of disease (i.e. the number of cases and the spectrum of severity) in their locality. Secondly, it is the starting point of the diagnostic process for any clinician. Diagnosis is an iterative process based on likelihoods of specific diseases or conditions.[1] Thus, as a patient with joint pain arrives for their first rheumatology consultation, the 'preconsultation' likelihood of osteoarthritis (OA) or systemic lupus erythematosus (SLE) varies according to the age, gender, and ethnicity of the patient. As the consultation proceeds and more information is elicited (e.g. on additional symptoms and signs, weight, or occupation) the likelihood of each diagnosis changes and further investigations and so on are directed towards the most likely diagnoses.

Whereas assessing the distribution of disease is largely a descriptive process; assessing the determinants of disease requires a comparison group. For example, only by comparing the occurrence of disease in smokers and non-smokers can one conclude whether or not smoking is likely to be a determinant of that disease.

This chapter addresses the basic concepts of epidemiology and epidemiological study design with specific reference to being able to apply these to the diagnosis and care of the patient with a musculoskeletal disorder. The epidemiology of specific musculoskeletal conditions is covered in the relevant chapters of this book, but this chapter includes templates of the age- and sex-specific incidence and prevalence of the most common musculoskeletal disorders taken, as far as possible, from the single perspective of primary care in the United Kingdom, in order to give some indication of their relative frequency in different age groups. The chapter also includes a summary of identified risk factors for the development of the more common musculoskeletal disorders.

Case definition

The first step in describing the occurrence of disease is to decide on a case definition. Comparison between studies is facilitated by the use of a widely accepted and validated case definition.

Unfortunately the vast majority of rheumatic diseases do not have a single pathognomic feature, such as characteristic histology or a biomarker that is found uniquely in that disease and no other. Thus case definitions have to be based on combinations of clinical, laboratory, and imaging characteristics. The methodology for developing and validating case definitions has been progressively refined over the decades, leading to the need to revisit case definitions at regular intervals. In the past, case definitions have generally used the 'physician's opinion' as the gold standard. However, the most recent case definition for rheumatoid arthritis (RA)[2] is based on the 'physician's decision to start methotrexate' in a patient with recent-onset inflammatory arthritis. The development of an acceptable case definition comprises a series of steps in which a list of variables likely to discriminate, in combination, between the disease in question and other similar diseases is assembled, tested, and refined[3]; then a large series of cases (according to the gold standard) and controls (who have similar diseases) is collected from a wide variety of sources, together with information on the list of variables. Then statistical modelling is used to develop algorithms which discriminate between the cases and controls with the greatest accuracy. Finally the algorithms are tested in a wide range of settings (e.g. different countries, different stages of disease, patients with a variety of comorbidities). Generally speaking, even when the process has been very rigorous, the accuracy of the algorithm is not sufficient for it to be used to diagnose disease in the individual patient. This is particularly the situation for diseases which have a wide variety of manifestations, not all of which can be encompassed within the criteria set. Thus generally the case definitions are referred to as 'classification' rather than 'diagnostic' criteria. Classification criteria are useful to ensure that homogenous groups of patients are being compared in studies of disease occurrence and as entry criteria for clinical trials and other clinical research studies. This ensures that the results of such studies can be generalized from one population to another. Many of the case definitions in current use have been developed by the American College of Rheumatology (www.rheumatology.org/practice/clinical/classification) and European League against Rheumatism (www.eular.org/) and can be accessed via their websites.

Disease classification

Most of the sources discussed in this chapter classify musculoskeletal conditions in accordance with the International Classification

Table 27.1 ICD codes for musculoskeletal disorders

Condition	ICD7	ICD8	ICD9	ICD10
	1955	1965	1975	1992
Rheumatoid arthritis	722.0[a]	712.1, 712.3	714.0–714.2	M05, M06
Juvenile idiopathic arthritis	722.0[a]	712.0	714.3	M08, M09
Ankylosing spondylitis	722.1	712.4	720.2–720.9	M45
Gout	288	274	712.0*274.0†	M10
Polymyalgia rheumatica	726.3	446.3	725	M35.3
Osteoarthritis	723.0	713.0	715	M15-M19
Systemic lupus erythematosus	456[a]	734.1	710.0	M32
Scleroderma	710.0[a]	734.0	710.1	M34
Psoriatic arthritis	706.0	696.0	696.0	M07.0–M07.3
Osteoporosis	733[a]	723.0	733.0	M80, M81
Fracture of neck of femur	N820	N820	820	S72.0
Fractured vertebra	733[a]	723.9[a]	733.1	S32.0

[a]Includes other conditions.

of Diseases (ICD).[4] This international agreed system of nomenclature and terminology is now in its 10th revision,[5] and the 11th revision is in an advanced state of preparation. The ICD codes for various musculoskeletal conditions are shown in Table 27.1. The changing codes reflect the evolving understanding of the nature of these disorders over the past half century. For example, ankylosing spondylitis was originally thought to be a variant of RA (until ICD9).

Describing the occurrence of disease (disease distribution)

The occurrence of disease is generally described in terms of incidence and prevalence.

Incidence

The *incidence* of disease should be expressed as a rate, i.e. the number of new cases occurring in the population at risk in a given time period (usually 1 year). In order to study incidence it is important to be able to determine the date of onset of symptoms. Sometimes the date of diagnosis is used as the incidence date, but this is influenced by many factors such as access to appropriate clinicians and the diagnostic acumen of those clinicians. Incidence can be studied by performing two cross-sectional studies 1 year apart and identifying those who have the disease at the second time point who did not have it at the first. However, more commonly new cases are ascertained as they present in either primary or secondary care, often, these days, from computerized records of the reason for consultation. It is difficult to keep the same population of people under surveillance for a year or longer—people move into or out of an area, some people may die. Thus it is better to express the denominator as person-years of observation with each person contributing the appropriate proportion of a person-year according to the proportion of the year that they spent within the sampling

frame for new cases (which might be a particular geographical area or on the list of a particular primary care physician). Individuals should only be included in the numerator of a study of incidence if they are also in the denominator.

Incidence can be expressed as the number of people who experience a disease or condition for the first time during that year or the number of new episodes of a disease or condition there are during the year (called *episode incidence*—in which individuals may contribute more than one episode to the numerator). For health service planners it may be more useful to know the number of new episodes, for example of back pain in a year, than the number of people who experience back pain for the first time. On the other hand, researchers interested in the aetiology of back pain may wish to study people who are experiencing their first ever attack of back pain or those who are experiencing recurrent attacks, so it may be important to be able to distinguish these. *Cumulative incidence* is the number of people who have ever had an episode of the disease in question (e.g. neck pain) divided by the number of people in the population at risk.

Prevalence

The *prevalence* of disease is the proportion of the population who have the disease in question at a particular point in time. In the case of chronic, non-resolving, and non-fatal conditions cumulative incidence and prevalence may be the same or very similar. Prevalence may be established in a cross-sectional population survey or, again more often these days, from computerized records of primary care physicians or health maintenance organizations. This may require adapting the case definition into a suitable format for use with computerized data, in which the completeness of information on some variables may be rather poor. As with studies of incidence, it is important that individuals should only be included in the numerator if they are also in the denominator. The denominator should only include those at risk of developing the disease.

Thus studies of the prevalence of childhood arthritis should define the upper age limit for the study and only include those below that age limit in the numerator and the denominator. It is a very common error to take studies of the prevalence of a musculoskeletal condition in the adult population and then apply the figures to the whole population. For example, the prevalence of rheumatoid arthritis (RA) is around 0.8–1% of the adult population.[6] However, many publications estimate the number of individuals with RA in a given population by applying the figure of 0.8–1% to the whole population, thus assuming that the prevalence of RA is the same in children as in adults. This leads to massive overestimation of the number of cases.

Disease duration

Incidence and prevalence are related by the equation:

incidence × disease duration = prevalence

Disease duration is influenced by recovery and death. Conditions with a similar incidence rate may have very different prevalences if one has a short duration (e.g. gout) and another a long duration (e.g. RA); or one a high case fatality rate and another a low one. Treatments which prolong life, for example renal dialysis for patients with scleroderma and renal failure, may increase prevalence without any change in incidence.

Studies of incidence and prevalence

There are several available methods of measuring disease occurrence. In the past this was done predominantly using cross-sectional surveys. This is still the most appropriate method for common conditions such as back pain, for which sufferers do not always seek medical attention. Such surveys may either be specifically designed for the purpose or may be incorporated into government-sponsored national or regional health interview or health examination surveys which can study several medical conditions and lifestyle factors simultaneously. Examples of musculoskeletal health surveys include the COPCORD programme which has conducted surveys in a wide range of countries.[7] Examples of government-sponsored health surveys include the Health Survey for England which has been conducted annually since 1991 (www.dh.gov.uk/en/Publicationsandstatistics/PublishedSurvey/HealthSurvey For England /Healthsurveybackground/index.htm) and the National Health and Nutrition Examination Surveys (NHANES) in the United States (www.cdc.gov/nchs/nhanes/about_nhanes.htm).

For less common conditions—or for conditions where patients generally seek medical attention—studies of disease occurrence can take place in the primary or secondary care setting. As might be expected, the incidence and prevalence of conditions measured by attendance at primary care is lower than the prevalence of self-reported symptoms. Examples of primary care databases that can be interrogated for the incidence and prevalence of musculoskeletal disorders include the General Practice Research Database (GPRD) (www.gprd.com/) in the United Kingdom and health administration databases such as Kaiser Permanente in the United States. The GPRD is a computerized database based on the consultation records of approximately 630 practices. Data are currently being collected on around 5 million people, which is just under 10% of the entire United Kingdom population.

Much information on the incidence and prevalence of common musculoskeletal conditions has come from the Rochester Epidemiology project.[8] The Mayo Clinic in Rochester, Minnesota, together with the Olmsted medical practice, provides the only source of medical care to the local population (which is predominantly of Scandinavian extraction) of around 100 000 residents. These two organizations maintain a single medical record for all medical contacts for each resident. These records have been indexed by diagnosis and procedure since 1910 and can be retrieved with considerable accuracy.

The occurrence of disease may be described in terms of person (by age, sex, occupation, and ethnicity), place (e.g. country or region) and time (looking for secular changes or birth cohort effects). Studies of incidence and prevalence which present their results only for the whole population or the whole adult population are of limited value beyond the local situation. Ideally studies should be large enough to present their results by age and gender. Thus, by a process known as standardization, it is then possible to apply the results from one study population to a different population in order to estimate the likely number of cases in the second population. Also it is possible to compare age- and sex-specific incidence and prevalence between populations, whereas any differences in disease frequency for the whole population may simply be due to differences in population structure. Over the next decades the age and sex structure of the population of most countries will change substantially—predominantly with an increased number of elderly people, particularly those aged over 80. This will have dramatic effects on the burden of musculoskeletal conditions, most of which increase in incidence and prevalence with age.

Mortality

Mortality is clearly an important outcome measure for many musculoskeletal disorders. Mortality may be expressed in a variety of ways. *Case fatality* is the probability of death among diagnosed cases of disease during a particular time period. It is calculated by dividing the number of deaths due to the disease in the specified time period by the number of cases of the disease alive at the beginning of the time period. For musculoskeletal disorders the 1 year or 5 year mortality of some connective tissue diseases or vasculitis may be of relevance. Similar figures can be used to discuss and present the 1 year or 5 year survival. More often it is of relevance to compare the all-cause (or cause-specific) mortality in a disease population with that of the local general population. These results are presented as *standardized mortality ratios* (SMRs). SMRs are calculated by a process called indirect standardization. The disease population (who must all be alive at the beginning of the period of the study) is divided into a number of age and gender groups (e.g. 10 year bands) and each death that occurs during the period of observation is assigned to one of these groups. The total time of observation for each patient is assigned to one or more of these age bands (as the patient ages they may contribute observation time to different age bands). Then the total time of observation for each band is calculated. The expected number of deaths for each age band for the person-time of observation may be estimated using published data (most countries and/or regions publish mortality rates for the general population). The SMR is the number of observed deaths divided by the number of expected deaths multiplied by 100. An SMR of 100 indicates that the disease population has the same mortality as would be expected from the general population.

SMRs cannot be directly compared between studies for a number of reasons: first, the background population may not be the same (in terms of geography, calendar time, age, and gender make-up); secondly, the period of observation may not be the same (the longer the period of observation the more the SMR is likely to approach 100 as, in the end, everyone dies and is expected to die).

Practical examples of relative disease frequency

Tables 27.2–27.5 show the estimated incidence and prevalence of the most common musculoskeletal disorders for men and women in the United Kingdom. These figures were assembled by conducting a literature search up to the end of 2010. To be eligible, studies had to include age- and sex-specific rates and be based on attendance in primary care in the United Kingdom. Where more than one relevant study was identified we selected the one which was based on the GPRD or the most recent one. For some diseases (SLE, scleroderma) only data from secondary care were available and for a few diseases (e.g. ankylosing spondylitis) data had to be taken from overseas. Until 1991 the Royal College of General Practitioners (RCGP) in the UK conducted a 10 yearly morbidity survey in the year of the national census.[9–12] A representative sample of GPs recorded the reason for every consultation and whether this was the first time that the patient had consulted with that complaint. The last RCGP morbidity survey

Table 27.2 Incidence of common musculoskeletal disorders in men

Incident cases per 100 000 males							
Condition (reference)	**Age 0–14**	**Age 15–24**	**Age 25–44**	**Age 45–64**	**Age 65–74**	**Age 75+**	**All ages[a]**
Inflammatory arthritis[13]	=Childhood arthritis	13	25	45	49	64	32
Childhood arthritis[14]	4	–	–	–	–	–	–

[b]Age bands for prevalent SLE are 0–18, 15–24, 25–44, 45–59, 60–74, 75–84 years. 'All ages' is for 18+ years.

was conducted in 1991. Since then a smaller sample of GPs (collectively termed the RCGP Research and Surveillance Centre) has continued to record the reason for every consultation. Where no published data from the GPRD were available, this was used as the source of the incidence and prevalence estimates. However, this source only records the reason for consultation to three digits of the ICD (which is adequate for some musculoskeletal disorders but not others). Some smoothing of figures has been done to provide internal consistency. As the published studies used were conducted at different time points and with varying definitions of the background population at risk they are not directly comparable and should be used as a guide to the relative frequency and burden of disease rather than an absolute indication of the number of cases.

These data show that, amongst these musculoskeletal conditions, back pain is the most frequent reason for consultation. The incidence of most musculoskeletal conditions in higher in women than in men, with the exception of ankylosing spondylitis, gout, and back pain. The incidence of most musculoskeletal conditions increases with age, with the exception of ankylosing spondylitis which peaks at age 25–44 and back pain which peaks at age 45–64.

These data show that the prevalence of most musculoskeletal conditions rises with age. The exceptions are scleroderma (possibly due to premature mortality), ankylosing spondylitis (possibly because patients cease to consult for this in older age), and back pain (reflecting the episodic nature of this complaint and the peak age of onset in middle age). Overall, 1 in 6 males and 1 in 5 females consults with a prevalent musculoskeletal condition each year.[14]

Describing the determinants of disease

Diseases do not occur at random. Although a few rheumatic diseases are the result of, for example, a single gene mutation or a single environmental trigger, most occur as a consequence of a complex interaction of genetic factors and environmental triggers. Although the basic structure of genes is constant throughout life, genes may be modified by, for example, methylation, or the gene product (protein) may be modified by, for example, citrullination. Thus the influence of a person's genetic make-up on disease susceptibility changes during the lifespan. Environmental risk factors are also very diverse and include lifestyle factors (e.g. smoking, diet, alcohol), occupational factors, infections, other medical conditions and their therapy, hormones, and air pollution among others. Some environmental factors may exert their influence many years before disease development and some quite close to the onset of symptoms. A variety of epidemiological study designs is available to investigate the associations between genetic and environmental risk factors and the subsequent development of disease. All involve the use of a comparison cohort (usually individuals without disease) so that exposure status may be compared between those with and without the disorder. This is known as analytical epidemiology, and is hypothesis testing as opposed to hypothesis generating. Increasingly complex statistical methodology and increasing computing power mean that it is possible to explore multiple risk factors and their interactions simultaneously.

Study designs for assessing determinants of disease or disease outcome

To be a determinant of disease or outcome, a risk factor must operate before the onset of disease or the outcome of interest. Thus study design should ideally incorporate the perspective of time. There are essentially three types of study design in epidemiology: cross-sectional, cohort, and case-control studies.[23] The reporting of observational studies in epidemiology is covered by the STROBE statement (STrengthening the Reporting of OBservational studies in Epidemiology).[24]

Cross-sectional studies

Cross-sectional studies collect information about disease and exposure status simultaneously. They can be used to demonstrate associations between, for example, obesity and osteoarthritis (OA), but they cannot determine the direction of association. In other words, they cannot discern between the hypothesis that obesity is associated with

an increased risk of OA, and the hypothesis that OA is associated with an increased risk of obesity. There are now statistical methods to test whether a confounder such as physical activity acts as a 'mediator' of the link between obesity and OA in the context of a cross-sectional study. However, this still does not provide information on the direction of the association between obesity and OA.

Cohort studies

In cohort studies individuals are usually recruited before the onset of disease and then followed prospectively. The cohort can be divided into those with and without the exposure of interest and the relative incidence (relative risk) of disease in the two groups compared. Sometimes two separate cohorts are assembled—one with and one without the exposure of interest (which might be exposure to a particular drug or occupation). Cohort studies have the advantage that information about exposure status is collected at the start of the study and so they are not subject to recall bias. However, they have the disadvantage that individuals may have to be followed for long periods of time before the disease of interest develops and so a robust system of case ascertainment and follow-up is necessary.[25] They are thus expensive and often not as efficient as case-control studies in addressing a specific question. However, sometimes cohorts can be identified retrospectively. For example, the databases of health maintenance organizations and the GPRD already exist and may include information on some exposures, such as smoking, weight, and occupation as well as the subsequent medical history of millions of individuals. Such studies tend to suffer from large amounts of missing data on either or both of the exposure status or outcome, as the data were not collected with this purpose in mind. The investigator must establish the extent and degree of bias in missing data before deciding whether this is a viable setting to test the study hypothesis, and whether and how missing data should be imputed. Most computerized multivariable models can only include subjects with complete sets of data. Thus the more variables that are included in the analysis, the more critical becomes the issue of missing data.

Case-control studies

Like cohort studies, case-control studies include the perspective of time. In case-control studies subjects (cases) are selected on the basis that they have recently developed the disease or outcome of interest.[26] Information about exposure status is then collected retrospectively, perhaps by administering a questionnaire to the participants or searching their medical records.[27] The selection of an appropriate control group is often challenging. The controls should be subjects who would have been eligible to be cases if they had developed the disease. In matched case-control studies, the controls are matched to the cases for items that are not the immediate subject under study—such as age and sex. This makes the study design more efficient. However, if the study has a matched case-control design then the matching must be maintained during the analysis (i.e. the case and their control(s) are analysed as a unit according to whether they are concordant or discordant for the outcome of interest). If the number of available cases is limited (perhaps because the disease is rare) then the power of the study may be increased by recruiting more than one control per case. Results from case-control studies are expressed as odds ratios.

Some environmental predictive and protective factors for musculoskeletal conditions are listed in Table 27.6. For genetic risk factors for these diseases, readers are referred to the individual chapters.

Table 27.6 Some examples of environmental predictive and protective factors for musculoskeletal conditions

Musculoskeletal condition	Environmental risk factor	Protective factor	Risk factors for a poor prognosis
RA[28]	Female gender Smoking Obesity Silica exposure Nulliparity	Oral contraceptive use High fruit intake Moderate alcohol intake	Rheumatoid factor and anti-citrullinated peptide antibodies
Ankylosing spondylitis	Male gender Certain infections	Smoking	
Psoriatic arthritis[29,30]	Psoriasis Trauma		
Gout[31]	Alcohol (especially beer and spirits) Dietary factors (e.g. meat, seafood, sugary drinks, fructose) Early menopause Thiazide and loop diuretics Chemotherapy for cancer Components of the metabolic syndrome	Dietary factors (e.g. dairy produce, cherries, coffee)	
SLE[32]	Female gender Ethnicity[33,34] Current smoking Silica exposure Female hormones Some drugs	Moderate alcohol intake	Ethnicity Lower socio-economic status[35]
Scleroderma[36]	Female gender Ethnicity Silica exposure Organic solvents Some drugs (e.g. bleomycin)		
Polymyalgia rheumatica[37]	Female gender Age >50 Northern latitude		
Osteoarthritis of the hip[38]	Obesity (bilateral disease) Childhood hip disease (e.g. Perthes) Hip dysplasia High bone mass Certain occupations (e.g. farming)	Frequent squatting	
Osteoarthritis of the knee[38]	Obesity High bone mass Joint laxity Certain sports (e.g. football) and occupations	Smoking	Obesity Quadriceps muscle weakness Low vitamin C or D intake
Back pain[39]	Smoking Anatomical factors Psychosocial factors Certain occupations and activities Driving		Psychosocial factors
Osteoporosis[40]	Smoking Excess alcohol Low body mass index Reproductive factors: e.g. late menarche, early menopause Inflammatory disorders: e.g. RA, SLE Endocrine disorders: e.g. thyrotoxicosis, Cushing's, type 1 diabetes Malignancy Immobilization Drugs: e.g. corticosteroids, anticonvulsants, heparin	Obesity African origin	Conditions predisposing to falls [41]

RA, rheumatoid arthritis; SLE, systemic lupus erythematosus.

Clinical trials

Treatment is one of the major determinants of disease outcome. The role of treatment in disease outcome should be formally assessed in clinical trials. A clinical trial is an example of an epidemiological cohort study in which the exposure (treatment or placebo) is assigned to the patient by the investigator. In phase I and II trials there may be no comparison group and the trial is analysed as a descriptive, or hypothesis-generating study. In phase III trials the patient will be assigned (usually randomly) to receive either the study treatment or an active comparison or a placebo. The primary outcome measure must be specified in advance. Phase III trials are thus hypothesis testing and should be analysed like any other longitudinal cohort study comparing the outcome of interest in the two or more groups.[42] Clinical trial design is addressed in Chapter 30.

Pharmacoepidemiology

Pharmacoepidemiology is a relatively new discipline which studies the use of and the effects of drugs in large numbers of people.[43] Generally speaking pharmacoepidemiology studies focus on drug safety. Whereas treatment efficacy can be assessed in clinical trials (controlled epidemiological experiments), trials are usually too small to study any but the most common side effects. In addition, clinical trials often have strict inclusion criteria which mean that many patients who are prescribed a new medication after licensing would not have been eligible for inclusion in the trials—usually because of comorbidity. Thus studies of drug safety are usually conducted either by setting up registries specifically for the purpose or in the context of existing large administrative databases such as the GPRD or health maintenance organizations in the United States. Such databases provide many methodological challenges including their size, the large number of potential covariates and often also large amounts of missing data, the fact that the data were not collected for the purpose that they are now being used (and so terminology may not map), and individual patients may be followed in them for very varying and non-overlapping lengths of time.

Expressing the results of epidemiological studies—uses and abuses

As described above, the results of analytical epidemiological studies are usually expressed as either *relative risks* or as *odds ratios*. In both cases this describes the risk associated with a particular determinant in multiples of the background risk. The higher the multiple, the more likely the association is to be biologically important and statistically significant. However, from the patient's and clinician's perspective such figures are not easy to interpret—and can sound very alarmist. What matters to the patient is not, for example, by how many times a particular drug increases their risk of skin cancer, but what their *absolute risk* of skin cancer would be if they were to take the drug and if they were not. This difference is known as the *attributable risk* and should be expressed as a rate, e.g. 1 per 100 patient years of exposure. This can be interpreted as saying that, for every 100 patients treated with this drug for a year, one additional skin cancer will occur. In the case of a patient with RA treated with an anti-TNF agent it is more meaningful to be told that their absolute risk of admission to hospital in the next year with a serious infection is 1 in 20 than to be told that their risk of infection is increased by 60% compared to the background rate in patients with RA not treated with anti-TNF. Another meaningful way of looking at such data is in terms of number needed to treat or number needed to harm.[44] How many additional patients with RA would need to be treated with anti-TNF for a year in order to see one additional infection? Or, in the context of a clinical trial, how many patients would need to be treated with a new drug to, for example, prevent one patient from developing radiological erosions?

Much is often made of the high relative risk of myocardial infarction (MI) in young women with SLE. In the University of Pittsburgh lupus cohort, women with SLE aged 35–44 were more than 50 times as likely to have an MI as women without SLE in the Framingham Offspring study (RR 52.43; 95% CI 21.6–98.5).[45] And yet the background rate of MI in young women is so low that, even with this much higher relative risk, both the absolute rate and the rate of MI attributable to SLE is much higher in older than in younger women with SLE. Failure to appreciate this may lead to preventive strategies being targeted exclusively at the young.

The *population attributable risk fraction* is the proportion of cases of the disease in the population that can be attributed to the risk factor. This is a useful figure for those concerned with population health. So, for example, it would indicate what proportion of cases of RA would be prevented if no one smoked; or what proportion of cases of OA of the knee can be attributed to obesity.

Conclusion

In summary, the study of epidemiology in general and the epidemiology of specific musculoskeletal conditions in particular is the starting point in terms of understanding disease aetiology and making a diagnosis. All physicians need to know the relative frequency of the conditions which they see in the clinic, and their distribution by age and gender. An understanding of the environmental risk factors enables the likely diagnosis to be refined after taking a detailed history and may enable public health physicians to formulate preventive strategies. Patients look to their healthcare team to be able to predict their prognosis and to choose therapies accordingly. Epidemiology provides the methods for studying treatment interventions and evaluating their safety. An ability to interpret basic disease statistics and expressions of risk will enable the healthcare professional to explain to others the results of studies and also to rationalize sensational reports of disease cures or treatment harms which may appear in the popular press.

CHAPTER 28

Assessment of rheumatic disease

Piet van Riel

Introduction

The examination of the musculoskeletal system can be considered under two headings: (1) the systematic screening of virtually all the accessible joints of the body to identify abnormalities such as signs of inflammation, destruction, or abnormal function, and establish their distribution; (2) the more detailed analysis of an abnormal joint or group of joints, trying to quantify inflammation and loss of function. The screening is intended to be brief but comprehensive and efficient. It can be accomplished in a few minutes and should be part of the routine examination taught to all medical students (see Chapter 6).

The patient is best examined lying comfortably on a couch or bed for most of the examination, but sitting up for the shoulders and neck, and standing for the final stages of examining the feet and the movements of the back. Walking should be observed, either at the start when the patient comes into the room or at the end of the examination if the patient is already undressed. For a very young patient, much of the examination can be carried out while the child sits on the parent's lap.

The examination starts most logically with the hands, the calling cards of many of the rheumatic diseases, then moves up the arms to the joints of the shoulder girdle and the jaw, down the spine from the neck to the coccyx and on to the legs, finishing with the toes. The same basic pattern governs the examination of the most of the joints: inspection, palpation, and establishing the range of movement. This pattern is altered for some parts— the back, for example—in the interests of efficiency. It is important to realize that sometimes pain in a certain joint is being caused by a process outside the musculoskeletal system. For instance, a patient with a malignant tumour in the lung can have complains of severe pain in the shoulder. This is also called 'referred pain'; in this case no abnormalities will be found by examining the painful joint.

Inspection

Where a joint is paired, both should be exposed to allow comparison of the two sides. Redness overlying a joint is an important indicator of acute, severe inflammation, as in gout or septic arthritis. Any skin rash, subcutaneous nodules, cysts, scars, or evidence of local infection are noted. Muscle wasting is often associated with joint disease, but may be masked by joint swelling. Swelling or deformity should be sought. Discrepancies in limb or digit length may indicate growth problems secondary to inflammation, as in juvenile idiopathic arthritis.

Palpation

Temperature change is assessed relative to the same joint on the other side, or to surrounding normal skin. The back of the hand is rapidly moved between the areas to be compared. Errors may occur if one side has been kept warmer by a bandage, glove, or splint. Tenderness is elicited with firm pressure along the joint margins, and over tendons and ligaments. This should be carried out with the examiner's eyes on those of the patient, rather than on the joint, so as to pick up the first signs of discomfort. Swelling noted on inspection is palpated, to answer the question: 'Is this swelling bone, soft tissue, or fluid?' Bony swelling is especially a feature of osteoarthritis. Other causes are new bone formation with psoriatic arthritis, Charcot's joints, and callus formation after a fracture. Soft tissue swelling about a joint is most often synovial. The consistency of synovial swelling is more doughy than bouncy, like foam rubber. Where synovial fluid and synovial swelling coexist, the fluid can be pushed away or aspirated, allowing the synovium to be palpated. Fluid is recognizable for its compressibility; palpating a lax effusion is easy, because the fluid can be pushed from one part of the joint to another (fluctuation). A tense effusion can be recognized by its bouncy quality, like a firm rubber ball. Joint noises are frequently better felt than heard. Loud cracks and snaps, particularly on pulling the fingers or rotating the ankles, may be quite normal. Pulling the fingers creates a vacuum and the popping sound represents the sudden development of a gas cavity in the joint fluid. The snap on rotating an ankle is related to the slipping of one tendon over another. Similar, harmless snapping and crunching noises occur when the head is extended and rotated from side to side, or the shoulders are braced back and rotated. Velvet crepitations are too soft to be audible, but may be felt. They occur when the joint contains small particles of proteinaceous material, most typically in rheumatoid arthritis (RA). Crepitus in the joint of a patient with osteoarthritis feels like a dull, coarse crunching, and is caused by irregularities in the cartilage.

Eburnation crepitus is both heard and felt, occurring when the cartilage has been destroyed and the two bony surfaces are in contact. The name means 'turning to ivory' and the sound is thought to be similar to that of ivory grinding on ivory. Most often it emanates from the hip or the knee, and then care is

needed to work out which is the affected joint as the vibrations are well transmitted up or down the femur. To demonstrate eburnation crepitus, the examiner lays a hand on the joint and asks the patient to move it. Passive movement may fail to elicit the sign because the joint surfaces are not so closely opposed when the muscles are relaxed.

Range of movement

The patient is usually first asked to move the joint actively. If a full range of active movement can be carried out without discomfort, there is rarely any need to proceed to passive movement. If the patient is unable to carry out the full range of active movement, then the passive movements will be most informative. In general, where active and passive restriction are the same, limitation of movement will reflect one of the following: inflammation of a joint; contracture of the tendons or ligaments surrounding the joint; destruction of bone or cartilage in the joint. Restriction of active but not passive movement indicates rupture or inflammation of a tendon, muscle weakness, or failure of the nerve supply to the muscle. The 'normal' range of movement must be interpreted with caution. There is much variation in joint mobility with age and race, and from individual to individual. An excessive range of movement in otherwise normal joints is referred to as hypermobility. An excessive range in diseased joints reflects damage to the articular surfaces or the capsule and ligaments, leading to instability.

Systematic survey

Rheumatic diseases are often multisystem in their effects, and many systemic diseases will present with rheumatic complaints. The discussion of the examination of the other systems in the body is outside the scope of this chapter, but it should be remembered that the examination of the musculoskeletal system is only one aspect of the careful and comprehensive history-taking and general physical examination that makes up the assessment of the patient with rheumatic symptoms.

Hands

Inspection
This is summarized in Box 28.1.

Nails
The nails may show the pitting or lifting from the nail bed (onycholysis) typical of psoriasis, nailfold infarcts typical of vasculitis, or the shaggy cuticles and periungual erythema of dermatomyositis (Figure 28.1). Dilated capillary loops in the nailfold can be seen with the naked eye, though more easily with a magnifying glass or with a capillary scope, and tend to accompany certain rheumatic diseases, for example systemic sclerosis and dermatomyositis.

Skin
A rash on the backs of the hands may be due to psoriasis or to dermatomyositis, best distinguished from each other by the distribution. Dermatomyositis tends to affect the extensor surfaces of the joints in a neat and symmetrical fashion, while psoriasis is more likely to be distributed at random across the hand. Palmar erythema is common in patients with connective tissue diseases, and is frequently different in nature from the palmar erythema of pregnancy or liver disease, looking more mottled and indeed more like

palmar livedo reticularis than erythema. This appearance seems to be associated with systemic vasculitis.

Muscle wasting
This is common whenever joints are inflamed, but attention should be paid to any significant patterns of muscle wasting, such as the wasting of the thenar eminence in carpal tunnel syndrome, which spares only the adductor pollicis, visible as a band parallel to the wrist. Wasting of opponens pollicis commonly accompanies osteoarthritis of the first carpometacarpal joint (see Box 28.1).

Tendon involvement
Tenosynovitis of the flexor tendons may be seen as a fullness in the palm. It differs from contracture by the absence of skin tethering over the surface, and the presence of crepitus on flexing the fingers. To detect crepitus of the flexor tendon, the examiner places

Fig. 28.1 The shaggy cuticles and periungual erythema seen in connective tissue diseases, especially mixed connective tissue disease or dermatomyositis.

Fig. 28.2 Polyarticular gout affecting the hand, with visible tophi.

Fig. 28.3 Psoriatic arthritis with typical distal interphalangeal (DIP) joint involvement and nail dystrophy with pitting.

the index and middle fingers over the course of the tendon, with the thumb on the back of the hand exerting firm pressure. The patient is then asked to make a fist, and crepitus or nodularity may be felt as the tendon moves within its sheath. The procedure is repeated for each of the flexor tendons in turn. Trigger finger occurs when the finger locks in flexion, but can be passively (albeit painfully) straightened. This is caused by a nodule on the tendon passing through a stricture in the tendon sheath. The weaker extensor muscles are unable to pull the nodule back through the same obstruction. The nodule is usually to be found in the palm just proximal to the metacarpal head, but will only be detected during active movement of the affected digit.

Swelling

The hands may look generally puffy with no localization of this over joints. This is especially common in mixed connective tissue disease or early systemic sclerosis, where the hands may resemble a bunch of sausages, and also occurs with systemic lupus erythematosus (SLE), dermatomyositis, polymyalgia rheumatica, reflex sympathetic dystrophy, and early RA.

Where only one or two fingers have a diffuse, cylindrical swelling, not centred on a joint, we speak of a 'sausage' digit. These may represent swelling of the flexor tendon, as in the seronegative spondyloarthropathies (particularly in psoriatic arthritis), diffuse soft tissue inflammation as in gout (Figure 28.2), or infection as in leprosy or tuberculosis.

Synovial swelling in the proximal interphalangeal (PIP) joints is sometimes called spindling because of the fusiform appearance. Osteoarthritis causes a swelling of these joints that is bony and irregular, occasionally with effusions.

Distribution

The distribution of joint swelling gives an immediate clue to the diagnosis. Swelling predominantly of the terminal (distal) interphalangeal joints indicates osteoarthritis, psoriatic arthritis (Figure 28.3), or occasionally gout. Osteoarthritis also predominantly affects the first carpometacarpal joint, an articulation spared by most other arthropathies. The carpus looks to be squared, because of osteophyte formation, wasting of the surrounding muscles, and adduction of the thumb. RA has a predilection for the metacarpophalangeal joints, as well as the proximal interphalangeal joints.

Deformities

Note deformities such as swan neck, boutonnière, ulnar drift, and Z thumbs. Palmar subluxation of the metacarpophalangeal joints is often mistaken for synovial swelling, but the exposed metacarpal heads are rounded and bony on palpation. Palmar subluxation is easily confirmed by running a finger along the back of the patient's hand and fingers to assess whether the phalanges are on the same plane as the metacarpals.

Range of movement

The patient should be able to make a fist, burying the fingertips in the palm, a movement that requires 90° of flexion in each of the three phalangeal joints. Hypermobility is indicated by more than 90° extension in the metacarpophalangeal joints and ability to approximate thumb to forearm, passively.

Wrist

Swelling

In RA, exuberant soft tissue swelling may be seen, originating either from the wrist joint itself or from the synovial tendon sheaths, and spreading both sides of the extensor pollicis retinaculum. An undulating swelling of the ulnar border of the wrist is a particular

feature of RA. The undulations are the result of synovial swelling pushing its way through the fibres of the extensor retinaculum. This appearance is associated with an increased risk of rupture of the fourth and fifth extensor digitis tendons.

Swelling of the wrist joint is associated with compression of the median nerve in the carpal tunnel. Particular attention should be paid to looking for evidence of this complication. Inflammation of the abductor pollicis longus tendon at the wrist (de Quervain's tenosynovitis) is best diagnosed by inspecting the wrists from the radial side, with the palms together and any watches or bracelets removed. Unilateral swelling may then easily be seen, extending from the first carpometacarpal joint proximally. The diagnosis can be confirmed using Finkelstein's test. In this the patient is asked to bring the thumb across the palm and clasp the fingers around it. The examiner holds the clenched fist and tweaks it sharply in an ulnar direction, putting a sudden but not excessive pull on the inflamed tendon. This elicits a sharp pain, and should be done with care, watching the patient's face for signs of discomfort.

Deformity

Deformity of the wrist joint usually takes the form of radial deviation (with ulnar deviation of the fingers in the metacarpophalangeal joints) and palmar subluxation, owing to the stronger pull of the flexor than the extensor muscles of the forearm. Prominence of the lower end of the ulna is also common, because synovial proliferation at the inferior radioulnar joint weakens the ligaments and allows the bone to ride up in a deformity that may be either fixed or mobile. When the bone is mobile it is often painful, giving rise to the 'piano-key' sign, whereby pressure on the bone leads to the production of an audible protest from the patient.

Range of movement

The 'prayer position' normally allows 90° of passive palmar and dorsiflexion (Figure 28.4). The active range is 20° less in each direction.

Elbow

Inspection

Inspecting the elbows is a fruitful source of clues to the diagnosis in many rheumatic diseases. Rheumatoid nodules, gouty tophi, tendon xanthomata, olecranon bursitis, and the rash of psoriasis or of dermatomyositis may all be detected by a glance at the extensor surface of the elbow, just distal to the olecranon. The joints are most easily compared with the elbows flexed and the arms folded.

Palpation

Palpation for synovial proliferation or joint effusion is best done in the groove between the lateral epicondyle and the olecranon process. The radioulnar joints are frequently involved in RA, leading to loss of pronation and supination. The examiner places one thumb on the radial head and the other on the inferior radioulnar joint at the wrist, then passively pronates and supinates the patient's forearm, feeling for crepitus in one or both joints.

Tenderness of the lateral or medial epicondyles and the muscles inserting into them is found in 'tennis elbow' or 'golfer's elbow', respectively. To confirm, the patient is asked to clench the fist and to extend or flex the wrist against resistance. These manoeuvres should cause pain at the affected muscle insertion.

Range of movement

Flexion is usually limited by the interposition of soft tissues, and should be about 150°. Extension beyond 10° implies hypermobility. Pronation and supination take place at the superior and inferior radioulnar joints and must be done with the elbows flexed to exclude movement at the shoulder joint. The hands can normally be fully supinated and pronated.

Shoulder girdle

The three shoulder girdle joints are best considered together, as all three work together in movements of the shoulder, and pain from all three is felt around the shoulder and upper arm. Acromioclavicular pain is usually felt at the tip of the shoulder. Pain in the glenohumeral joints is most often felt over the deltoid muscle and midhumerus. The manubriosternal joint is often swollen and sometimes painful in RA and in seronegative spondyloarthritis.

Sternoclavicular joint

The sternoclavicular joint is often neglected, despite the fact that it is frequently affected in a variety of arthropathies, including polymyalgia rheumatica, RA, the seronegative spondyloarthropathies, and septic arthritis. Pain is rarely localized to the joint, even when there is obvious swelling and redness, but is referred to the upper arm. Palpation should include the inner end of the clavicle and the articular surface of the manubrium, directly below it. Pain can best be elicited by asking the patient to brace the shoulders forward and back, or to shrug the shoulders up and down, movements which do not involve the glenohumeral joint. If these movements are painful but external rotation of the shoulder is not, there is strong evidence of sternoclavicular disease.

Acromioclavicular joint

The acromioclavicular joint is near the surface and can easily be seen and palpated if swollen. Passive adduction of the arm across the chest will often cause pain if the joint is inflamed. There may be a painful arc on abduction above 90°.

Shoulder (glenohumeral) joint

Inspection

Wasting of muscles should be noted both from the front and the back. Swelling of the shoulder joint is not always obvious. A shoulder effusion in a patient with RA may give that shoulder a more normal-looking contour. Rupture of the shoulder capsule may lead

Fig. 28.4 The reversed 'prayer position', demonstrating wrist palmar flexion.

to fluid tracking down to the upper arm. A dislocated shoulder may appear square and dropped, while in RA the shoulders appear both square (due to muscle wasting) and raised, owing to upward subluxation of the humeral heads as a result of dysfunction of the rotator cuff and muscle contracture.

Palpation

A shoulder effusion is best felt by placing the thumb in front and the fingers behind the joint and fluctuating the fluid back and forth across the shoulder. Tenderness may be elicited over the whole line of the joint in capsulitis or inflammatory arthritis, or may be localized where there is an isolated lesion of the tendon. Inflammation of the long head of biceps gives tenderness in the bicipital groove anteriorly, while supraspinatus tendinitis causes tenderness in the subacromial bursa. Rupture of the long head of biceps is best appreciated by asking the patient to contract the muscle against resistance. The affected muscle will form a ball (the 'Popeye sign').

Movements of the shoulder girdle

Although individual arcs of movement may be attributed to each of the three joints of the shoulder girdle, in practice they work smoothly together when the arm is raised. The sternoclavicular joint is the single point of bony connection between the arm and the trunk, and allows considerable movement of the clavicle, which in turn acts as a strut to add freedom of movement to the arm. The acromioclavicular joint has less movement, but allows for rotation of the scapula on the thorax. Pure glenohumeral movement can be isolated from movement of the scapula across the thorax by fixing the inferior angle of the scapula with one hand and passively abducting the arm with the other. Normally, the scapula starts to move at 30° of abduction, but if it is fixed at least 90° of glenohumeral movement is possible. Passive external rotation is another reliable measure of pure glenohumeral movement. Restriction of this movement is a first sign of inflammation of the glenohumeral joint. The last few degrees of abduction may be lost in patients with a painful neck lesion. Passive movements should always be checked if the active range is incomplete. Loss of active and passive range in equal measure suggests intracapsular disease such as arthritis or adhesive capsulitis ('frozen shoulder'). Loss of active more than passive movement, accompanied by pain, suggests a lesion of tendon or rotator cuff. Limitation or weakness of active movement with a full and pain-free passive range suggests muscular or neurological disease.

The painful arc

During abduction of the arm, pain may be experienced in an arc, above or below which movement is pain free. The most common cause is supraspinatus tendinitis. In this condition pain occurs somewhere in the arc from 60 to 100° as the greater tuberosity impinges on the acromion, pinching the supraspinatus tendon. The pain may be severe enough to prevent abduction. The patient is often able to elevate the arm fully by forward flexion, but if asked to take it down sideways, will complain of pain as the upper limit of the painful arc is reached. A painful arc above 90° occurs in acromioclavicular disease.

Resisted movements

Specific tendon lesions can be identified by using resisted movements to elicit pain. Pain on resisted abduction suggests a supraspinatus lesion. Pain on resisted external rotation suggests an infraspinatus lesion. Pain on resisted internal rotation suggests a subscapularis lesion.

Range of movement

Movement at the shoulder comprises forward flexion to 180°, abduction to 180°, extension to 45°, and rotation to 70° internally and externally. Movement at the sternoclavicular joint includes protraction and retraction of the clavicle in an arc of 60°, and elevation of the clavicle to 60°.

Temporomandibular joint

Palpate the joints for tenderness or swelling and ask the patient to open the mouth wide. These joints are most frequently involved in RA. The complaint is of pain on chewing or yawning and sometimes of pain in the ear. The joints rarely look abnormal, but there is local tenderness and pain on opening the jaws. Normally, it is possible for the fully open jaws to accommodate the middle three digits of the patient's hand, held vertically between the teeth. Restricted mouth opening from disease of the temporomandibular joints may be differentiated from that caused by scleroderma by inspecting the lips and the skin around the mouth, which will be drawn tight in scleroderma. Micrognathia occurs as a result of temporomandibular joint inflammation in childhood, as in juvenile idiopathic arthritis. Premature closure of the epiphysis leads to failure of normal development of the mandible.

Cervical spine

Inspection

Neck posture may indicate underlying disease. A poking chin with dorsal kyphosis often accompanies cervical spondylosis. Acute torticollis can be recognized as the patient enters the room: one sternocleidomastoid muscle in spasm and the head tilted to the side and slightly rotated. The patient with RA will often have lost neck height and there may be a lateral asymmetry if there has been softening and erosion of bone.

Palpation

Palpation of the neck should include the occipital ridge, the spinous processes, and the paravertebral muscles overlying the facet joints. The occipital ridge is frequently tender in cervical spondylosis, especially over the greater occipital nerve. The spinous processes normally form a lordotic arc, with C2 and C7 being prominent at either end of the curve. Loss of lordosis or even a reversed curve can be appreciated by palpation. Palpation of the paravertebral muscles may reveal spasm in any case of neck pain, but especially after a whiplash injury or in cases of headache and neck pain related to stress. Through the paravertebral muscles, the facet joints can be felt, and tenderness or swelling elicited. Each pair of facet joints should be palpated in turn.

Range of movement

The patient should be able to touch the chin to the chest, tip the head back until the forehead and nose are parallel to the ceiling, and rotate in each direction to 70°. Lateral flexion is normally 45° each side, and this movement is lost early in ankylosing spondylitis. Passive neck movements are not a part of the routine examination, as neck instability is a feature of the rheumatic diseases. Lhermitte's sign is more correctly a symptom. The patient complains of paraesthesia down the body on flexing the neck. It is sometimes

present in cases of compression of the cervical cord, especially in RA. The examiner should not attempt to elicit this sign by forcible neck flexion.

Thoracic spine

Inspection

This will reveal postural abnormality such as kyphosis or scoliosis. Destruction or collapse of vertebrae may lead to a sharply angled kyphosis, or angular gibbus, most often seen in tuberculosis. Kyphosis in adolescents suggests Scheuermann's disease or an osteoporotic vertebral fracture. Scoliosis may be developmental, in which case there is usually some rotation of the ribs, which can be exaggerated by asking the patient to bend forward so that the rotation is more easily appreciated. Scoliosis resulting from muscle spasm becomes less obvious on forward flexion.

Palpation

The spinous processes and paravertebral muscles are next palpated, especially for tenderness. Recent collapse of a vertebra, malignant deposits, or vertebral osteomyelitis all produce local or 'point' tenderness. If direct pressure over the spinous process is insufficient to elicit this, it is worth trying percussion, laying two fingers over each process in turn and striking these with the fist, gently at first, then more firmly if no discomfort is elicited. Tenderness of the upper thoracic vertebrae and the paravertebral muscles is a common feature of thoracic spondylosis.

Range of movement

Rotation is best assessed with the patient seated to fix the pelvis and is usually 45°. Flexion is most easily measured with a tape measure. Distraction on flexion between marks made at C7 and T12 is normally at least 2.5 cm. Costovertebral movement is measured by chest expansion at the level of the nipples, usually more than 7 cm.

Lumbar spine

Examination

Patient standing

The examiner inspects the back for abnormality of posture or deformity, such as scoliosis or kyphosis, then palpates the paravertebral muscles for evidence of spasm. Palpation for tenderness is best left until the patient is lying down.

Forward flexion and extension are relatively more restricted in the patient with a mechanical back pain, while lateral flexion is the first to be lost in ankylosing spondylitis. Schober's test is a useful method of measuring lumbar flexion, especially in ankylosing spondylitis. Using a tape measure, the examiner makes two marks, one 5 cm below the level of the sacroiliac dimples and one 10 cm above. The patient bends forward and the examiner measures the distance between the marks. Distraction of at least 5 cm is normal. Asking the patient to take a few steps on the heels and toes is a crude but useful test of power in the legs and feet, and at the same time the buttocks can be inspected for any evidence of a Trendelenburg sign (dipping down of the pelvis when the ipsilateral foot is raised from the ground) suggesting muscle weakness.

Patient lying face up

Straight-leg raise (Lasègue's sign): the patient lies supine while the examiner grasps one ankle and raises it from the couch, keeping the knee straight with a hand on the knee, and watching the patient's face for any sign of discomfort. Normally 80–90° can be attained without discomfort, depending on the tightness of the hamstrings. Irritation of the dural sleeve of any of the nerve roots contributing to the sciatic nerve will result in pain when the sciatic nerve is put on the stretch, and a much reduced straight-leg raise on the affected side. The usual cause of this is a prolapsed lumbar disc protruding posterolaterally. Bilateral reduction in straight-leg raising implies a central disc prolapse. To distinguish between sciatic irritation and hip disease, the leg is raised with the knee flexed. This will now be painless in sciatic irritation, but just as uncomfortable in hip disease.

Sciatic stretch test: this may be useful in distinguishing sciatic irritation from tight hamstrings if the straight-leg raise is reduced. Once the limit of straight-leg raising is established, the leg is lowered a fraction until the pain is relieved. Now the examiner dorsiflexes the foot. If the pain was due to sciatic irritation, it returns. After the straight-leg raise, the examiner tests the knee, ankle, and plantar reflexes. Testing power in each of the major muscle groups of the legs, especially the hip muscles, may cause difficulties if the patient is in pain. It may be necessary to reassess the patient after adequate control of the pain. Sensation to light touch and pinprick is next elicited, following a dermatomal pattern over the anterior aspects of both legs and the soles of the feet.

Patient lying face down

It is important to have the couch flat, with pillows removed, to avoid painful hyperextension. A pillow under the patient's abdomen will usually increase comfort and render the examination easier. The examiner palpates each spinous process in turn, gently at first, then increasing the pressure by using one hand laid on the other. Then the examiner palpates for tenderness in the paravertebral muscles, the posterior iliac crests, and over the sacrum and coccyx. Coccygeal tenderness may also be felt by a rectal examination.

Point tenderness is a feature of local infection or malignancy. More diffuse tenderness is common in patients with mechanical back pain. The femoral stretch test is the parallel of the straight-leg raising test, putting the femoral nerve roots on the stretch. The examiner takes the prone patient's ankle in one hand, flexing the knee to 90°, and raising the bent leg to extend the hip. Pain during this manoeuvre may indicate a lesion of a high lumbar disc or hip disease. Loss of sensation around the saddle area is an important clue to the presence of cauda equina lesions and should always be tested for. Buttock tone is assessed by asking the patient to pinch the cheeks of the buttocks together as hard as possible, and palpating the two sides. A rectal examination is helpful where there is any hint of a lesion of the cauda equina, to assess sphincter tone and sensation, in addition to its importance as part of the general assessment of the patient.

Sacroiliac joints

Inspection and palpation

Inspecting the joints from behind may reveal evidence of swelling or deformity, especially in tuberculous infection. Palpation is best done with the four fingers of the hand along the length of the joint. Nodules of tender fibrofatty tissue often overlie the joints, and are of no significance except that they are often found in patients with chronic back pain. Bony fusion of the joints in ankylosing spondylitis obliterates the joint line. The synovial portion of the joint lies too deep to be felt under normal circumstances.

Range of movement

Moving the sacroiliac joints is not easy, as there is only a small amount of rotational glide, but they may be stressed by a variety of manoeuvres. The simplest method is to press firmly on the sacrum while the patient lies prone, then on the pelvic brim as the patient lies supine and on one side. If the sacroiliac joints are inflamed, these manoeuvres may elicit pain. Instability of the sacroiliac joints, especially postpartum, may cause pain, which is aggravated when the patient is asked to stand on one leg. Sometimes the excessive movement can be appreciated by placing one finger on each side of the joint as the patient makes the manoeuvre.

Hip

Screening
Inspection

The gait is particularly important in the assessment of the lower limb joints. The patient with a fixed flexion deformity of the hips throws the spine into an exaggerated lordosis to compensate. The patient with weak hip muscles walks with a waddle, and one with a painful hip walks in such a way as to spend the least possible time on the painful leg, leaning to the opposite side, often with a walking stick. This is called the antalgic gait. Inspection of the hips should always include comparison of leg lengths and attention to the position of the leg. The leg that is short and externally rotated suggests a fractured neck of femur, or a legacy of juvenile idiopathic arthritis. Failure to observe the back of the hips may mean that the evidence of previous surgery is missed.

Palpation

Palpation of the hip is difficult because the joint is so deep, although occasionally an effusion can be detected by fluctuation just beneath the inguinal ligament. A psoas abscess may cause a very painful, stiff hip with spasm that cannot be overcome without anaesthesia. The psoas abscess will eventually point as a mass below the inguinal ligament. The greater trochanteric bursa lies over the greater trochanter and if it is inflamed, tenderness can easily be elicited with the patient lying on the unaffected side.

Range of movement: flexion, 110°; extension, 30°; abduction, 50°; adduction, 30°; internal and external rotation, each 45°.

A fixed flexion deformity can be demonstrated with Thomas's test. The patient lies supine and one knee and hip are flexed until any lumbar lordosis has been obliterated. Flexion of the other hip during this manoeuvre indicates a fixed flexion deformity of that hip. A catch for the inexperienced is the patient with a painful knee that is held in flexion. Attempts to straighten the knee in the bed are unsuccessful because of pain, and yet no other abnormality is seen in the knee. This patient probably has disease of the hip, with a fixed flexion deformity and pain referred to the knee. If the examiner were to straighten the knee while maintaining a flexed hip, a full range of movement would be found in most cases. Rotation may also be tested in extension, by rolling the leg. Where both hips have a limited range of abduction, it is useful to record the maximum distance between the two medial malleoli. Extension of the hip is best measured with the patient lying on the side or prone.

Knee

Inspection

Knee swellings can be recognized by fullness of the suprapatellar pouch and obliteration of the hollows either side of the patella.

Quadriceps wasting may be masked by swelling of the knee and measurement of quadriceps bulk should be made above the upper limit of the suprapatellar bursa. Deformities may be varus or valgus, forward or backward slip.

Palpation

Tenderness of the medial collateral ligaments occurs early in osteoarthritis,followed by the development of a tender bony ridge as osteophytes develop. A knee effusion can be demonstrated in one of three ways, depending on the quantity of fluid present, as follows:

◆ A small effusion can be milked from one side of the patella to the other in the 'bulge sign'. Any fluid in the medial side of the joint is swept firmly laterally and upward into the suprapatellar pouch. Then the back of the hand presses firmly and sharply on the lateral side of the joint. When a small effusion is present, a bulge will appear on the medial side of the joint as the fluid returns.

◆ A moderate effusion is best detected by eliciting the 'patellar tap'. One hand is placed on the suprapatellar pouch, the finger and thumb exerting side-to-side pressure, squeezing any fluid in the pouch to the retropatellar space. The patella is then sharply depressed with the fingers of the other hand, so that it floats through the fluid to strike the lower end of the femur. This sharp tap will not be felt if the undersurface of the patella is covered with synovial pannus, which acts as a blanket to muffle the impact. A tap may be felt in the absence of fluid if intra-articular fat is squeezed behind the patella.

◆ A large, tense effusion can be confirmed by fluctuation across the joint, from one side of the patella to the other.

A cyst of the calf or popliteal fossa is often easier to feel than to see, and has the consistency of a firm rubber ball.

Testing stability

To test the cruciate ligaments the examiner grasps the flexed knee just below the knee, with both hands, and exerts pressure first anteriorly, then posteriorly. To test the medial and lateral collaterals the examiner raises the patient's leg, supported with the fingers of one hand under the knee, holding it slightly flexed, and the other under the ankle. Then pressure is exerted with the heel of each hand, producing a stress across the knee joint, centred on the ligament to be tested.

McMurray's sign

This is a test for cartilage tears. The patient lies supine and the examiner grasps the knee in one hand and the ankle in the other. The examiner then flexes the knee fully, internally rotates the lower leg as far as it will go, and slowly straightens the knee. Then the test is repeated with external rotation. If the hand over the knee detects a clunk on straightening, accompanied by wincing or other expression of pain from the patient, the test is positive.

Range of movement: extension, 0°; flexion, 135°. Hyperextension can be tested by holding the knee firmly on the bed and lifting the ankle. Extension beyond 10° is abnormal.

Ankle joint

Inspect for swelling or deformity. Palpate the anterior joint line for tenderness, swelling. Assess dorsiflexion and plantar flexion. Swelling can be detected anteriorly, between the malleoli, where it has the appearance and feeling of a 'spare tyre', quite unlike the diffuse swelling of ankle oedema. Swelling behind the lateral malleolus

suggests peroneal tendinitis. Synovitis of the extensor tendons results in swelling both above and below the extensor retinaculum.

Range of movement: dorsiflexion, 20°; plantar flexion, 70°.

Subtalar (talocalcaneal) joint

Inspect for varus or valgus deformity of the hindfoot. Grasp the heel and assess inversion and eversion. Swelling is seen below the malleoli. This joint is prone to symptomless involvement, especially in RA and juvenile chronic arthritis. Talipes valgus deformity usually results, and is best appreciated from behind, with the patient standing.

Range of movement: inversion, 25°; eversion, 15°.

Heel and foot

Inspect both the dorsal and plantar aspects of the foot, and the back of the heel. Palpate the Achilles tendon insertion, the plantar fascia insertion, and the metatarsophalangeal joints. Apply torsion to the midfoot to test movement in the midtarsal joints. Painful feet may be caused by vascular or neurological lesions. The peripheral pulses and sensation should always be assessed, and search made for ulcers, sinuses, or skin infarcts. Occasionally a prolapsed lumbar disc will present with foot pain without back pain or sciatica.

Achilles tendon

This is inspected from behind, either with the patient standing or lying prone. Thickening, tenderness, and rupture can be detected. With rupture, the patient may have difficulty in standing on tiptoe at first, though fibrosis later occurs, rendering the movement possible. The Achilles tendon is a common site for traumatic bursas related to pressure from shoes, rheumatoid nodules, gouty tophi, and tendon xanthomata.

Heel

Heel pain is commonly due to plantar fasciitis. The heel can be inspected from below with the patient lying down. It is unusual to see swelling or discoloration, though the affected side often feels firmer. Tenderness is elicited by pressure directly cranial from the centre of the heel and by pressure from side to side at the level of the anterior margin of the calcaneum.

Midfoot

The naviculocuneiform joint is subject to osteoarthritis and is often found to show bony enlargement.

Sole

Callosities under the metatarsal heads develop when the metatarsophalangeal joints are subluxated. The rash of psoriasis or keratoderma blennorrhagica may be detected on the soles.

Toes

Inspect the toes for deformities such as hallux valgus, clawing, overlapping toes, undersized toes. In RA, fibular drift of the toes is common. Clawed toes press on the uppers of shoes and callosities form over the proximal interphalangeal joints. 'Sausage toes' suggest seronegative spondylarthropathies, gout, or psoriatic arthropathy. A bursa between the joints will spread the toes. Diffuse swelling over the metatarsophalangeal joints may be easier to feel than see; tenderness may be elicited by palpating each joint individually. Beware of squeezing the forefoot, as this can cause severe pain if the joints are inflamed.

Standardized quantification

Standardized instruments are useful and required for the evaluation of disease progress and treatment efficacy in rheumatic patients. Measures that are reproducible, valid, and sensitive to relevant changes are used both in clinical trials and daily clinical practice. Many of these have been reviewed in detail recently.[1]

Several devices have been developed and validated to quantify for instance range of motion, muscle strength, and skin elasticity. Furthermore, indices are developed that combine clinical assessments into a single outcome measure (see Chapter 29).

Objective assessment

Skin

Skin elasticity can be assessed with a cutometer SEM 474 or 575. This cutometer exerts a controlled vacuum force on a skin area using a 2 mm or 8 mm probe. In systemic scleroderma it showed good correlation with the subjective skin score, with better reproducibility. It can assess changes in skin extensibility over time, and may be useful in monitoring the disease and its treatment.[2]

In scleroderma skin thickness can be measured, next to that the maximal oral opening, and the distance between third finger and the distal palmar crease in full flexion respectively extension (flexion/extension index) can be done.

In systemic sclerosis the severity of skin thickness is determined by physical examination of specified sites. Each site is graded on a three-point scale, and to obtain a total skin score all scores are summed (modified Rodnan skin score).[1] Capillaroscopy may be used to assess the extent and severity of nailfold capillary lesions in scleroderma.[3]

The extent of psoriatic lesions in psoriatic arthritis can be assessed using the Psoriasis Area and Severity Index (PASI).[4]

Muscles

Muscle strength—both isometric and isokinetic—can be assessed using dynamometers produced by several manufacturers. RA patients show decreased muscle strength compared to healthy controls. For patient or trial evaluation no standards for muscle strength assessments are recommended. The reliability and validity of the different dynamometers are still to be determined. Grip strength is the most frequently assessed aspect, although the type of instrument used is not standardized. A sphygmomanometer cuff is inflated to 30 mmHg and the patient squeezes it with one hand. The maximum reading achieved in three attempts is recorded. The muscle strength index is the mean score of standardized isometric extension and flexion strength of the knee and elbow joints. The index is reliable and correlates with self-reported functional disability and radiological damage in RA.

Muscle tenderness can be measured, in fibromyalgia for example, using a dolorimeter (or palpometer). The dolorimeter (Fisher or Chatillon) consists of a flat circular rubber probe of varying diameters, attached to a spring-loaded gauge. The probe is placed on a skin area, and the minimum pressure is recorded that provokes tenderness. However, the validity of the dolorimeter compared to a manual tender point examination is disputed. The tender point score is an index of 18 selected points which are frequently tender on pressure in patients with fibromyalgia.[5] The score is moderately

reliable as diagnostic criterion, and is moderately responsive to perceived symptomatic change.

Joints

Joint tenderness is usually ascertained by manual pressure on the joint margins, or by passive movement for less palpable joints. These methods show large interobserver variation because the pressure is not standardized. Swelling of superficial joints is mostly assessed by manual palpation.

A goniometer is necessary: for accurate measurement of angles of movement or degrees of deformity in range of motion assessment. It is useful to have a long-armed one for large joints and a smaller one for joints of hands and feet. The arms of the goniometer should be lined up along the long axis of the joint, the hinge on the joint line, and the maximum angles of flexion and extension recorded. The position of the joint in the extended anatomical position is taken as zero, and further extension is recorded as a minus value.

Several joint counts have been developed, counting a varying number of joints that are tender and/or swollen. Examples frequently used in RA are the 28-joint count for pain and for swelling, the 68-joint count for pain, and the 66-joint count for swelling. The Ritchie articular index is a method of recording activity in RA by means of grading the tenderness to firm pressure or pain on movement in 53 joints, divided over 26 units, with a score ranging from 0 to 78. The most widely used is 28-joint count for tenderness (yes/no) and swelling (yes/no), and this is used in the DAS28 (see Chapter 28).

For the spinal and chest mobility several tests are described that are frequently used in ankylosing spondylitis[6]:

- Occiput–wall distance, measured in centimetres with the patient standing as erect as possible with heels and back against the wall.
- Chest expansion, assessed as the difference in centimetres between the circumference of the chest at nipple line on full inspiration and full expiration.
- Schober 10 cm test (measured in centimetres), with the patient erect, mark the skin at the level of the posterior superior iliac spines (dimples of Venus) and another 10 cm above in the midline. Ask the patient to bend maximally forward without bending the knees.
- Fingertip-to-floor-distance, recorded as the distance in centimetres between the third finger and the floor with the patient bending forward maximally, without flexing the knees.
- Lumbar lateral flexion, measured as a percentage of the body height.

Enthesitis

Several enthesitis indices have been developed to assess the extent of inflammation at site of ligament, tendon and joint capsule insertion into bone. These involve standardized palpation and ascertaining the presence of absence of tenderness. They can be used in AS and psoriatic arthritis.[4]

Outcomes

David L. Scott

What are disease outcomes?

Each disease has its own natural history. These histories reflect what would happen without medical interventions. Outcomes assess differences between the overall benefits of medical treatments and the natural histories of untreated disease. Although effective treatment generally improves outcomes, some patients have poor outcomes due to adverse events. Clinical outcomes must therefore focus on groups of patients, with successful management giving substantially more positive than negative outcomes.[1–5]

In short-term diseases with sudden onset it is simple to assess relationships between clinical interventions and disease outcomes. However, in long-term diseases, which include many rheumatic disorders, outcomes reflect a large range of influences in addition to the disease itself and its treatment. These multiple confounding factors create challenges for judging the overall impact of treatment on outcomes.

Types of outcomes

Clinical outcomes can be classified in several ways. First, there is the type of outcome assessed. These fall into several broad areas:

- *Disease measures:* reflecting the presence and severity of the underlying disease, e.g. the presence and severity of joint inflammation in arthritis

- *End-organ damage:* indicating the severity of the unwanted consequences of disease, e.g. the extent and severity of joint damage in arthritis.

- *Quality of life measures:* these more general assessments made by patients indicate the impact of their disease on their lives in general. Some are disease specific; for example, the HAQ assesses disability in arthritis. Others are generic and are applicable in all disease; examples include the Short Form 36 (SF-36) and EuroQol.

Some crucial outcomes are of limited relevance in rheumatic diseases. The best example is death. Mortality rates associated with different medical interventions, though useful guides to the value of treatments, are only relevant in diseases with high mortality rates. In most rheumatic diseases death is uncommon. Another example, the ability to work, is an increasingly important assessment of the overall impact of disease, but is not relevant in diseases affecting elderly patients who will usually have retired.

Another issue is the nature of the outcome assessed. Some outcomes are categorical, which range from binary outcomes, like alive or dead, to longer scales dividing patients into three, four or five categories. Some outcomes have longer numeric scales; examples include joint counts, radiographic scores, and quality of life measures like HAQ scores. Their apparent simplicity hides complex analytical issues. For instance, in measures like the HAQ, increments in scores along the scale from 0–3, although numerically similar, may not equate to identical changes in the disability.

The final domain is time. Outcomes can be short term—weeks and months—or long term, extending over years and decades. Short-term outcomes, though readily related to treatment, are often less relevant to patients. Clinical trials focus on short-term outcomes whereas observational studies explore longer-term outcomes.

Interrelationships between outcomes

Different clinical outcomes are closely interrelated. Patients with arthritis who have good clinical outcomes usually have reduced joint counts, less joint damage and better quality of life. The converse is equally true. As a consequence there is no need to measure all outcomes; a few carefully chosen outcomes can capture the overall response to treatment. Reducing the number of outcomes measured has some limitations. Several other factors are involved in determining individual outcomes. For example, in patients with rheumatoid arthritis the presence of rheumatoid factor increases the likelihood of erosive joint damage irrespective of the response to treatment. Similarly, the presence of comorbidities worsens patients' quality of life irrespective of their responses to treatment.

One crucial issue is whether some outcomes provide more useful information than others. Outcomes which capture issues of direct importance to patients are preferable to overtly medical outcomes. For instance, most experts believe it is more important to assess quality of life than laboratory measures like the erythrocyte sedimentation rate (ESR) or erosive damage on radiographs. However, these patient-related outcomes have drawbacks: they can be highly subjective, they may showed marked variations between patients, and their accuracy and reproducibility may be limited.

An associated issue is the generalizability of outcome measurements. Generic measures like the SF-36 and EuroQol can be applied across a wide range of diseases, including arthritis, connective tissue diseases and non-rheumatological disorders. They provide comparable measures of the benefits of medical treatment in

many patients. Such broad comparability is offset by reductions in sensitivity to changes in arthritis and a lack of specificity in detecting treatment effects.

Confounding factors

Clinical outcomes attempt to capture the impact of treating rheumatic diseases. However, many other factors, often not directly related to the disease itself, are of equal importance. These confounding factors can make it challenging to compare outcomes between centres, because they may have very different confounding factors, which may not be unravelled by attempts to correct for them. Key confounding factors are:

◆ *Demography*: age, gender, ethnicity, and disease duration are all relevant, with worse outcomes anticipated in elderly patients from ethnic minority groups who have long disease durations.

◆ *Deprivation:* poverty shortens life and invariably worsens outcomes.

◆ *Comorbidities:* patients with multiple comorbid conditions usually have worse quality of life and their outcomes are poorer for all diseases.

These multiple confounding factors mean that comparing outcomes across units without adjustment will invariably show major differences. Given the difficulties making appropriate adjustments, it appears inevitable that all comparisons will be flawed. In addition, treatment probably ought to vary across units as they will see very different patients. Within the United Kingdom there has been concern about 'postcode' prescribing, with treatments varying depending on where patients live. However, such concerns are based on mistaken assumptions; variations between centres make postcode prescribing inevitable.

Outcomes in arthritis—rheumatoid arthritis as model

It is impractical to outline outcome assessments in all rheumatic diseases. Instead it is best to use one major disorder as an exemplar for outcomes in rheumatology. The obvious example is rheumatoid arthritis.

The rheumatoid arthritis outcome matrix spans five domains (Table 29.1). Outcomes include symptoms and assessments of disease activity,[6] damage and quality of life, the overall result—remission—and end results like joint replacement and death. There is no need to record all outcomes. A few measures can capture the impact of treatment. Joint counts and acute-phase measures like the ESR

are most useful in short-term studies whereas joint replacement and death are more relevant in long-term studies.

Disability and quality of life

Patients assess their disability, function, and quality of life. Consequently these measures are termed 'patient-related outcome measures' (PROMs).[7] In the United Kingdom National Health Service (NHS), PROMs have assumed central positions. One reason is that they are easily measured. In addition, treatment should result in improvements noticed by patients.

The main limitation of PROMs is that they are highly subjective. If patients believe they are disabled or have major health problems, their scores will reflect these health beliefs. In addition, generic outcome measures were not designed for patients with arthritis and therefore are relatively insensitive in detecting improvements in health status. The various measures may not give identical findings. Patients may record poor outcomes in some scores but not in others. Finally, the various PROMs have scales of differing lengths with views on how to describe normal. Some consider normal function should be scored as zero, with limitations of quality of life giving higher scores. The HAQ and the Nottingham Health Profile (NHP) are examples of such positive scoring. Others consider normal function should be classified as scoring 100% or 1 (on a 0–1 scale), with limitations of quality of life giving lower scores. The Short Form 36 (SF-36) and EuroQol are examples of such negative scoring.

Patient-related outcome measures

There are three dominant measures—HAQ, SF-36, and EuroQol—which are summarized in Table 29.2. There are also many other measures which are less commonly used.

Health Assessment Questionnaire

HAQ scores, also termed the HAQ Disability Index (HAQ-DI), assesses function by asking questions across eight categories—dressing, rising, eating, walking, hygiene, reach, grip, and usual activities.[8] Patients respond on four-point scales, ranging from 0 (no disability) to 3 (completely disabled). These are added to give the HAQ score on a 0–3 scale. The smallest increment is 0.125. It is a disease-specific measure, designed for patients with arthritis, and is used mainly in rheumatoid arthritis. The HAQ has been widely translated into many different languages.

Short Form 36

The SF-36 gives eight scaled scores based on patients' responses to 36 questions. Each domain is transformed into 0–100 scales.

Table 29.1 Outcome matrix for rheumatoid arthritis

Symptoms	Damage	Quality of life	Overall	End result
Joint counts	New erosions	HAQ	Remission	Joint replacement
ESR	Sharp scores	AIMS2	Work disability	Death
C-reactive protein	Larsen scores	SF-36		
DAS28 scores		EuroQol		
		NHP		

AIMS2, Arthritis Impact Measurement Scale 2; ESR, erythrocyte sedimentation rate; HAQ, Health Assessment Questionnaire; NHP, Nottingham Health Profile; SF-36, Short Form 36.

Table 29.2 Patient-related outcome measures for function and quality of life

Measure	Health Assessment Questionnaire	Short Form 36	EuroQol
Abbreviation	HAQ	SF-36	EQ-5D
Use	Disease specific	Generic	Generic
Components	Function	Function, pain, general health, vitality, social role, mental health	Mobility, self-care, usual activities, pain, mental health

The eight domains are physical function, physical role, bodily pain, general health, vitality, social role, emotional role, and mental health.[9] The first four can be combined into a physical component summary score and the latter four into a mental component summary score. There are also shorter similar scores, such as the SF-12, which are brief but less sensitive to changing health. The SF-36 is a generic measure, designed to capture health status in many different conditions. Like the HAQ, the SF-36 has been widely translated. There are many datasets available for SF-36 scores in healthy control groups.

EuroQol

The EuroQol or EQ-5D consists of the EQ-5D descriptive system and the EQ visual analogue scale. The EQ-5D descriptive system has five dimensions: mobility, self-care, usual activities, pain/discomfort, and anxiety/depression.[10] Each dimension has three levels: no problems, some problems, extreme problems. EQ-5D can be presented for each dimension. Usually they are combined in an index which ranges from 1 (completely healthy) to 0 (no health at all, which can be viewed as being equivalent to death); for technical reasons some patients have scores below 0. The EQ visual analogue score assesses patients' current health as a 100 mm visual analogue score. The EuroQol is another generic measure which has been widely translated. Scores for normal healthy controls are widely available.

Others

There are many other disease-specific and generic PROMs. Examples include the Arthritis Impact Measurement Scale (AIMs-2),[11] the Nottingham Health Profile (NHP)[12] and the Rheumatoid Arthritis Quality of Life (RAQoL) questionnaire.[13] All have strong points and are useful and valid. However, for a variety of reasons, they are less widely used.

Health economics

PROMs inform health economic assessments. They are useful in the first steps of such analyses, which involve identifying the impact of an intervention on patients' quality of life. Utility scores (on scales of 0–1, like EuroQol) when combined with information about time, can generate quality-adjusted life years (QALY). These are based on the number of years of life added by treatment based on the concept of perfect health being assigned the value of 1.0 down to a value of 0.0 for death.[14] Multiplying the average utility score by the time spent in this health state generates QALYs. Health economic analyses then compare the difference in QALYs attributable to treatment. The EuroQol can be used to directly measure QALYs, the SF-36 and SF-12 scores can be used to generate utility data, and HAQ scores can be used in modelling studies to provide data on QALYs. The potential role of these PROMs in judging the cost-effectiveness of treatments is an important part of their role in assessing health.

Outcomes in inflammatory arthritis

The multiplicity of outcome measures and rheumatic diseases make it impractical to provide detailed information on all outcomes in all diseases. Rheumatoid arthritis provides a good as an example for what happens to outcomes over time with treatment. Findings in rheumatoid arthritis are broadly similar in other forms of inflammatory arthritis, including early undifferentiated arthritis and psoriatic arthritis.

HAQ scores

Early rheumatoid arthritis

HAQ scores are often relatively high at disease onset and improve over the next 6–12 months due to the impact of treatment. Thereafter they gradually increase over time. This has been termed the 'J-shaped' curve (Figure 29.1a).[15] There is some evidence that the nature of rheumatoid arthritis is changing over time. Although the pattern of change is similar, more recent patients have lower mean HAQ scores, which may reflect changes in the disease itself, better treatment, and differences in referral patterns.

Established rheumatoid arthritis

After the initial treatment has been completed, mean HAQ scores in established rheumatoid arthritis gradually increase over time (Figure 29.1b).[16,17] The rate of increase varies between studies: it reflects the severity of disease, the extent of erosive damage, the effectiveness of treatment and the presence of comorbidities. The annual rate of increase in HAQ scores is in the region of 0.03 per year. This equates to an average 1% increase.[18] In groups of patients with rheumatoid arthritis a change in HAQ scores of more than 0.22 is considered clinically important.[19]

Mean changes in HAQ scores do not show individual variation over short time periods, which can be marked. Mean changes hides the marked fluctuation in HAQ scores over months in individual patients.[20]

HAQ scores fall with effective treatment, particularly with disease modifying antirheumatic drugs (DMARDs) and biologics. The changes are maximal by 6 months and thereafter stabilize. Systematic reviews show broadly similar falls with both simple treatment with DMARD monotherapy and intensive treatments with combination DMARDs and tumour necrosis factor (TNF) inhibitors in more severe disease (Figure 29.2).[21]
Fig. 29.1 Changes in health assessment questionnaire scores in rheumatoid arthritis: (A) early disease (Welsing et al. 2005).[15] (B) established disease (Drossaers-Bakker et al. 1999; Wolfe, 2000).[16,17]

SF-36 scores in rheumatoid arthritis

SF-36 shows a complex profile of outcomes in rheumatoid arthritis, and this is shown in Figure 29.3.[22] Functional domains show marked changes, with very low scores. Mental health domains show less severe changes, though these are reduced compared to healthy individuals. There is some evidence that mental health domains show similar changes to those seen in major treated psychological diseases like depression.

Treatment with disease modifying drugs and biologics improves SF-36 scores. This can be seen both in individual domains and in summary scores. Interestingly, there is some evidence that biologics improve both physical and mental components of health whereas conventional treatments only improve physical components.[23]

EuroQol

This is a different type of measure and has very different properties from assessments such as HAQ. The nature of the three-point scoring system means that the way patients complete the assessments impacts on the measurements. This is shown by comparison to HAQ scores in a cross-sectional study of rheumatoid arthritis.[24] HAQ scores have a Gaussian distribution, albeit with a tail towards normal. In contrast EuroQol scores have two peaks; most patients cluster around the midpoint, but a few patients have very low scores, with some being below zero. This means it is difficult to transpose HAQ scores directly into EuroQol scores.

Successful treatment increases EuroQol scores, although the changes can be relatively small as the scale is very compressed. Changes of 0.1–0.2 are clinically relevant. The impact of biologics on EuroQol scores is shown in an observational study from Sweden, which indicates that there are greater changes with the first TNF inhibitor compared to second and third inhibitors.[25]

Integrated outcomes

Ideally outcomes should be captured using a single score or profile. This would have the benefits of simplicity and speed and would also allow comparisons to be made across units and countries. However, simple assessments may be inadequate and superficial and there is a complex balance between straightforward, easy approaches and oversimplifying complex problems.

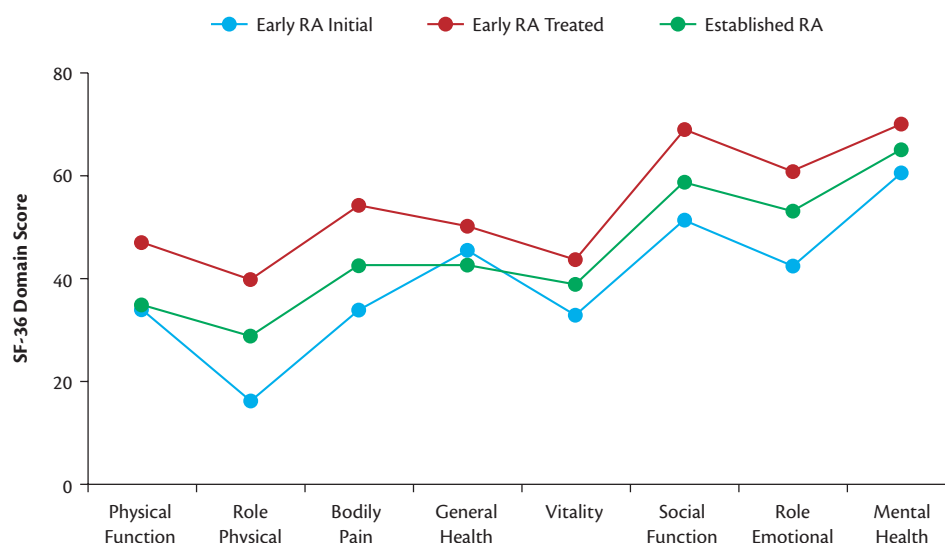
One new measure, which may achieve wide use, is the Rheumatoid Arthritis Impact of Disease (RAID) score, which is a patient-derived composite measure of the impact of rheumatoid arthritis. RAID uses a simple questionnaire which has individual numeric rating scales that record seven key outcomes—pain, functional capacity,


Fig. 29.3 Mean SF-36 domain scores in early rheumatoid arthritis (RA)—initial and treated—and established treated RA (after Lempp et al. 2011).[22]

fatigue, physical well-being, emotional well-being, sleep, and coping. Values in each domain are weighted by patients' assessments of their relative importance. They are then combined in a single score. Its proponents believe it will give clear and reliable data on overall outcomes.[26] However, it is premature to draw firm conclusions about its likely value.[27]

Outcomes in connective tissue diseases—inflammatory myositis as another model

Just as rheumatoid arthritis can act as a model for outcomes in arthritis, inflammatory myositis—polymyositis and dermatomyositis—can provide a comparable guide to outcomes in connective tissue diseases.[28] The myositis outcome matrix can also be divided into five domains, which are shown in Table 29.3. Key outcomes include clinical features like muscle weakness, overall activity from measures like the myositis disease activity assessment tool,[29] and biochemical measures like creatine phosphokinase levels. Damage can be assessed by muscle biopsies or end-organ failure assessed by the myositis damage index.[30] Quality of life can be assessed by specific measures like the myositis functional index,[31] generic assessments of quality of life like the SF-36, the overall result—remission—and end results like death.

The general approach to assessing outcomes is similar in myositis and rheumatoid arthritis, though the specific clinical measures used varies considerably. There are also differences in responses to treatment and in the frequency of different types of outcome. Other connective tissue disease, such as systemic lupus erythematosus, involve comparable outcome assessments.[32]

Conclusions

Measuring disease outcomes is an essential for good medical care, which can only improve when clinicians know the results of their treatments and involves patients' views.[33] Rheumatologists need to appreciate who they are seeing as patients and what happens as a consequence of their treatments. These sentiments are widely held but rarely followed. However, change seems inevitable with the widespread use of electronic records and the linking of records within and between institutions.

It is tempting to use outcome assessments to compare individual clinicians or units. However, this approach may be inappropriate and misleading. The diversity of patients and resources means heterogeneity is inevitable between and even within units. Rather than comparing absolute outcomes, we should focus on changes in outcomes. Despite the heterogeneity between units, clinicians should all be showing improved outcomes over time. The real cause of concern is not variations in absolute outcomes but differences in the direction of change. Poor performance is not having bad outcomes so much as having worsening outcomes over time.

Design of clinical trials in rheumatology

Vibeke Strand, Jeremy Sokolove, and Alvina D. Chu

Introduction

Randomized controlled trials (RCTs) in the rheumatic diseases have undergone a rapid evolution since 1998, driven by approval of 11 new disease-modifying anti-rheumatic drugs (DMARDs) for treatment of rheumatoid arthritis (RA), 9 of which are biologic agents. In addition to many detailed reviews on clinical trials in rheumatic diseases,[1–6] guidelines for development of new agents for treatment of RA, osteoarthritis (OA), and systemic lupus erythematosus (SLE) have been issued by the United States Food and Drug Administration (FDA)[7] and the European Medicines Agency (EMA)[8] as well as by the International Conference on Harmonisation (ICH) for use by worldwide regulatory agencies.[9] This chapter is intended to provide a basic overview of clinical trial design and terminology while also providing some important lessons specific to clinical development in individual rheumatic diseases.

Phases in development of new therapeutic agents

Phase 1

Phase 1 trials are intended to demonstrate the initial safety and pharmacokinetics (PK) and/or pharmacodynamics (PD) of a new agent in humans, based on extensive preclinical data in animal models of disease, toxicology, absorption, distribution, metabolism, and excretion (ADME) studies and pharmacokinetics data in mice, rats, and primates as well as dogs, rabbits, and pigs.[10] 'First in human' studies are first single ascending dose (SAD) followed by multiple ascending dose (MAD) escalation studies to confirm successful delivery of the product and initial PK/PD data. They may be performed in healthy volunteers or in subjects with the disease in question—especially if the agent is immunologically active, as are most biologic agents. Ideally the goal of phase 1 is to determine the maximum tolerated dose (MTD) as well as the minimally effective dose, and characterize pharmacokinetics: half-life ($t_{1/2}$), maximal and minimal achieved concentration (C_{max}, C_{min}), and average concentration over time known as area under the curve (AUC). Sometimes a smaller phase 1A study is performed to assess safety with a longer phase 1B study performed subsequently for additional PK/PD and dose-finding data. As these may differ between healthy volunteers and subjects with disease, due to differing immunologic processes in play, typically only healthy volunteers are utilized in phase 1A trials. However, if phase 1A or 1B studies are performed in subjects with disease then they may provide preliminary signs of efficacy, especially if a specific biomarker or early marker of 'response' can be measured.

Phase 2

Phase 2 studies are designed to provide additional PK/PD data and to establish proof of concept, e.g. that an agent has activity in the disease in question. Proof-of-concept trials in RA generally require at least 12 weeks' treatment duration to prove benefit for a sufficient duration of time that longer-term trials as well as 'rescue' with the experimental agent are warranted. It must be emphasized that careful and thorough conduct of phase 2 trials will result in a more efficient phase 3 programme and significantly increase the probability of success. By the conclusion of phase 2 studies, the pharmacokinetics of the agent should be well characterized, including MTD and minimal effective dose, and one or at most two doses and/or dosing regimens should have been selected for study in phase 3 trials. Additionally, clinical data generated in phase 2 should allow sample size calculations for phase 3 trials by estimating the effect size of the experimental agent. This is especially important given the size and cost of phase 3 trials designed to support regulatory approval of a new therapy.

Phase 3

Phase 3 RCTs are designed to support approval of a new therapy, and must be studied in an adequate number of subjects with the disease in question to support its safety, and in replicate (but not identical) trials to confirm its efficacy. Though regulatory agencies require two studies to confirm statistical superiority, it is risky to conduct an identical study twice as it is highly unlikely one will obtain the same results, especially in heterogeneous rheumatic diseases. This is well illustrated by the phase 3 RCTs comparing leflunomide and MTX, equivalent DMARDs where in one trial (US301) leflunomide was statistically superior and in the other, (MN302) MTX was superior.[11,12] Ideally the same question, efficacy in a certain disease indication, can be confirmed with two complementary but not identical patient populations, such as DMARD-failure

and DMARD-naive subjects, or by comparing induction with maintenance therapy.

Issues common to randomized controlled trials

Treatment allocation and rescue

Allocation refers to assignment of subjects to specific treatment groups. To enrol any subject into a well-controlled trial there must exist equipoise, or genuine uncertainty on the part of the investigator (or evaluator) of the benefit of an intervention. If proof-of-concept studies have already indicated a positive effect for a promising therapy then equipoise may be maintained if there is an imbalance in randomization, such as a 2:1 assignment of subjects to active vs control therapy. This can result in loss of power and offers the opportunity for more adverse events to accrue in active than in control therapy. Another strategy is adaptive randomization in which the next randomization depends on previous responses. This works best with proof-of-concept studies utilizing biomarkers and/or early markers of response, typically in phase 2. Adaptive studies are not generally accepted for phase 3 RCTs.

'Treatment rescue' is another means to maintain equipoise whereby subjects are offered rescue with active therapy after documented non-response after 3–6 months of enrolment. If there exists a positive proof-of-concept study, then subjects may be rescued with the new therapy in an open-label continuation protocol designed to accrue safety data over longer-term exposure. Otherwise, subjects may be considered 'treatment failures' and exit the protocol for active therapy, having met a predefined protocol endpoint for statistical analysis. Alternatively, they may continue protocol participation but be considered 'non-responders', provided they have not experienced an adverse event that would require treatment withdrawal.

Blinding and bias

Blinding is a critical, if imperfect, tool to prevent bias in RCTs. The ability to balance randomization such that significant covariates do not interfere with trial results is critical. In most cases 'perfect' balance is impossible and thus most trials are subjected to analyses of covariance (ANCOVA).

There are well-known confounding characteristics to be considered when studying biologic agents in RCTs. Parenteral administration may result in first dose reactions (injection site or infusion reactions) and or rapid onset of effect leading to unblinding. Expectation bias on the part of subjects and physicians may result in higher placebo responses.[13] Concomitant effects of background therapy, immunogenicity, and use of 'industrial strength' rather than pharmacological or physiological doses may confound results.[10] For this reason regulatory agencies frequently require different treating and evaluating physicians.

Statistical analyses

Size/power

Statistical significance is *always* predefined, referred to as the alpha (α) level and often set by convention to be p <0.05, thus representing a less than 5% risk that the difference observed is due to chance (or the alternative, more than 95% confidence that the observed effect is real.) The power of a study refers to the ability of trial results

to reject a false null hypothesis, thus identifying a true treatment effect. Mathematically, power can be represented by the expression 1-β, where β is the risk of a false-negative decision (type 2 error). Thus, the lower the risk of a type 2 error, the greater the power. Calculating power is not difficult, but rather, factors entering into the assumptions of a power calculation require extensive understanding of estimated effect sizes as well as standard deviations of the observations. Typically these are generated from earlier phase 2 studies which also demonstrate the variability of responses around both active and control treatments. Phase 3 trials must account for heterogeneity among subjects enrolled and disease characteristics at baseline, geographical and site variability, and other potential influential factors such as presence or absence of biomarkers. Thus, all phase 3 analyses make use of a 'model' which takes into account those covariates that are statistically significant when assessed by univariate analyses.

Analysis populations

No trial is likely to have all enrolled subjects complete the trial. Thus, investigators must plan in advance for dropouts, and typically increase sample sizes to accommodate expected dropout rates. The 'intention to treat' (ITT) population refers to all subjects who were randomized, and in the case of biologic agents, received at least one dose of study drug. The 'per protocol' (PP) population includes only those subjects without major protocol violations and may be used as supportive analyses in phase 2 trials and as the primary analysis population in an active controlled trial that does not include a placebo group. The 'safety' population includes all patients randomized, whether or not they receive treatment. Although some therapies may have a delayed onset of benefit, it is expected that use of adequate sample sizes will allow sufficient randomization that there will be equal numbers of early dropouts in both active and control arms.

Missing data

'Last observation carried forward' (LOCF) has been the typical means for accounting for missing data whereby the last value available for a subject is brought forward for endpoint analyses. Although a well-accepted statistical analysis, it imputes the 'best value' for a subject who may be a responder but is forced to discontinue early due to an intolerable adverse event. This analysis can be used to assess responses over time (e.g. American College of Rheumatology (ACR) responses over time) but will falsely elevate responses if an agent displays early efficacy yet ultimately has a poor safety or tolerability profile. A more conservative statistical approach to account for dropouts is use of the non-responder imputation (NRI), where 'all cause' dropouts, due either to lack of efficacy, adverse events, or other reasons are considered non-responders, regardless of their response status at time of dropout. These subjects remain in the denominator as the ITT population, but only those who complete the trial are eligible for consideration as responders. Another more conservative approach, popular for use in analgesic trials, is 'baseline carried forward' (BOCF), where changes from baseline in early dropouts are set to zero. In a sense this is a measure of 'effectiveness' in that a therapy that cannot be tolerated over 3–6 months would not be considered effective in the relief of chronic pain.

Another option is use of regression models to impute missing data such as radiographic results at 12 months in subjects who discontinue treatment or are rescued at 6 months (or earlier). To test the validity of such modelling sensitivity analyses are performed,

substituting the worst data in the control population (placebo) for missing data in the active arm until statistical significance is lost, and vice versa.[14]

Interim analyses

Although not generally performed in phase 3 RCTs, other phases of clinical development may employ interim analyses, prespecified for safety or to ascertain the need to adjust sample sizes. A major risk of an interim analysis is that it will alter the conduct of the study or even unblind the results. In very large RCTs, an interim analysis based on an early marker of response may allow ascertainment of potential success with little loss of p value, but in general they put the final statistical analyses at risk. A preferred method is to utilize data safety monitoring boards (DSMBs) who review trial data on an ongoing basis for safety and efficacy and advise the sponsor to discontinue a treatment group without revealing specific results.

Non-inferiority vs superiority analyses

Classic regulatory trials are designed to demonstrate superiority of an experimental therapy over the control, be it placebo+failed background therapy or placebo+standard of care. Active controlled RCTs which lack a control arm are often performed post approval, as phase 3B or 4 studies; these include 'treat to target' and other trials designed to reflect clinical practice. As drug development is generally an iterative process, most regulatory trials are designed to demonstrate superiority to a control therapy, with or without 'non-inferiority' to an active comparator. If non-inferiority is satisfied, then an agent may be tested for superiority. Two major caveats apply: (1) that demonstration of true 'superiority' requires replicate results in separate RCTs, and (2) results in RCTs in RA and other rheumatic diseases differ across protocol populations, reflecting the heterogeneity of disease characteristics and demographics at baseline such that responses by accepted outcome criteria vary widely even with the same active, and approved, product. Thus, it is risky to conduct an active controlled trial for regulatory purposes without a control group to prove that the active comparator is, in fact, efficacious. And to demonstrate superiority frequently would require enrolment of an impractically large number of subjects. Thus, many trials are now designed to show non-inferiority or equivalence to an existing therapy.

Choice of outcome measures

A primary endpoint must be prespecified, with iterative analyses of secondary, 'supportive' outcome measures. Phase 2 RCTs are designed for data mining and even 'post hoc' or subgroup analyses may be employed to better define responsive populations and/or derive evidence-based responder analyses. However, in phase 3 studies, secondary analyses must be strictly prespecified, including the order in which they are analysed until such time as statistical significance is lost. If the outcomes are independent of each other, such that they do not closely correlate and are separated in time, then the order of their analyses may be prespecified without statistical corrections for multiple comparisons—the 'Hochberg principle'.[15,16] As examples, the US301 RCT comparing leflunomide vs methotrexate vs placebo utilized three co-primary endpoints: the first two at 6 and 12 months for improvement in signs and symptoms of RA and inhibition of radiographic progression, and maintenance of physical function and health-related quality of life (HRQoL) at 24 months.[11] Similarly, the first phase 3 trial

of a biologic agent, infliximab, in ATTRACT (Anti-TNF Trial in Rheumatoid Arthritis with Concomitant Therapy), had a primary endpoint at 30 weeks for signs and symptoms,[17] radiography at 52 weeks,[18] and physical function and HRQoL at 104 weeks.[19]

Types of analyses

Unlike cardiovascular or cancer studies which utilize dichotomous outcomes such as mortality, rheumatic studies have required development of reliable composite indexes to define responses to therapy. Responder analyses are now standard in rheumatology, in part due to the efforts of the international consensus effort, Outcome Measures in Rheumatology (OMERACT) in collaboration with ACR and European Leagues Against Rheumatism (EULAR). Figure 30.1 demonstrates a model of the core (required), secondary (nice but not necessary), and ancillary (research agenda) outcome measures recommended for use in several rheumatic disease trials. In general, responder indices decrease sample sizes by including parameters which do not directly correlate with each other. An example is the ACR 20/50/70 response criteria for RA, which includes tender and swollen joint counts, physician and patient global assessments of disease activity, patient-reported pain, and a measure of physical function, generally the Health Assessment Questionnaire, as well as an acute-phase reactant, either C-reactive protein (CRP) or erythrocyte sedimentation rate (ESR). Improvement of 20% or more in five of seven criteria, including joint count, is required for responses. Of the seven criteria, only tender and swollen joint counts are moderately correlated with a coefficient of approximately 0.4—thereby indicating the breadth of improvement necessary across multiple independent measures to achieve a response. Validated responder indices across a wide variety of rheumatic diseases are presented in Table 30.1. All were proposed based on evidence-based data mining and have been prospectively validated in RCTs.

External validity of randomized controlled trials

External validity reflects the ability of the results of a RCT to be extrapolated to the real-world patient population. It is well recognized that subjects enrolled in RCTs tend to be healthier with fewer comorbidities than 'wild type' populations, because exclusion criteria rule out patients with significant concomitant diseases that could affect both safety and efficacy, and inclusion criteria requiring active disease exclude many patients 'typically' seen in practice. Several series have demonstrated that most patients followed in practice and enrolled in RA registries would not be eligible for RCTs.[20,21]

The ICH Guidelines (ICH E9, Section 2.2.1) clearly acknowledge that no individual RCT can be expected to be representative of future users. This is due to the possible influences of geographical location and variability in medical practice. Especially for rheumatic diseases with their heterogeneity and extended natural history, disease duration and timing of the trial with respect to the course of disease progression pose challenges when extrapolating results from trials to individual subjects, well illustrated by results of therapies in subjects with early vs longstanding RA.

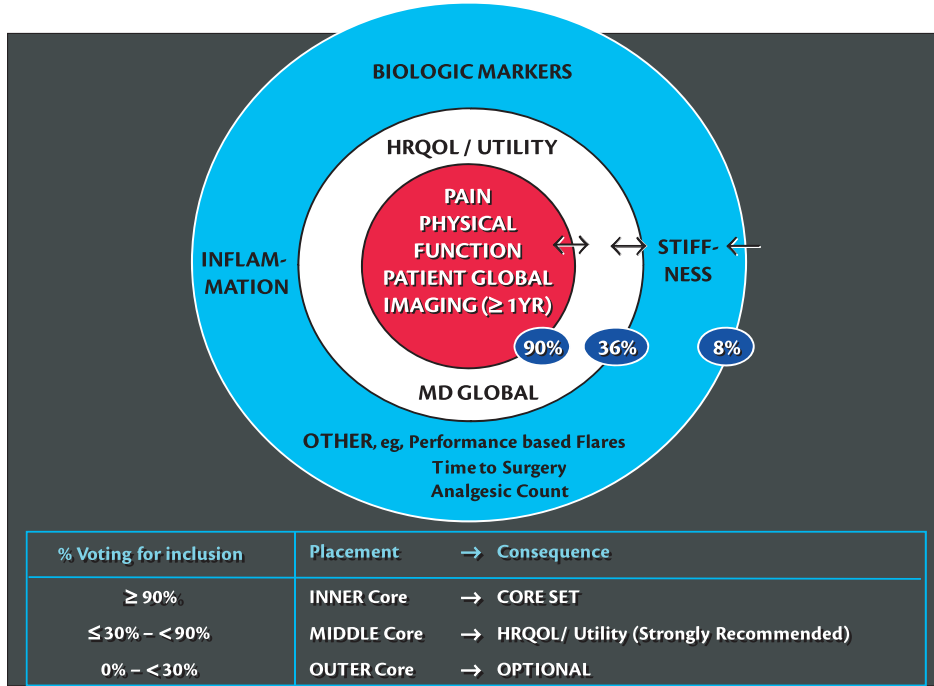
Increasingly trials must be multinational and multicultural to enrol adequate numbers of subjects to demonstrate a treatment response—this is certainly true in RA and SLE, and raises concerns about variability in clinical practice, definitions of 'treatment


Fig. 30.1 Domains recommended by OMERACT for inclusion in RCTs in osteoarthritis: inner core: required; intermediate ring: nice but not necessary; outer ring: research agenda.

Table 30.1 Rheumatic diseases and outcome measures

	Rheumatoid arthritis	Osteoarthritis	Systemic lupus erythematosus	Psoriatic arthritis	Ankylosing spondylitis	Gout
Clinical development activity	10 new therapies approved since 1998	No disease-modifying drugs approved; only symptomatic relief	1 new therapy approved in 2011	4 new therapies approved since 2002	4 new therapies approved since 2003	2 new therapies approved since 2009
Patient populations tested	◆ DMARD-naive ◆ Failed DMARD ◆ Biologic-naive RA ◆ Failed biologic	◆ Knee OA ◆ Hip OA ◆ Hand OA	◆ Active SLE receiving SOC therapy ◆ Active lupus nephritis ◆ Induction vs maintenance	◆ DMARD-naive ◆ Biologic naive ◆ Failed TNFi	◆ DMARD-naive ◆ Failed TNFi	◆ Chronic gout ◆ Acute gout
Common outcome measurements	◆ Composite responder indices: ACR, DAS/EULAR responses ◆ Radiography ◆ Physical Fxn/HRQoL	◆ Composite responder index: OMERACT-OARSI ◆ WOMAC ◆ Structure modification (radiography, MRI)	◆ Composite responder indices: SRI, BICLA ◆ Changes in corticosteroid doses ◆ Time to flare and incidence of flares	◆ Composite responder indices: ACR, PsARC ◆ GRAPPA scoring system in progress	◆ Composite responder indices: ASDAS, ASAS	◆ Serum uric acid level ◆ Acute flares ◆ Tophus burden
Patient-reported outcome measurements	◆ Pt global VAS ◆ pain VAS ◆ HAQ ◆ SF-36 ◆ FACIT fatigue ◆ WPS-RA ◆ WIS	◆ Pt global VAS ◆ WOMAC ◆ SF-36	◆ Pt global VAS ◆ SF-36 ◆ FACIT fatigue	◆ Pt global VAS ◆ pain VAS ◆ HAQ ◆ SF-36	◆ Pt global VAS ◆ BASDAI ◆ BASFI	◆ Pt global VAS ◆ pain VAS ◆ HAQ ◆ SF-36

failure', and generalizability to populations with less disease activity and/or more comorbid conditions.

Beyond statistics, what is clinically meaningful?

Regardless of statistical significance, patients and their physicians want to interpret results of RCTs in the context of the individual subject. These are defined improvements (and/or deteriorations) in patient-reported outcomes (PRO) perceptible to patients, as well as degrees of change and/or attainment of a state that feels acceptable: a patient-acceptable state (PASS).[22] The minimum clinically important difference (MCID) reflects that amount of improvement that is detectable to patients, and the number of subjects who report improvements meeting or exceeding MCID in a given PRO or multiple PROs can be considered 'responders' and used to derive a 'number needed to treat' (NNT) to gain the defined benefit. Similarly, larger improvements, or 'really important differences' (RID) or attainment of defined levels of PASS offer higher goals for treatment. Finally with the use of generic measures such as the Health Assessment Questionnaire (HAQ) or the Medical Outcomes Survey Short Form 36 (SF-36), patient-reported data may be compared to normative values to better understand the impact of disease on physical function and/or HRQoL, offering goals for attainment when evaluating treatment associated improvements.

'Number needed to harm' (NNH), or the number of subjects potentially at risk for a bad outcome, can similarly be calculated based on the incidence of serious adverse events (SAEs) of interest, reflecting the effects of the experimental treatment and/or the underlying disease. Although they are estimates only, NNT vs NNH comparisons are increasingly utilized to understand better the potential benefits of a new therapy.

Disease-specific trial design

Rheumatoid arthritis

The development of the ACR response criteria[23,24] and EULAR 'good and moderate' responses[24] has contributed to the introduction of 10 new DMARDs since 1998; significant progress from the two 6-month studies in 126 subjects which supported the approval of methotrexate in 1986.[25,26] Trials in RA are now expected to be at least 3–6 months in duration for improvement in signs and symptoms, with radiographic progression assessed at 6 and 12 months. Seminal RCTs in RA tested primary endpoints at no earlier than 1 year.[11] The time required for assessment of the primary endpoint of signs and symptoms has been shortened over the years to 3 months, based on concerns over duration of placebo exposure and with the precedent of 10 approved products in RA since 1998.

Background therapy

The clear benefit of early DMARD therapy in RA has made use of pure placebo difficult for ethical reasons. With current evidence for rapid progression of irreversible damage as manifest by worsening in HAQ scores and progression in structural damage even over 3–6 months of placebo treatment,[27,28] the standard has become to perform step-up trials in which patients are randomized to experimental therapy or placebo added to failed background DMARD therapy. This poses challenges: (1) variability in responses due to background therapy in both placebo and active treatment arms, and (2) inability to assess directly the effect of the new therapy as monotherapy, thus essentially 'wedding' a new molecule to its background therapy.[28,29] Active controlled trials are another alternative, the challenge being documented variability in responses of the active comparators. For example,

ACR20 response rates in methotrexate control arms have ranged from 46% to 72% with nearly as wide variability among trials of biologic monotherapy. Thus, the requirement for an abbreviated placebo arm as was utilized in the relatively recent AMBITION trial[30] investigating the efficacy of tocilizumab compared with methotrexate. This assured that both active monotherapies were efficacious.

Additionally, step-up designs have led to concerns that results may be confounded by the background therapy, even if patients were no longer responsive to it. It is clear that the duration of the failed therapy prior to study enrolment as well as how long it was administered at stable doses have influenced overall placebo response rates—not to mention issues regarding definitions of 'treatment failure'. Patients may still be accruing responses to methotrexate as a background therapy if they have not received at least 3 months' treatment at maximally tolerated doses. Further, background therapy, even if failed, may offer benefit when coadministered with a biologic agent, such as prolongation of half-life and decreased immunogenicity.[10] Because of these issues, it has been advocated that phase 3 include a three-arm RCT in DMARD-naive subjects comparing either monotherapy or DMARD vs experimental agent; vs combination of the two.

Treatment to target

Although RCTs remain the gold standard for evaluation of therapeutic efficacy, protocols designed for regulatory approval clearly do not mimic clinical practice. Lack of flexibility to adjust treatment over time limits extrapolation of the results to 'real-world' use. The advent of 'treatment to target' studies, although not designed for regulatory approval, provides an opportunity to study therapeutic regimens with predefined changes based on responses/nonresponses, including their effect on patient expectations[3] which might occur with any perceived change in therapy. These trials are particularly helpful in comparing recently approved therapies as well as understanding responses in more heterogeneous disease populations.

Other inflammatory arthritides

Specific challenges in RCT design have accompanied clinical development of therapeutics for psoriatic arthritis (PsA), ankylosing spondylitis (AS), and gout, different from those in RA. Although RA-specific outcome measures have been adapted and validated for use in PsA trials, they most accurately reflect changes in polyarticular disease.[31,32] The Disease Activity Index for Reactive Arthritis (DAREA) has been utilized in PsA studies, which combines patient pain and global assessments, joint counts, and CRP, but this index also emphasizes peripheral arthritis.[33,34] Because PsA includes skin disease and spondyloarthropathy as well as enthesitis and dactylitis, a PsA-specific disease severity and responder index is being developed by the Group for Research and Assessment of Psoriasis and Psoriatic Arthritis (GRAPPA) to assess skin as well as different articular manifestations (Figure 30.2).[31]

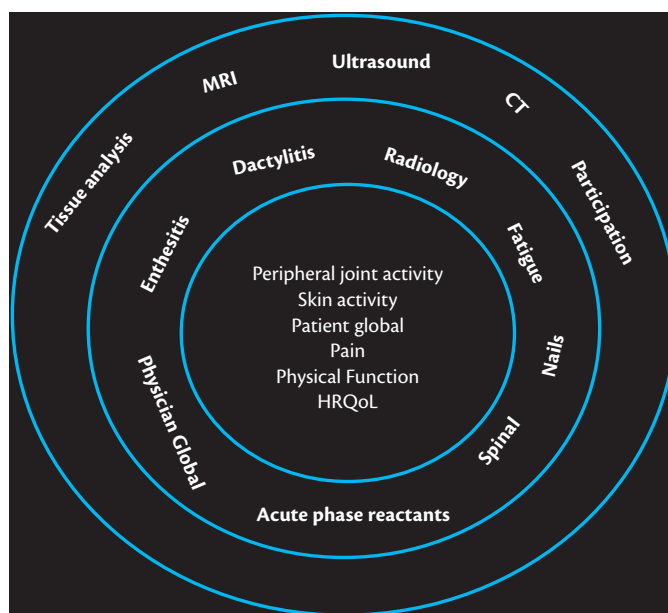
Studies in AS have utilized disease-specific outcome measurements, but have not been successful to date in demonstrating benefit on progression of structural damage. The Spondylitis Disease Activity Index (BASDAI) does not correlate with structural damage and may not accurately reflect the full spectrum of disease where both axial and peripheral joints are involved.[31] The Assessment of SpondyloArthritis international Society (ASAS)


Fig. 30.2 Domains recommended by OMERACT for inclusion in RCTs in psoriatic arthritis: inner core: required; intermediate ring: nice but not necessary; outer ring: research agenda.

disease activity score (ASDAS), which incorporates components of pain, inflammation, peripheral signs, and PRO, has been recently validated, and discriminates between high and low disease activity states.[35]

In gout, different challenges are posed by trials in acute vs chronic gout.[36] Two recent product approvals, febuxostat and pegloticase, have facilitated trial designs in chronic gout. The lowering of serum urate levels to less than 6.0 mg/dL has been accepted as a pharmacodynamic measure of efficacy in chronic gout, as well as objective measures for assessing tophus size and PRO of pain, physical function, and HRQoL.[36,37] Efforts continue to define flare and accurately measure its duration in acute gout (Figure 30.3).

Osteoarthritis

To date no agent has been shown to have disease-modifying effects on structural progression of OA. Many have been demonstrated to offer symptomatic relief including non-steroidal anti-inflammatory drugs (NSAIDs), cyclooxygenase-2 selective agents (COX-2s), intra-articular hyaluronic acid (IA-HA) injections and opioids. FDA[7] and European Medicines Agency (EMA)[8] guidelines for evaluation of new therapeutic agents for symptomatic relief of OA recommend measures of patient pain and function and for structural modification measurement of joint space width (JSW) by radiography and/or MRI, currently the best-accepted methodology.

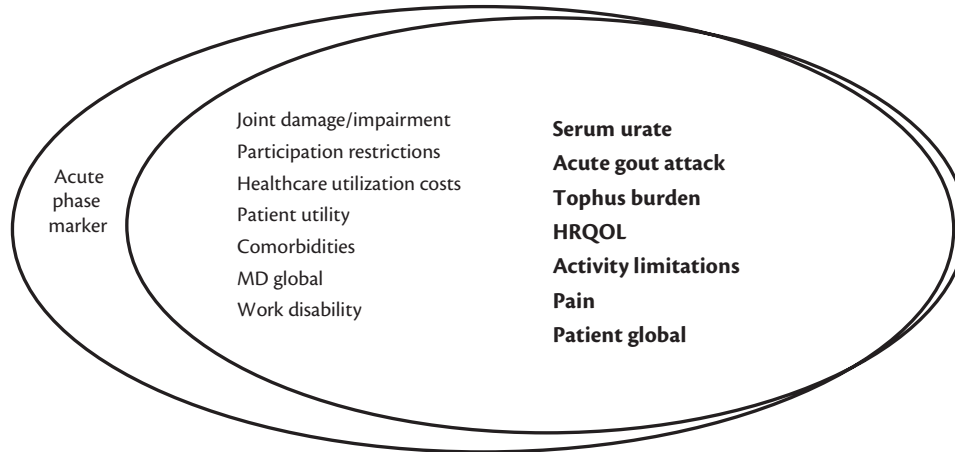
Major challenges for development of disease-modifying OA drugs (DMOADs) include the need for improved measures of structural damage (beyond use of radiography) as well as improved understanding of the appropriate population and/or disease stage for intervention. OA is a final common pathway following many predisposing factors and thus therapeutics may have limited, if any, efficacy in those with pre-existing joint damage, biomechanical predisposition, and/or obesity.[38]


Fig. 30.3 Domains for inclusion in RCTs in acute and chronic gout: those in bold type are required; within the inner ring nice but not necessary; acute-phase marker part of the research agenda.

Measures of pain and function

Historically, the most widely used metric for outcome in OA trails has been the Western Ontario and McMaster University OA Index (WOMAC), consisting of three subscales: pain (5 questions), physical function (17 questions), and stiffness (2 questions).[39] Extensive evaluation of the WOMAC pain subscale compared to the McGill Pain Questionnaire and a single 10 cm visual analogue (VAS) pain scale has been performed. Although all scales correlated well, the severity of anxiety, depression, and fatigue correlated with McGill and not the WOMAC pain score. Similarly, total osteophyte score by joint radiography correlated well with WOMAC but not McGill pain score,[40] further indicating that responses in evaluation of treatment of OA should include physical function as well as pain. More recently the OMERACT/Osteoarthritis Research Society International (OARSI) responder definition has been validated and adopted. This index defines responders by improvements from baseline in WOMAC pain or physical function subscores by 50% or more with absolute changes 20 mm or more (termed 'strict responders'), or 20% or more with absolute changes of at least 10 mm in two of three measures: pain, physical function, and/or patient global assessment of disease,[41] again demonstrating the value of a composite metric in identifying response.

Measures of structure modification

To be defined as a DMOAD, an agent must be demonstrated to retard, arrest, or reverse the degenerative processes seen in OA. Although conventional radiography cannot directly visualize articular cartilage, the use of JSW on plane radiographs has been validated to follow progression of OA. However, measuring JSW by radiography in RCTs is limited by variability in (1) technique including positioning of the joint, (2) location of disease and rate of progression among individuals, and (3) duration of time over which loss of cartilage can occur.[4] Recent trials have attempted to use MRI to directly delineate structure and preservation of cartilage volume. Whole-organ scoring systems to provide semiquantitative assessments of structural damage over time (WORMS),[42] and to assess changes in signal intensity considered to represent degrees of inflammation or joint synovitis, will hopefully improve sensitivity and specificity of JSW determinations.[43]

Other outcome measures in OA RCTs have ranged from direct arthroscopic visualization[44] to use of surrogate markers for cartilage turnover[45] to the more pragmatic, but highly variable, measurement of time to joint replacement,[46] which is influenced by multiple factors such as standard of practice, economics, and healthcare practices beyond the impact of OA itself.

Systemic lupus erythematosus

The variety of different RCT designs to date in SLE reflects the heterogeneity of disease manifestations and a relapsing/remitting disease course. FDA guidance documents for new products for treatment of SLE and SLE nephritis have provided recommendations for trial designs and outcome measures.[47,48] A regulatory precedent was set in 2011 when the first therapy after 40 years was approved for treatment of SLE in the United States and the European Union after completion of two pivotal RCTs (BLISS-76 and BLISS-52) of belimumab, a monoclonal antibody against B-cell activating factor (BLyS/BAFF).[49,50] As the regulatory history of approved products in SLE has been brief, trial design will likely evolve as lessons are learned with successive RCTs.

Study duration

The recommended period of time to conduct an RCT in SLE is at least 1 year to evaluate the following endpoints: reduction in disease activity, complete clinical response or remission, reduction in flare or increase in time to flare, and maintenance of response.[47] A trial should be of sufficient length to measure durability of response as well as safety. Nonetheless 'induction' regimens or treatment of acute flares may be evaluated at earlier time points, such as 6 months, provided there is evidence of 'maintenance' of effect over 12–24 months.

Superiority over standard-of-care therapy

As in RA, most trials in SLE have been parallel, randomized, controlled superiority RCTs. These are typically add-on trials in which either the experimental agent or placebo are added to standard-of-care (SOC) therapy, as denial of active therapy could potentially lead to irreversible harm. In comparison to failed background therapy in RA, SOC has been active, e.g. the 'best that we can do', including antimalarials, immunosuppressive agents, and corticosteroids. The phase 3 belimumab trials (BLISS-76 and BLISS-52) demonstrated superiority of belimumab+SOC compared with SOC alone.[49,50] The practice of adding experimental

therapies to SOC has underscored the importance of controlling changes in concomitant background therapy in SLE RCTs. In the phase 3 RCTs, adjustments to doses of background immunosuppressive agents were allowed through week 16, and corticosteroids through week 24, with no increases between weeks 44 and 52.[49,50] These restrictions in background therapy were designed to decrease variability in responses as the primary endpoint approached, when achievement of corticosteroid doses of 7.5 mg or less per day was a goal for treatment. In contrast, in the phase 2b study of abatacept, a CTLA-4-immunoglobulin fusion protein, and the phase 2/3 trial of rituximab, an anti-CD20 monoclonal antibody, high doses of prednisone were required at initial and retreatment time points with prolonged tapering regimens over 6–9 months.[51,52] Together these may have confounded the ability to distinguish treatment responses from SOC.

In SLE nephritis trials, the experimental agents have been compared to a single SOC medication for superiority. The Aspreva Lupus Management Study (ALMS) included a 6 month induction phase followed by a 36 month maintenance phase. While the primary endpoint was not achieved in the induction phase,[53] superiority of mycophenolate mofetil (MMF) over azathioprine was demonstrated in the maintenance phase by prolongation of time to treatment failure and fewer treatment failures.[54]

In contrast to the ALMS study, the phase 3 trial of rituximab in patients with active SLE nephritis examined the addition of rituximab vs placebo to background with MMF and corticosteroids.[55] The primary endpoint at week 52 was not achieved; again, high doses of corticosteroids may have confounded treatment differences. Similarly, a phase 2/3 study of abatacept in patients with SLE nephritis showed no significant improvement in renal outcomes when abatacept was added to background therapy of MMF and high-dose corticosteroids compared with background therapy alone.[56]

Predefinition of 'treatment failure'

The definition of 'treatment failure' in a protocol allows patients to exit the trial to receive necessary therapy, having met a statistical endpoint for analysis in the RCT. This is important whether 'treatment failure' is the primary efficacy variable, such as in the ALMS study,[54] or as a component of a responder index, and allows equipoise to be maintained, thereby permitting close adherence to protocol mandated restrictions regarding changes in background therapy, yet enabling flexibility for appropriate treatment of a disease manifestation.

Patient population

Selection of the patient population to include in the RCT has been important to recent success of trials in SLE. Identification of biomarkers associated with the mechanism of action of an experimental therapy may help to enrich for a responsive population. Post-hoc analyses of the phase 2 belimumab RCT revealed that 71.5% of patients were seropositive by anti-nuclear (ANA) and/or anti-double-stranded DNA (dsDNA) antibody, associated with higher BLyS/BAFF levels, disease activity, renal involvement, and hypocomplementaemia.[57,58]

Outcome measures used in systemic lupus erythematosus trials

A variety of outcome measures have been used to assess disease activity, damage, HRQoL, and adverse events in SLE, as recommended by OMERACT.[6,59]

Of six existing disease activity indices (DAIs) in SLE, the two most commonly used are the Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) and its modifications: SELENA-SLEDAI and SLEDAI-2K; and the British Isles Lupus Assessment Group (BILAG). SLEDAI DAIs are based on presence or absence of specific clinical features and laboratory results, and yield a global score that reflects the extent of disease involvement.[60] The BILAG scores disease activity by organ systems according to need for therapy; e.g., 'A' reflects severe disease, requiring increases in prednisone and/or addition of immunosuppressive agents, 'B' active disease, requiring low-dose prednisone and/or symptomatic treatment with NSAIDs and/or antimalarials.[61] An A or 2Bs are indicative of severe flares, C reflects mild disease, D reflects previous but no current organ system involvement, and E an organ system never involved. It is the only DAI that captures improving, unchanged, or worsening features of disease activity.[6]

No disease-specific HRQoL measures have been validated for use in multinational SLE RCTs; the generic Medical Outcomes Survey Short Form 36 (SF-36) is validated and has been most commonly used.[59] SF-36 includes 'physical' domains: physical functioning, role physical, bodily pain, and general health perceptions; and 'mental' domains: vitality (which includes fatigue, energy, and pep), social functioning, role emotional, and mental health impact.[6] Domain scores generally better reflect the impact of SLE and its treatment than exclusively using the physical and mental component summary (PCS and MCS) scores, and can be compared with population norms.[62] Two measures of fatigue, Krupp Fatigue Severity Scale and Functional Assessment of Chronic Illness Therapy (FACIT) Fatigue scale, have been utilized in RCTs, although the vitality domain of SF-36 may be more sensitive to treatment effects.[6] Finally the transition question of SF-36: 'Compared to one year ago, how are you today?' can offer valuable information as to whether patients consider themselves 'somewhat better' or 'much better' following treatment.[63]

Recently, composite responder indices have been developed that are evidence based, derived from data-mining phase 2 trials. The SLE Responder Index (SRI) is a composite index used as the primary outcome in the phase 3 BLISS trials.[49,50,57] An SRI response was defined as a reduction of 4 points or more in SELENA-SLEDAI score, no new BILAG A or 2B domain scores, and no deterioration from baseline in physician's global assessment (MDGA) by 0.3 or more on a 3.0 point scale, provided a patient is not a 'treatment failure,' defined by increased or new use of prohibited medications or early withdrawal from the study. A BILAG-based composite index (BICLA) is the primary endpoint variable for the ongoing phase 3 trials with epratuzumab, an anti-CD22 monoclonal antibody.[64,65] Components include reduction of all baseline As to B/C/D and Bs to C/D in all organ systems, no worsening in other organ systems, and no deterioration in SLEDAI or MDGA. An enhanced BILAG responder index is defined as resolution of all As and Bs to C/D in all organ systems.[64]

Other multisystem rheumatic diseases

Many of the challenges faced in trial design in SLE are also present in heterogeneous multisystem diseases such as systemic sclerosis and vasculitis. A recent approval for rituximab for treatment of ANCA-associated vasculitis offers encouragement,[66,67] while RCTs in systemic sclerosis remain limited by variability in natural history of skin, lung, and other internal organ disease, thus limiting reliability of standardized outcome measures.[68]

Conclusion

Considerable progress has been made in trial design over the last 10–15 years in rheumatology, largely facilitated by the development of composite responder indices—important when evaluating treatment effects in multisystem, heterogeneous diseases. Based on the work accomplished so far, it is fair to expect that trial design will continue to evolve as promising therapies are introduced to the clinic.

CHAPTER 31

Health economics

Sonja Merkesdal and Wilfried Mau

Cost of illness in rheumatic diseases

Low back pain, osteoarthritis, and inflammatory diseases account for substantial proportions of the overall costs of musculoskeletal diseases, and have been scientifically recognized as important targets for cost-of-illness analyses.[1,2]

Cost-of-illness studies are used to describe the health-economic impact of a disease due to costs incurred by (1) direct healthcare-related resource consumption, (2) non-medical disease-related resource consumption, and (3) productivity losses. Depending on the perspective chosen, patients' out-of-pocket expenses or intangible costs (e.g. quality of life) may also be incorporated. This costing data is useful for a comparison of disease entities (see Table 31.1 for the diagnoses included) but also enables us to learn more about the cost-structure of a disease and to generate input data for health-economic models.

Low back pain

The costs of low back pain have been addressed by some European studies in the last decade showing annual estimates of €211 (Sweden),[3] €260 (United Kingdom),[4] and €1322 (Germany)[5] per person. The huge impact of this condition on healthcare costs results from its high prevalence (15–30%).[6–8]

A more recent cost evaluation has been carried out as an economic piggy-back study accompanying a randomized controlled guideline implementation study in primary care (Germany).[9] Acute low back pain incurred mean overall costs of €1002 and chronic low back pain as much as €1790 during a 6 month study period. These costs are clearly higher than in other studies and might partly be explained by different study settings but also by an increasing use of imaging and surgical procedures.

All costing studies identified productivity costs as the main cost contributor, representing more than 50% of overall costs. Direct costs are mainly driven by in-patient treatment (acute or rehabilitation facilities) and therapeutic procedures.[9] The identification of subgroups with increased costs should be an important focus of further health-economic evaluations, in order to assign resources to tailored cost-limiting procedures in these patients.

Osteoarthritis

There is some evidence on disease-related costs in osteoarthritis, although the types are mostly not differentiated and the term 'general osteoarthritis' is used. Estimates of direct costs (adjusted to 2005 US dollars) range from $345 in France, $1272 in Italy, and $2878 in Canada, to $4792 in the United States; productivity losses range from $864 in Hong Kong, $1210 in the United States, and $1683 in Italy to more than $9000 in Canada.[10] This review demonstrates that there are major differences in cost assessment in the cited studies. The most important source of these observed variations seems to be the choice of cost components included in the cost-of-illness studies, but the nature of the underlying database and specific features of the respective healthcare systems also contribute. There is still a lack of standardized cost-of-illness data that will have to be addressed in future economic studies of osteoarthritis.

Rheumatoid arthritis

Of the inflammatory rheumatic diseases, rheumatoid arthritis (RA) has attracted most attention from the health-economic viewpoint. Many studies have addressed cost assessment in RA and a recent review summarizes the results of all evaluations presenting original costing data.[11] Mean costs of 26 studies were calculated by converting to 2006 euros. Overall average direct cost estimates amount to €4170 per year. Depending on the methodology use, productivity costs ranged from €1441 (friction cost method; see 'Methodological aspects of cost-of-illness evaluation' for details of methods) to €8452 (human capital approach). Mean patient- and family-related costs account for €2284, underlining the importance of costs from the patient's perspective. Medication and hospitalization costs are the most important contributors to direct costs, amounting to €1567 and €1243, respectively.

Although these results provide a sound basis for cost estimation in RA, it has to be kept in mind that costing structures might change over time. Since the introduction of biologicals in the treatment of RA the medication costs have risen markedly, whereas hospitalization and productivity costs appear to have decreased.[12] The economic impact of these changes has to be explored in detail in order to capture the potential economic benefits of expensive treatments from the societal perspective.

Ankylosing spondylitis

Ankylosing spondylitis (AS) has a high prevalence of about 0.5%,[13,14] creating substantial societal costs caused by productivity losses from patients at a relatively young age. The review by Franke et al.[11] also addressed the literature relating to cost-of-illness evaluation

Table 31.1 Average cost estimates or cost estimate ranges derived from the literature converted to 2011€ for back pain, osteoarthritis, rheumatoid arthritis, ankylosing spondylitis, psoriasis arthritis, and systemic lupus erythematosus

Indication	Direct annual costs	Indirect annual costs	Ratio (direct:indirect costs)
Back pain	249–3831[3–9]		n.a.
Osteoarthritis	417–10, 890[10]	1047–10,890[10]	1:1–1:2.5
Rheumatoid arthritis	4900[11]	1693 (FC)[11] 9931 (HC)[11]	1:0.3–1:2
Ankylosing spondylitis	234 + 1297 (OOPE) = 1531[11]	2668 (FC)[11] 7377 (HC)[11]	1:1.7–1:4.8
Psoriasis arthritis	1858–4150[15]	2873–3174 (HC)[15]	1:0.7–1:1.7
Systemic lupus erythematosus	3302–6404[19] 11 762–12 738[19a]	966–3781 (FC)[19] 3702–12919 (HC)[19]	1:0.3–1:1.2

FC, friction cost approach; HC, human capital approach; n.a., not applicable; OOPE, out-of-pocket-expenses.

[a] Three studies with longer disease duration (<10 years).

of AS. Their estimation of average costs is based on seven studies providing original costing data. The direct annual costs are lower than in RA, amounting to €1992 per patient, and patient and family costs account for €1104 per patient. When it comes to productivity losses, however, it becomes obvious that they are comparably high, ranging from €2271 (friction cost method) to €6278 (human capital approach). Productivity costs are shown to be even more important in AS (mean proportion of overall costs 66%) than in RA (57%). Outstanding cost components of direct costing are medication (€628), hospitalization costs (€592), and non-physician service utilization (€428, mainly physiotherapy). Future economic research should also focus on the assessment of long-term productivity costs in AS using incidence-based cost-of-illness studies, since the lifetime costs might even be higher than in RA because of the younger age at onset.

Psoriatic arthritis

Some cost-of-illness studies for psoriatic arthritis (PsA) have been conducted in Hong Kong, Hungary, Italy, and Germany.[15] These studies show similar costs to those reported for AS. In the Hong Kong cost-of-illness study,[15] direct costs were estimated to be $4141 (in 2006 US dollars) for all patients, and a separate description of peripheral and axial disease showed costs for patients with axial manifestation to be substantially higher (peripheral $3530, axial $6711). The main contributors of direct costing were physician visits, in-patient treatment, and patient costs (out-of-pocket expenses). Indirect costs were also remarkable: $3127 for all patients and $2604 and $5199 for patients with peripheral or axial disease, respectively. A Hungarian study[16] reported figures of €1681 for direct costs and €2600 for indirect costs. This sample included no patients on biological therapy, possibly explaining the lower direct costs, but described high costs of non-medical services. An Italian cohort of patients failing usual care[17] incurred direct costs of €943 in 6 months. Higher costs were reported in a study of German data for 2002[18]: €3156 direct and €2414 indirect costs (friction cost method). This substantial economic burden of PsA is mainly related to pain and physical function;[15] further studies will have to address the impact of cost-saving measures.

Systemic lupus erythematosus

The evidence regarding systemic lupus erythematosus (SLE) is not so wide-ranging: a recent summary of cost-of-illness studies identifies 11 evaluations reporting on original data.[19] Direct cost estimates range from $3735 to $7244 (in 2008 US dollars) and three studies identify even much higher costs ($13 305–14 410). The reason might be the older age and longer disease durations of these cohorts. As with to the other inflammatory diseases, in-patient costs and medication costs are the outstanding contributors to overall costs. However, in SLE subsets with longstanding disease, the costs for diagnostic procedures become similarly important.

Most of the studies did not report on patient costs or non-medical costs. Indirect costs exceed direct costs in almost all studies, but the range of estimates is wide because of the use of different assessment methods ($1093–4277 for the friction cost method and $4188–14 614 for the human capital approach).

In contrast to other inflammatory diseases where costing is mainly associated with physical functioning, in SLE costs are, to a substantial extent, independently associated with the occurrence of disease flares. This makes the development of novel expensive biological therapies for the prevention of flares a challenging health-economic target. In order to identify patient subsets who bear most of the costs, it would be important to learn more about lifetime costing data while the disease progresses.

Methodological aspects of cost-of-illness evaluation

Summarizing disease-related cost components for a specific disease entity is often used to point out its health-economic relevance, and the cost estimates are subsequently compared between diseases that are competing for resources to be allocated. While doing this, we have to keep some methodological confounders in mind. The choice of cost components to be included is very important for the completeness of cost description and the perspective of the cost study carried out. Standardization of this procedure has been achieved for RA,[20] for example, by developing and structuring a matrix of

cost domains. Based on this subset of defined cost components, all domains that are relevant from a certain perspective are chosen for cost-of-illness assessment. To avoid double counting, it is crucial to consider the perspective of the evaluation. For example, from the patient's perspective, indirect costs are represented by lost wages; productivity losses at work must not be counted in addition, since this would be double counting of the same costing aspect.

Another methodological issue is the aggregation level of cost assessment. The level of detail that can be achieved and the accuracy of the information are dependent on the data source. In addition to insurance data, questionnaires may be employed for the additional assessment of domains such as non-medical costs, or patient and family costs. The breakdown of medical costs may also include detailed information on therapeutic and diagnostic procedures, but the accuracy with which patients can report these facts is limited. In RA it has been shown that the major domains such as physician visits, hospitalization, medication, non-physician service utilization, and therapeutic and diagnostic procedures can be reported accurately by the patient[21] when highly aggregated items are used.

The strong influence of methodological approaches on the costing results can be seen in the evaluation of productivity costs.[22] In early cost-of-illness studies the *human capital approach* was generally used to describe the value of lost productivity. In this approach all times of lost or impaired productivity at work (short and long term) are summarized and subsequently evaluated using the average gross hourly income of an employed worker. This approach was subsequently altered because it is now recognized that there is underemployment in most economic systems and the lost productivity of an impaired worker will be replaced after a period defined, for example, by the mean duration of job vacancies. This is the *friction cost method*. The difference between these approaches is striking,[18,22] and the results cannot directly be compared between studies. The valuation of lost productivity is subject to similar limitations. The recommended method of valuation is to use the average income, but alternatively the individual income of the patient can be employed. Because there is a tendency for patients with lower income to have more productivity losses and vice versa, valuation with individual incomes leads to substantially lower costs than valuation with average incomes.

These examples of methodological variations illustrate the general need to develop standardized assessment methods for cost-of-illness evaluations. In RA all of these standardization issues have been addressed by recommendations and guidelines[23,24] and the evidence regarding cost of illness is quite broad and consistent.

Cost-effectiveness of biologicals in rheumatic diseases

The assessment of cost-effectiveness in cost-effectiveness analysis (CEA) or cost-utility analysis (CUA) yields some kind of relation between economic input (costs) and clinical output—e.g. response in in terms of American College of Rheumatology outcome measures ('ACR response') or quality of life (QoL) improvement. In CUA this relationship is generally transformed to the monetary outcome (e.g. in euros) per quality-adjusted life-year (QALY). A QALY represents 1 year at perfect health. Results showing costs lower than €50 000/QALY are usually found to be cost-effective in the countries of the euro zone. According to the United Kingdom National Institute for Health and Clinical Excellence (NICE) the threshold is

about £20, 000–30,000/QALY. Results about 50% above this frontier are often called 'conditionally cost-effective' in the current literature. The QALY construct is used to create comparability between the respective main clinical outcomes in different diseases (e.g. ACR response and reduction of blood pressure in mmHg). Since the assessment of QALYs often requires mathematical transformation and mapping processes, the validity of this construct is still under discussion. More recent CEAs have also employed stricter outcomes such as clinical remission. The obvious advantage of these clear-cut outcomes is that they are far more meaningful to a rheumatologist.

For rheumatic disease, a special health-economic focus has been placed on biological therapies, which are all characterized by high treatment costs and comparably high effectiveness compared to traditional therapeutic options. There is already a comprehensive body of evidence with contradictory results, especially for RA.

Rheumatoid arthritis

The first health technology assessment (HTA) performed for TNF-inhibiting drugs in RA rendered discouraging results.[25] In the following years it became obvious that it is crucial to differentiate subsets of RA patients according to disease duration and prior treatment, leading to more favourable results in a subsequent HTA.[26]

For modelling purposes the term 'early RA' is used for patients with a disease duration of less than 2 years and either no prior treatment with disease-modifying anti-rheumatic drugs (DMARDs) or monotherapy with methotrexate or sulfasalazine. The results of CEAs in this field[26–28] show concordantly that TNF inhibitors are cost-effective if used according to guidelines[29] after two consecutive unsuccessful DMARD therapies. When TNF inhibitors were employed as initial therapy results were less favourable and were judged as conditionally cost-effective with incremental cost-effectiveness ratios (ICERs) ranging from €50 000 to €75 000/QALY. Cost-effective results were also reported by Davies et al.[28] comparing a defined DMARD sequence with adalimumab and methotrexate combination therapy followed by the same DMARD sequence in early RA (see also Table 31.2, showing a summary of cost-effectiveness results).

All RA patients with disease durations of more than 2 years are classified as having advanced disease in the cost-effectiveness models. In TNF-inhibitor-naive patients with advanced RA treated according to current guidelines, two CEAs[26,30] report on cost-effective results for the use of etanercept and adalimumab in combination with methotrexate (ICER <€50 000/QALY). In both of these studies, infliximab proved not to be cost-effective (ICER >€50 000/QALY).

Regarding RA patients with advanced disease who have discontinued one TNF-inhibiting therapy due to either lack of efficacy or side effects, the most prominent health-economic issue is whether another TNF inhibitor should be employed, or an alternative biological treatment such as rituximab or abatacept. There are three CEAs investigating this issue,[31–33] regarding rituximab in comparison to a change of TNF inhibitor. These studies agree that rituximab is more cost-effective used in TNF-inhibitor-refractory patients (ICER <€15 000/QALY). In a recent HTA[34] for the use of biologics in patients with TNF failure these results are emphasized and cost-effective ICERs for all biological options (infliximab, etanercept, adalimumab, abatacept, and

Table 31.2 Evidence for the cost-effectiveness of biological treatment in patients with rheumatoid arthritis, ankylosing spondylitis, psoriasis arthritis, and systemic lupus erythematosus, derived from the current literature

Indication	Evidence for cost-effectiveness of biological compounds
Rheumatoid arthritis Disease duration <2 yrs	As initial therapy: ◆ ETN and ADA conditionally cost-effective (ICERs €50 000–70 000/QALY) vs MTX[26,27] ◆ ADA cost-effective[28] compared to a prior DMARD sequence After 2 DMARDs (according to recommendations): ◆ IFX, ETN, and ADA cost-effective vs DMARDs[26]
Rheumatoid arthritis Disease duration >2 yrs	After 2 DMARDs (according to recommendations): ◆ ETN and ADA (+MTX) cost-effective versus MTX[26,30] ◆ IFX (+MTX) versus MTX not cost-effective[26] ◆ TNF inhibitors cost-effective based on registry data vs DMARDs[35] After failure of a standard DMARD sequence: ◆ ETN, IFX, and ADA cost-effective versus DMARDs[26] After failure of a prior TNF inhibitor: ◆ change from TNF inhibitor (IFX, ETN, ADA) to ABA, and RTX cost-effective compared to another TNF inhibitor[34] ◆ RTX dominates TNF inhibitors (more effective and less costly)[34] ◆ RTX economically more favourable than ABA[34]
Ankylosing spondylitis	In active NSAID-refractory disease: ◆ ETN and ADA cost-effective vs NSAIDs[41–44]
Psoriatic arthritis	In moderate to severe active disease: ◆ ETN cost-effective vs DMARDs[46–49] ◆ ADA, IFX, GOL cost-effective vs DMARDs[48,49]
Systemic lupus erythematosus	◆ No evidence on cost-effectiveness ◆ Preliminary report on belimumab shows conditionally cost-effective ICERs well above €50 000/QALY[50]

ABA, abatacept; ADA, adalimumab; DMARD, disease-modifying anti-rheumatic drug; ETN, etanercept; GOL, golimumab; IFX, infliximab; NSAID, non-steroidal anti-inflammatory drug; RTX, rituximab.

rituximab) are reported. However, rituximab and abatacept have better cost-effectiveness than TNF inhibitors and the comparison of rituximab and abatacept reveals even more favourable results for rituximab.

The employment of biological therapies in RA patients with advanced disease who have been treated with all conventional DMARD options available is defined as a last resort. Chen et al.[26] have compared the cost-effectiveness of the TNF inhibitors infliximab, adalimumab, and etanercept given as a final option in patients with advanced RA. For this indication, all TNF inhibitors investigated appear to be cost-effective with ICERs of about €38 000/QALY for infliximab, €30 000/QALY for adalimumab, and €24 000€/QALY for etanercept. Other biological therapies have not been economically assessed in this patient subset.

In summary, the use of TNF inhibitors in biologic-naive patients seems to be cost-effective in most subsets with the exception of early RA when TNF inhibitors are employed as initial therapy. However, these models should be re-run with observational data and a longer time horizon in order to capture the real-life effectiveness. A model using registry data has further underlined the cost-effective use of the TNF inhibitors as a class compared to DMARDs according to the current recommendations in RA.[35] Regarding TNF-inhibitor-resistant RA, the summarized evidence shows that a change of TNF inhibitor as well as the use of another biological

(rituximab, abatacept) is cost-effective. The most favourable results in this group are found for rituximab.

Ankylosing spondylitis

Current cost-effectiveness data on the biological treatment of AS is restricted to the TNF inhibitors infliximab, etanercept, and adalimumab. There are five CEAs reporting on infliximab,[36–40] of which four report on cost-effective results in comparison to usual care in different settings (United Kingdom, Canada, Spain). All studies present data from the societal perspective, and two of them additionally adopt the insurance perspective, where cost-effective results were also found. The study by Boonen et al.[40] compares infliximab and etanercept and finds more favourable results for etanercept.

Two further CEAs investigate etanercept alone vs usual care. In a United Kingdom setting[41] etanercept was cost-effective from the insurance perspective, employing both a short- and a long-term horizon. A recent German CEA study[42] reproduced these results using the societal perspective, but from the insurance perspective the results were not cost-effective. This contradictory finding was explained by the different pricing of etanercept in the United Kingdom and Germany.

There is only one cost-effectiveness study for adalimumab.[43] This CEA is from the United Kingdom and compares adalimumab to usual care adopting the insurance perspective. Employed according

to current guidelines, adalimumab proves to be cost-effective in the short and long run. This data is partially contradicted by the NICE appraisal,[44] with CEAs for infliximab, etanercept, and adalimumab all showing ICERs well above £50 000/QALY. However, due to marked differences from the manufacturers' model a decision support unit revised this model and came to the conclusion that etanercept and adalimumab are cost-effective in active AS with ICERs of £20 000–30 000/QALY. Infliximab was considered not to be cost-effective as its ICER was clearly less favourable.

In summary, all economic models developed according to current recommendations report on cost-effective results of TNF inhibition in active AS refractory to non-steroidal anti-inflammatory drugs (NSAIDs) from the societal viewpoint. Adherence to ASAS guidelines (i.e. discontinuation of TNF inhibition in non-responders after 12 weeks) reduces the costs remarkably. Two comparative models propose that the cost-effectiveness of infliximab is potentially less favourable, but this finding has to be interpreted cautiously (e.g. different dosing regimens). In AS these results have to be seen within the context that TNF inhibitors are the only option available for patients refractory to usual care.

Psoriatic arthritis

In PsA three approved biologicals—infliximab, etanercept, and adalimumab—are used. A current CEA[45] incorporates all biological options into the model and reports that for PsA patients with mild to moderate skin disease etanercept is the most cost-effective option (ICER vs palliative care, £16 000/QALY). In comparison to etanercept, infliximab proved not to be cost-effective (ICER £54 000/QALY). Adalimumab is also found not to be cost-effective in this model compared to etanercept. The superior ICER of etanercept compared to infliximab was supported by a UK-based analysis,[46] whereas Cummins et al. show comparable and cost-effective results for all TNF inhibitors with the most favourable ICER for infliximab.[47] A current CEA on golimumab[48] also reports cost-effective results. The updated HTA[49] and the current CEAs by Cummins et al. support the evidence that all biologicals are cost-effective in patients with moderate to severe psoriasis.

Systemic lupus erythematosus

The only targeted biological therapy option for SLE, belimumab, has recently been approved. Up to now there is no evidence on cost-effectiveness in the published literature. Some preliminary information is given on the NHS HTA programme website,[50] developing a base case scenario with costs of £64 410/QALY. No information on cost-effectiveness is available for other biologicals that are investigated in SLE or that are used off-label in patient subgroups, such as rituximab, infliximab, or tocilizumab.

Limitations of cost-effectiveness studies

Regarding the summary of evidence on cost-effectiveness of biologicals for different diseases, some common limitations have to be pointed out. The comparability of CEAs is generally limited, for several reasons. An outstanding issue is the 'QALY problem'—every CEA uses its own more-or-less complex construct to transform (for instance) ACR responses or BASDAI improvements into QALYs. Even the same outcome parameter might be mapped onto the QALY scale by different approaches. Furthermore, there are also relevant variations in the assessment of disease-related costs (see

'Methodological aspects of cost-of-illness evaluation') and in many CEAs the cost components included and the valuation methods employed are not broken down. Especially in chronic inflammatory disorders, the disease progression rate under treatment is important and in many CEAs it represents a sensitive parameter that can influence results considerably. The certainty of these estimates can be improved by long-term results provided by registries and observational studies. This is true also for other sensitive variables such as the continuation rates of biologicals. Still, the health-economic evidence already collected helps to inform health-political decision-making by showing how the high costs of medication might be partially offset. Most of the CEAs demonstrate that biologicals can be employed in different indications in a cost-effective way.

CHAPTER 32

Comorbidities of rheumatic disease

Tuulikki Sokka, Kari Puolakka, and Carl Turesson

Introduction

In this chapter, we discuss the impact of comorbidities in rheumatic diseases. We address the challenge that common comorbidities bring to daily rheumatology care. We also discuss practical strategies against comorbidities, to improve patients' outcomes. We use rheumatoid arthritis (RA) as an example of a prototype of inflammatory rheumatic diseases.

Comorbidities—impact in patient care

All other diseases that coexist with a disease of interest are called comorbidities.[1,2] Comorbidities in inflammatory rheumatic diseases may be associated with persistent inflammatory activity or disease-related organ damage, or may be related to medications. Lifestyle choices such as smoking or physical inactivity contribute to comorbidity. Patients with rheumatic diseases meet health professionals regularly and are more often tested for osteoporosis or cholesterol levels than individuals without rheumatic disease, which may contribute to a higher prevalence of some comorbidities in patients with rheumatic diseases. Comorbidities can also be unrelated to rheumatic diseases or their treatments.

Comorbidity indices such as the Charlson Comorbidity Index[3] or the Index of Coexistent Diseases[4] estimate the frequency and severity of comorbidities and are used in clinical studies. Higher scores for these and other comorbidity indices predict morbidity, mortality, costs, and hospitalization in rheumatic diseases. In clinical care, comorbidities are reviewed and recorded by a health professional by indicating whether a medical condition exists or not. In surveys, patients select from a list comorbidities that apply and a plain number of comorbidities is calculated without an indication of severity.

The impact of comorbidities in rheumatic diseases is multidimensional. Some comorbidities, such as cardiovascular disease, lymphoma, renal and pulmonary diseases, and infections are associated with premature mortality. As inflammation is the common pathophysiology in rheumatic diseases and in many comorbidities, suppression of inflammatory activity is essential. This emphasizes timely and active treatment of every patient with early RA to bring the disease to sustained remission in order to diminish the risk of these comorbidities. Furthermore, careful monitoring of patients at high risk of comorbidities, in particular those with severe, treatment-refractory disease, is necessary. This may require close collaboration between rheumatologists and other specialists. Education of the medical community on these issues is of major importance.

In addition to the risk that is caused by inflammation, patients with rheumatic diseases are at least as likely as the general population to have traditional cardiovascular risk factors such as hypertension, diabetes, and hyperlipidaemia. Furthermore, patients with RA are more likely to smoke and be physically inactive than the general population. Therefore, traditional risk factors for cardiovascular disease need to be reviewed and addressed on a regular basis, and interventions against adverse lifestyle factors and other important predictors should be initiated when indicated.

Depression and fibromyalgia are comorbidities that increase the risk of work disability, which is the most costly consequence of RA. A review of patients' psychological well-being should be routine practice at rheumatology visits. A multidisciplinary team including nurses, physiotherapists, social workers, and psychologists facilitates the management of patients with these comorbidities. It is particularly important to differentiate such problems from complications driven directly by inflammation, as the management is completely different.

Osteoporosis is a prevalent comorbidity in rheumatic diseases. Patients need to be screened and treated for osteoporosis. Patients at high risk, in particular those who are treated with long-term corticosteroid treatment, should preferably be started on preventive treatment before osteoporosis develops.

Some comorbidities are drug-related, e.g. gastrointestinal ulcers with perforation or bleeding, and in the past these were often seen in patients who made heavy use of non-steroidal anti-inflammatory drugs (NSAIDs). Serious infections and pulmonary diseases are rare but potentially life-threatening side effects of current antirheumatic medications. However, it is worth to remember that 'side effects' of untreated or poorly treated RA overall are worse than the side effects of current antirheumatic drugs.[5] It is also important to communicate this to patients.

Rheumatoid arthritis and comorbidities—burden in daily life

Active and severe RA causes a burden in daily life, which is heavier in older than in younger people. In general, women experience a heavier burden from RA than men do.[6] On the other hand, patients who reach early clinical remission may live a normal life, including fully preserved work capacity.[7]

As with the effects of RA itself, the burden from comorbidities may vary. Asymptomatic conditions that are kept under control with simple medications, such as hypertension or thyroid disease, may not cause any significant burden. However, in general, individuals with several comorbidities have higher scores for functional disability, pain, and global health assessment compared to those who have fewer or no comorbidities (Figure 32.1).[8]

Mortality as a consequence of comorbidities

According to an old saying, 'the way to live a long life is to acquire rheumatism'.[9] There was a period when RA was regarded in the majority of patients as a disease with a good prognosis. The traditional teaching was that RA could be controlled in most patients with aspirin and later alternative NSAIDs. However, data from RA cohorts and epidemiological studies revealed that patients with RA on average died many years earlier than the general population. The traditional view reflected the previous lack of systematic follow-up data and the lack of available potent interventions. Over time, the interest in long-term outcomes, including mortality, as well as preventive measures, has increased considerably.

Cardiovascular disease is the most common acute cause of death in patients with RA, similarly to the general population.[10] (Table 32.1). In a review of 50 reports of patients with RA in the United States and western European countries in 1953–2008, cardiovascular disease was the acute attributed cause of death in 40.5% of patients. It appears that infection and renal, respiratory, and gastrointestinal diseases are over-represented as an immediate cause of death in patients with RA.

It may be tempting to try to classify causes of death in patients with RA as 'related to RA' or 'not related to RA'. However, this classification may be artificial as inflammation appears to be part of the underlying pathophysiology for many comorbidities such as infectious, pulmonary, renal, and cardiovascular diseases. When an individual with RA (or any inflammatory rheumatic disease) dies of any cause 5–15 years earlier than expected according to that person's age and sex, the death appears in some way to be related to the inflammatory disease.

The most significant predictors of premature mortality in patients with RA are older age, male sex, comorbidities, patient's and physician's global estimates, severe extra-articular manifestations, and poor functional status assessed by physical measures and patient questionnaires.

Poor physical function and low muscle strength are significant predictors of mortality in RA and other chronic diseases, in ageing individuals, and in the general population.[11] Poor physical function predicts earlier mortality in diseased and normal populations as well or better than most known biomedical predictors, such as laboratory tests. In the Quantitative Monitoring of Patients with RA (QUEST-RA) study, which reviews patients who receive usual care in several countries, only 13.8% of 5,235 patients in 21 countries reported physical exercise 3 times a week or more.[12] A majority of the patients were physically inactive: more than 80% of patients in seven countries, 60–80% in 12 countries, and 45% and 29% of patients in two other countries reported no regular weekly exercise. Physical function is a modifiable risk factor for mortality, regardless of underlying health condition. The importance of regular exercise should be communicated to all individuals with rheumatic diseases whether or not they have comorbidities, to promote general health and longevity.

Some therapies for RA, including gold salts,[13] methotrexate,[14,15] and tumour necrosis factor (TNF) inhibitors,[16] have been reported to be associated with reduced mortality rates in patients with RA. This is to be expected, as these therapies are associated with improved values for quantitative prognostic indicators of premature mortality. Mortality in RA that is attributable to therapies occurs in fewer than 2% of deaths, although therapies for RA can sometimes lead to fatal consequences. As with any potent, long-standing treatment, risks and benefits need to be balanced in treatment decisions for every individual patient.

Cardiovascular disease

During past decades, cardiovascular events have been found to occur approximately a decade earlier in RA than in the general population, suggesting that RA, similarly to diabetes mellitus, is an independent risk factor for premature ischemic heart disease. Non-traditional risk factors, in particular RA disease activity/severity measures, including inflammatory markers, disease activity scores, seropositivity, physical disability, destructive changes on joint radiographs, extra-articular manifestations, and corticosteroid use, have repeatedly shown significant associations with increased cardiovascular risk.[17,18] Taken together, this suggests that disease severity, in particular systemic inflammation, is a major predictor of cardiovascular comorbidity in patients with RA.

Scores that have been developed to estimate cardiovascular risk for the general population based on traditional cardiovascular risk factors alone are unlikely to accurately estimate cardiovascular risk in patients with active RA. In addition to targeting remission in RA, evaluation, care, and patient education concerning cardiovascular risk factors should be routine in every rheumatology
Fig. 32.1 Self-reported pain, global health assessment, and functional disability scores increase (deteriorate) with an increasing number of disease conditions.[8]

clinic. Current guidelines recommend that the method for calculating the risk score and/or the algorithm for intervening against traditional risk factors should be adapted in order to take into account the increased risk associated with severe RA itself.[19]

The risk of myocardial infarction is increased in patients who use NSAIDs and cyclooxygenase-2 inhibitors. On the other hand, treatment with methotrexate and other disease-modifying antirheumatic drugs (DMARDs) is associated with a lower risk for cardiovascular events in RA patients compared to patients who had never used DMARDs. In the QUEST-RA study, longer use of biologic agents and DMARDs such as methotrexate, leflunomide, and sulfasalazine was associated with a decreased risk of cardiovascular disease (Table 32.2).[20]

Many patients with RA are informed and worried about an increased risk of cardiovascular comorbidity. It is worth noting that studies that indicate an increased risk were conducted before the era of active treatment strategies for RA. Although a majority of RA patients worldwide still suffer from active disease,[21] remission is a realistic goal in the management of RA and can be achieved in the majority of patients with early and active treatment. In the NEO-RACo trial, more than 80% of all patients with early active RA were in DAS28 remission at 2 years—a comparator arm involved a triple therapy (methotrexate, sulfasalazine, hydroxychloroquine) plus prednisolone and the active arm was intensified with half-a-year initial infliximab therapy.[22] A Dutch pilot study (intensified COBRA) involved a triple therapy plus high-dose prednisolone. Infliximab was started in 6 of 21 patients who did not reach a treatment target.[23] At 40 weeks, 90% of the patients were in DAS28 remission. In a recent cross-sectional analysis, up to 40–50% of patients in clinics with active treatment strategies were in remission.[24,25]

Improved outcomes have been documented for many severe outcomes in RA, as will be discussed later. It can be anticipated that

cardiovascular comorbidity will become less prominent over the years, with active treatment strategies for RA and routine evaluation and care of traditional cardiovascular risk factors. Signals indicating such a development are already present, as discussed later.

Pulmonary disease

Pulmonary disease has recently attracted a lot of attention in RA for several reasons. Pulmonary disease, especially pneumonia, has been a major cause of death in RA for decades (Table 32.1). Pulmonary fibrosis—rheumatoid lung disease, 'RA lung', or RA-associated interstitial lung disease (RA-ILD)—is still one the of the most feared manifestations of RA as its treatment options are limited and it is associated with high mortality.[26] Fear of RA-ILD is not diminished by the fact that idiopathic pulmonary fibrosis (without rheumatic disease) has even worse prognosis and the clinical effectiveness of newly available anti-fibrotic drugs remains questionable.

In the QUEST-RA study, 4.5% of 9448 patients with a clinical diagnosis of RA in 34 countries were reported to have pulmonary fibrosis. However, symptomatic RA-ILD appears to constitute only a fraction of truly existing lung disease in RA. The availability of techniques such as high -resolution CT (HRCT) has revealed that interstitial lung disease may be found in 20–40% of patients with RA and was found in 19% in consecutive patients with RA in the United Kingdom in the late 1990s.[27] A 13–15 year follow-up of the cohort indicated that extensive interstitial involvement in HRCT, which was seen in 3.3% (5 of 150) cases, was associated with a poor prognosis and was leading to respiratory failure and death in 4 of 5 cases. However, in those who had borderline or limited HRCT involvement, lung disease remained silent and possibly would have needed no more intervention than smoking cessation.[28] This

suggests that evaluation of the extent of lung involvement with HRCT is a useful prognostic tool.

Respiratory symptoms reflecting an idiosyncratic drug-induced pneumonitis are sometimes seen in patients who receive methotrexate or leflunomide. Treatment with TNF inhibitors may lead to worsening of pre-existing RA-ILD, although the magnitude of this risk and the risk/benefit ratio in patients with RA-ILD remains to be defined. Therefore, a common practice before initiating these medications is to take baseline chest radiographs in all patients and pulmonary function tests in patients who are at higher risk for lung disease, as well as to advise patients to quit smoking.

Cancer

An association between long-lasting RA and haematological malignancies was first documented in the 1970s.[29] Later, it was demonstrated that continuous inflammatory activity is strongly associated with the risk of lymphoma.[30] The incidence of lung cancer is increased in RA,[31] possibly related in part to smoking, while the incidence of colorectal cancer is lower than in the general population.[32] It is presently unclear whether there is an association between skin cancer and RA.

In clinical practice, many patients and healthcare providers are concerned about whether medications for RA increase the risk of cancer. Such a risk was not found in a recent review of methotrexate monotherapy for RA.[33] Concerning biologic agents, the current understanding, based on extensive observational studies, is that these drugs do not increase cancer risk.[34]

Infections

Active inflammation in RA increases the risk of infections, including bacterial, tubercular, fungal, opportunistic, and viral infections. High doses of oral corticosteroids contribute to the likelihood of infections, as documented in observational series.[35] Anti-TNF therapy increases the risk of the activation of latent tuberculosis.

In order to prevent infections, patient education should include general advice to be cautious about infections. In particular, patients must be reminded about oral hygiene and regular dental check-ups. Feet with deformities and fragile skin need special attention, including consultation with a podiatrist. Patients who are planned to start biologic agents should be screened for latent tuberculosis. Such patients, and other patients with a complicated disease course, should also be considered for vaccination against *Streptococcus pneumoniae* and influenza. Current guidelines recommend that patients are vaccinated during a stable phase of their disease.[36] General vaccination programmes should also be followed.

Infection is the acute cause of death with the highest relative excess mortality in RA patients compared to the general population (Table 32.1): 14.3% in patients with RA compared to 1.0% in the United States population in 1977 and 4.4% in 2005 (suggesting an older population and/or more accurate reporting in 2005). It is worth to note that the proportion of deaths attributed to infection has not changed substantially over the years, being much the same in recent years as in the era before treatment with methotrexate and biologic agents.[10] In population-based studies from Olmsted County, Minnesota, conducted before the era of biologics, the risk of serious infections was increased compared to the general population,[37] and measures of disease severity were major predictors of comorbidity from infections.[38]

Osteoporosis

Patients with RA are at increased risk of developing osteoporosis compared to the general population. The development of osteopenia is associated with the extent of erosive changes in joints. Rheumatoid inflammation appears to be involved in the pathophysiology of both

general and local bone loss in RA.[39] Treatment of corticosteroids is a well-known risk factor for osteoporosis; physical inactivity and smoking contribute to the risk.

Osteoporosis is a comorbid condition that can be prevented. Routine patient education includes advice concerning physical exercise to prevent osteoporosis; smokers are advised to quit smoking. Patients should be given advice concerning calcium and vitamin D supplementation according to national guidelines. Adults should get 500–1000 g calcium every day, from food or calcium supplements. In countries that have long periods without sunshine, all elderly women are advised to consume a minimum of 800 IU (20 µg) vitamin D every day. If this amount is not received from food, vitamin D supplementation is advised, with a maximum of 2000 IU (50 µg) a day.

Patients with RA should be monitored for bone mass by dual-energy X-ray absorptiometry (DXA). It is worth remembering that corticosteroid therapy also has direct deleterious impact on bone and increases fracture risk even at osteopenic DXA values. Therefore, such patients should be considered for preventive treatment with bisphosponates. Parathyroid hormone may be considered in patients with refractory osteoporosis, or those who do not tolerate bisphosphonates.

Outcomes of RA are improving—does this apply to comorbidities?

Concomitantly with an increasing use of early and active treatment strategies, overall clinical outcomes in patients with RA have improved compared to previous decades. Even before the era of biologic treatments, improvements were seen in patients' clinical status according to disease activity,[40,41] functional capacity,[41–43] radiographic scores,[41,44] and other clinical measures.[41] Furthermore, lower mortality rates were reported in patients who responded to gold,[13] methotrexate,[15,45] and biologic agents,[16] and lower work disability rates were seen in patients who responded to anti-rheumatic drugs.[7] More recently, studies from Western countries and Japan suggest that rates of total joint replacement and other RA-related surgeries have been stable or even decreased in patients with RA in the last decade.[46] In addition, the health status of the general population in Western countries is currently better than in previous decades in many respects.

The improving health of patients with RA and the general population suggests that the prevalence and impact of comorbidities in patients with RA should also improve (i.e. become more like that of the general population); patterns of causes of death should become more similar to the background population; and, finally, the lifespan of patients with RA should increase to the population level.

In 2007, a mailed survey was conducted to study self-reported lifestyle, health status, and morbidities in patients with RA and in the general population. All RA patients from a hospital district of 275 000 people were included in a rheumatology clinic RA database. For each RA patient, three age-, sex-, and habitat-matched control subjects were randomly sampled from the population register. An extended health assessment questionnaire was mailed to patients and control subjects. The response rate was 70%. Table 32.3 presents the self-reported prevalence of selected health conditions in 1635 patients with RA and 4264 control subjects (in both groups, mean age was 65 years and 73% were women),

Table 32.3 Percentage of individuals with a self-reported health condition

Cataracts	15	18	0.014

matched for sex, age, and location, in the Central Finland Health Care district in 2007.[47]

The prevalence estimates of cardiovascular diseases and traditional cardiovascular risk factors were similar between groups or more favourable in patients with RA. Lung diseases, fibromyalgia, osteoporosis, and cataracts were more frequent in RA patients, likely related to RA and/or its treatments. More frequent diagnostic tests in patients with RA may influence the detection and reported prevalence of osteoporosis and fibromyalgia. The prevalence of cancer, chronic back pain, and musculoskeletal trauma was higher in the background population. RA may lead to changes in lifestyle that reduce the risk of these comorbidities. The data on cardiovascular disease and its risk factors indicates favourable changes in this comorbidity compared to historical data. On the other hand, studies on self-reported prevalent diseases may not reflect the full burden of fatal comorbidities. In a study with long-term follow-up of patients with RA enrolled in 1978 and 1995, the incidence of fatal and non-fatal cardiovascular events remained increased compared to the general population in the year 1995, with similar risk ratios in both cohorts.[48] Further studies of this issue are necessary, and efforts to reduce the burden of comorbidities should remain a high priority for rheumatologists.

Reviewing and managing comorbidities: clinic infrastructure

Quantitative monitoring of RA as part of daily clinical practice may have improved since Dr Wright's observation in 1983 that

'clinicians may all too easily spend years writing "doing well" in the notes of a patient who has become progressively crippled before their eyes…'.[49] Standard quantitative monitoring with a treatment goal has been shown to be beneficial to patient outcomes in randomized clinical trials. Quantitative monitoring has also contributed to improved long-term outcomes for RA seen in clinical care.

The QUEST-RA programme was established in 2005[50] to promote quantitative assessment in rheumatology, and by end of 2011 it had expanded to 34 countries involving 9000 patients. In this programme, the patient completes an expanded health assessment questionnaire including questions about functional capacity, psychological well-being, symptoms, lifestyle, life environment, and work status. The rheumatologist completes a

structured clinical evaluation including a checklist of past and current comorbidities, extra-articular RA manifestations, and current clinical status.

The idea of a structured patient evaluation was developed further, and currently many clinics use software that collects real-time data from each patient, to assist clinical decision-making and improve the quality of clinical care. The patient self-report clinical status and its changes, history of RA and medications, comorbidities, and surgeries are readily available as a flowsheet (Table 32.4) or a graph (Figure 32.2). Time is saved for a focused discussion, as reviewing dozens of pages of patient's medical records or numerous screens of electronic medical records is not necessary. Easily available data enables better adherence to a 'treat to target' approach, which is a preventive strategy against many comorbidities in RA. A structured electronic evaluation saves time for review and advice concerning clinically important comorbidities such as risk factors for cardiovascular disease and osteoporosis.

CHAPTER 33

Social aspects (work)

Ross Wilkie

Introduction

Rheumatic conditions are the most frequently cited reason for absence from work.[1] In recent years, the impact of rheumatic diseases on work has demanded more attention from all stakeholders, including clinicians and policy-makers. Work participation is important to individuals with rheumatic conditions and society. Reduced work participation affects the quality of life of patients and their families, and has major financial consequences for the individual and society. The ability to manage rheumatic diseases in order to continue in paid work has always been important for clinicians. This chapter outlines key aspects supporting increased interest in improving work participation for those with rheumatic diseases. It then draws on the results of empirical studies to highlight potential targets and strategies to reduce work restriction.

Why are we increasingly interested in the impact of rheumatic conditions on work?

The following sections highlight three of the key reasons for the increased interest in the impact of rheumatic conditions on work.

Impact on the individual

There is now greater acknowledgement of the benefits of work participation for the individual. A number of reviews have highlighted the benefits of work participation and the importance of 'good work' to health and well-being.[1–3] Extensive background evidence suggests that work is generally good for physical health, mental health and well-being; it is beneficial to an individual's prosperity and is important to psychosocial needs in societies where employment is the norm. It is central to identity, social roles, and social status, and employment and social status are the main drivers of social gradients in physical and mental health and mortality.[2] In contrast, not being in employment is associated with significantly poorer overall self-rated health, more depressive symptoms, and a greater decline in health status (although these are also reasons for being out of work).[4] The general view of work being positive for individuals has encouraged clinicians and policy-makers to focus on improving work participation through preventing premature work cessation (i.e. prior to retirement age) and encouraging return to work. Improving or maintaining work participation is encouraged as a target for working age adults with rheumatic conditions.

Size of the burden

There is considerable evidence of the size of the adverse impact of rheumatic conditions on work. Impact can be described in terms of:

◆ *work disability:* ceasing to work before retirement age

◆ *absenteeism:* missing part or whole days from work (e.g. number of days/hours off work)

◆ *presenteeism:* an individual remains in work but with difficulty or reduced efficiency/productivity.

Absenteeism and presenteeism contribute to the indirect costs of rheumatic diseases, which are far higher than for other diseases but are not considered as much by policy-makers, who usually focus primarily on direct costs based on healthcare usage and long-term disability directly attributed to rheumatic conditions. Work productivity loss is estimated to be far greater due to presenteeism than absenteeism.[5] Estimates of presenteeism vary and are dependent on the measuring tool. A challenge is to measure productivity accurately to provide a clear and meaningful understanding of rheumatic diseases on productivity. The following sections are not exhaustive but provide an outline of the extent to which rheumatic conditions impact on work, taking rheumatoid arthritis (RA, the most common autoimmune disease), low back pain (the most common musculoskeletal condition affecting working age adults), and osteoarthritis (OA, the most common form of arthritis) as examples.

Rheumatoid arthritis

The impact of autoimmune disease on work for individuals is high. Taking RA (where 60–75% of people are of working age at diagnosis) to illustrate this, the annual prevalence of sick leave for those with RA who remain in work is 53–82%.[6] On average patients take 46 days off per year compared to a population average of 11 days.[6] Numbers of days of sick leave is strongly associated with work disability (i.e. ceasing to work prior to retirement age).[7] One in four people (23%) who are diagnosed with RA stop working in the 3 years following diagnosis.[8] This increases to one in three (35%) by 10 years and more than half (51%) of those with duration longer than 25 years will have stopped working before retirement age.

The annual incidence of work disability is 10%.[8] Once out of work, most people with RA never return to work, and RA is thus linked to unemployment and underemployment.[9] However, the prevalence of work disability is decreasing; previously, 50% of newly diagnosed RA cases had work disability within 10 years of diagnosis. This is indicative of improved treatment, changes in the nature of employment, and perhaps improved conditions in the workplace, which is also evidenced by an increasing rate of return to work.[8] The reduction in the proportion of those with RA taking sick leave may result in an increase in presenteeism, if individuals are more likely to remain in work but with limited capabilities. Currently, 34% of workers with RA report a decrease in productivity due to their condition, although comparable data is not available over the past decade to determine whether this is an increasing trend.[10]

Non-inflammatory conditions—low back pain

Although the impact on the individual is often much greater, the cumulative burden of non-inflammatory arthropathies and disorders such as back pain, OA, and limb pain as a whole results in a much greater economic and human cost to society than autoimmune disease. Low back pain illustrates this point. The prevalence of RA in the United Kingdom is 0.81%, but low back pain affects over one-third of adults at any one time, and each year approximately 3.5 million people in the United Kingdom develop back pain.[11] It is the most common reason for middle-aged people to visit primary care, with approximately 6–9% of adults consulting for this condition each year.[12] Although many back pain patients stop consulting their GP within 3 months, 60–80% of people still report pain or disability a year later, and up to 40% of those who have taken time off work will have future episodes of work absence.[13–14] In the United Kingdom, the annual cost of absenteeism due to low back pain is estimated at 1% of gross domestic product.[15] The impact of presenteeism due to low back pain may be 7.5 times this due to lost productivity.

Non-inflammatory conditions—osteoarthritis/joint pain

OA is associated with work limitation, sick leave, being out of work (unemployment), and early retirement.[16–18] On average those with OA take 9.6 days sick leave per year.[19] Although the effect on work for individuals tends to be smaller than that for RA,[20] the sheer number of people with OA means that it has a larger impact on work. Like low back pain, OA and its main symptom (joint pain) is common in adults aged 50 years and over (i.e. annual prevalence of knee pain is 46% in those over the age of 50).[21] The effect of OA is more on presenteeism than on absenteeism.[18] In those with knee pain, around one in five indicate problems at work.[22] Reduced productivity is 3–5 times more likely in those with OA than in those without.[16,23,24] Three-quarters of working adults with OA make some changes to their work situation to maintain their participation in work.[25]

Extensions to working life

Policies to extend working life have become a central response to the development of ageing populations. Delaying retirement is viewed as a means to mitigate the effects of worsening demographic ratios while increasing financial resources for later life. Such policies are important from a fiscal and social point of view. Many governments have raised pension ages along with a range of other measures such as anti-age discrimination legislation. It is in this context that our ability to maintain the capacity of individuals

with rheumatic conditions to remain in work, or return to work, is increasingly under the spotlight. More than three-quarters of the population do not have disability-free life expectancy as long as 68 years, much of which is attributable to rheumatic conditions.[3] As the prevalence of rheumatic conditions increases with age and as working lives extend, there will be many more employees with musculoskeletal problems in years to come; there will be more people in work coping with rheumatic conditions which compromise their work ability and productivity. The challenge is to keep individuals with rheumatic conditions in work, reduce the size of the impact of rheumatic conditions on work and contribute to the health and well-being of individuals.

Targets and strategies to improve work participation

New approaches impose the view that work loss does not need to be a consequence of a musculoskeletal disorder or disability.[1] It is clear that the impact of rheumatic diseases on an individual's ability to remain in work depends on complex interactions between biological, psychological, social and occupational factors. This underlines the importance of a biopsychosocial and interdisciplinary approach involving interaction between those with a musculoskeletal condition, employers, clinicians, and policy-makers.

Factors that reduce work participation

The starting point for managing rheumatic conditions and work is to gain an understanding of the predictors of work loss and the potential targets for interventions. There are numerous predictors (not all are listed here) which can be considered in the following categories.

Condition-specific factors

Notably, disease duration and symptom severity are linked to poor work participation. However, clinical factors add little to models of work disability.[26] This is because clinical factors tend to be associated with poor work outcomes through their impact on physical function.

Comorbidity

Comorbidity contributes to work problems in those with joint pain.[2] More notably, the co-occurrence of mental health problems with rheumatic conditions has a big impact. For example, many patients with musculoskeletal pain also suffer from depression,[27] which is a key factor for developing chronic disabling pain.[28] This combination is associated with increased absence from work,[29] and return to work is increased by interventions that reduce the severity of depression in those with chronic pain.[30]

Socio-economic and environmental factors

Low socio-economic status, in terms of low income and low education, is linked to working patterns through links with pain and health behaviour.[3] Low socio-economic status is also linked to more physical occupations and poorer working conditions which have an impact on rheumatic conditions and work participation. Living in areas of higher socio-economic deprivation and low work opportunities is linked to increased work disability.[23]

Psychological factors

In addition to mental health problems, psychological factors are a major obstacle to maintaining work participation and return to

work. Examples of key psychological factors that impact on work are catastrophizing, negative illness beliefs (false beliefs and pervasive thoughts about personal illness), low self-efficacy, and lack of self-esteem.[31]

Occupational and workplace factors

Physically and mentally demanding or high-paced jobs have a negative impact on work participation for those with rheumatic conditions.[26,32] A non-supportive work environment is a key factor; the lack of work accommodations (e.g. flexibility and changes to working hours, adaptations to working practice and environment, use of aids and appliances), negative work culture, and a lack of support from colleagues and managers is linked to absence and reduced productivity.[33]

Models for organizing predictors of work disability

Psychological and occupational factors are increasingly recognized as the key reasons for reduced work participation. A framework to organize and understand the psychological, occupation and workplace influences is offered by the 'flags' concept, which has been developed in the fields of occupational medicine and psychology.[34] This system links with the clinical use of 'red flags' to highlight the existence of serious pathology (e.g. malignancy) and the need for immediate medical input. Three additional flags (yellow, blue, and black) are warning signals that psychosocial factors in or around the individual are acting as obstacles to full recovery and return to work, and each flag points to specific reasons for work disability:

◆ *Yellow flags* relate to the individual and to their thoughts, beliefs, behaviours, and emotional responses that are important predictors for the development of long-term problems. Many of these can be considered as the response of the individual to their rheumatic condition. These include beliefs about pain and injury, pessimism, catastrophizing, poor coping strategies, and low self-efficacy.

◆ *Blue flags* refer to perceptions of work and working conditions at an individual level. Examples of negative perceptions of work are fear of exacerbation of symptoms or disease induced by the job, high perceived physical job demand, job-related stress, low expectation of return to work. Poor working conditions are lack of job accommodations/modified work, and lack of employer communication with employees.

◆ *Black flags* are objective work characteristics and contextual conditions which may be specific to the individual's organization. Examples are unhelpful policies/procedures used by employers, such as the absence of a mechanism to provide alternate duty for employees returning from sickness absence. These are environmental factors that perhaps clinicians can do little about but must be aware of when managing patients' work participation, as they can communicate with employers about the importance of addressing these issues.

The flags approach directs a broad approach to the reasons for work problems and opens up different interventions and management strategies that can be adopted to improve work participation. The emphasis of this approach is to systematically identify and then categorize obstacles to returning to or staying at work, and then identify appropriate strategies for their removal or resolution. The different flags highlight the heterogeneity of issues with adults with rheumatic conditions leading to work problems. Taking this approach further, identifying common clusters or subgroups of people with similar characteristics may lead to efficiency in delivering common but tailored interventions to groups of workers. Based on a review of risk factors for work disability that can be identified early on in the course of a low back pain episode,[35,36] four distinct groups of workers have been identified:

◆ A group at *low risk* for prolonged work absence and disability.

◆ A *high risk-immobilized* group: key characteristics included fear avoidance, pain catastrophizing, physical dysfunction, and poor expectations for resuming activity.

◆ A *high risk-disemployed* group: key characteristics are workplace problems including having a job with high physical demands, poor employer responses to the report of injury, no modified duties available, and short job tenure.

◆ A *high risk-overwhelmed* group, characterized by multiple issues: depressive symptoms and otherwise negative mood symptoms, life adversity, high levels of work stress experienced, and high levels of fear and worry.

These subgroups have different propensities for absenteeism and presenteeism and different intervention strategies are indicated. The success of this approach is based on early identification of modifiable factors and requires an understanding of the barriers that prevent work participation.

Managing musculoskeletal disorders and work

The approach to managing musculoskeletal conditions and work is evolving. A coherent and effective response to the worker's need for support in continuing to work or returning to work is necessary. A greater emphasis on a 'joined-up' approach to the sick worker's problems involving the worker, the multidisciplinary team (e.g. rheumatologist, physiotherapist, occupational therapist, psychologist, occupational health professional, and/or employer advisor) and the employer is required. Improving work capability in older adults with rheumatic conditions requires a multifactorial approach which addresses physical, psychological, social, and occupational factors and focuses on managing the condition and associated comorbidities rather than all taking a narrow focus on treating or 'curing' the condition.[37] This is important as most people with musculoskeletal disorders have the potential to continue to work despite the persistence of symptoms.

Role of health professionals

Greater emphasis is now placed on early intervention, which is essential if a short-term problem is not to be translated into long-term sickness absence. Early diagnosis and treatment are key and a medical approach has a crucial role to play with autoimmune conditions. There is increasing evidence that aggressive treatment of autoimmune conditions leads to improved work participation. Aggressive treatment of RA with a combination of disease-modifying anti-rheumatic drugs (DMARDs) compared to a single DMARD significantly reduced the extent of sick leave and work disability.[38] Early treatment with a combination of a biologic therapy and methotrexate reduced absenteeism and presenteeism through a reduction in work cessation, number of sick days and improved work productivity.[39,40]

Increased involvement of allied health professionals may be required to enhance patient care; for example, a physiotherapist could make a functional assessment and initiate treatment to maintain or improve key functional abilities related to work.[41] Early physiotherapy intervention is linked with improved health and well-being in workers with rheumatic conditions.[42] Competencies in ergonomic job accommodation, communication, and conflict resolution could be even more important for success at work than physical treatments of the condition.[43] Ergonomic changes (restructuring work tasks, aids and appliances, workplace adaptations, work station redesign) are linked to maintaining work participation and return to work.[32] Patients with rheumatoid arthritis who have had received workplace ergonomic changes are 2.5 times more likely to remain in work.[26]

Identifying work-related problems may be as simple as directly asking about work absence and performance, but may require more systematic approaches, using already existing tools which allow patients or workers to report work performance, ability and barriers. The Work Instability Scale,[44] Workplace Activity Limitations Scale[45] and the Work Experience Survey-Rheumatic Conditions (WES-RC)[46] have been developed to aid clinicians to identify work limitation and the barriers that may impede resolution. These could potentially become part of routine information gathering before, during, or after the consultation; or may simply outline questions that will help the clinician and patient explore work issues together during consultation. A more thorough approach to identifying work problems and barriers to return to work is outlined in the following website—www.lni.wa.gov/IPUB/200-002-000.pdf). http://www.lni.wa.gov/IPUB/200-002-000.pdf

Role of the employer

Maintaining some people with rheumatic conditions in work rests on the ability to adapt the workplace and work requirements to the physical limitations of the worker. This highlights the need for clinicians to communicate with the workplace and become involved in managing occupational, as well as social and psychological factors for work problems (i.e. areas where clinicians have been reluctant to get involved[47]). The role of line managers, return to work coordinators, and human resource departments, and their interaction with health care professions, will become increasingly important and crucial to reducing absenteeism and presenteeism. Focusing on line managers is important because they provide support in the workplace and play a mediating role within organizations. Line managers need to consider the symptoms and functional limitations of such workers to optimize their performance. If they are deficient in relevant skills and knowledge in advising and supporting people with these conditions, there may be barriers to return to work and excessive work loss.

It is also important to recognize that individuals with musculoskeletal and work problems often identify and arrange their own accommodations or do so in concert with fellow employees, and there may be a role for training workers and coworkers to facilitate the accommodations process. Improving individuals ability to self-manage musculoskeletal conditions and work problems is extremely important and should be an important target for clinical interventions.[48] Indeed, the vast majority of people with short-term work disability should be able to return without involvement of any specialized services such as occupational health or vocational rehabilitation. The most important interaction is between the employee and employer, and only in the occasional instance where this is problematic might a return-to-work coordinator be helpful.[49]

At an organizational level, the provision of in-house health care will also be beneficial and links with the vocational rehabilitation approach described above. Good examples are available of the positive influence of vocational rehabilitation and linkage between health professionals and managers.[50] But occupational health services must engage with all stakeholders (particularly line managers and clinicians) to be effective in improving return to work. Large employers may be better placed to act in line with positive policies to prevent absence and encourage return to work. Smaller and medium-sized employees may not have the capacity to offer these accommodations in the same way, and for these employees, health professionals become even more important.

Further considerations

Prevention of the impact of rheumatic diseases on work

The sheer size of the current burden of rheumatic diseases on work, and the potential for this to increase, signals the need for preventive strategies to prevent work disability and aid return to work. Prevention will need to target both the impact of the musculoskeletal disorder and work disability. Current models of care to reduce the impact of musculoskeletal disorders on work will need to move towards more proactive preventive health policies related to the workplace, in similar ways to those which have emerged in primary care, which has moved from exclusive concern with sickness to being concerned with prevention of disease and reduction of disability, through health promotion and screening programmes. This requires a shift towards promoting health in the worker and in the workplace as distinct from an exclusive concern with avoiding injury or dealing with sickness when it arises.

Following this, there is a need to explore the cost-effectiveness of accommodations and support programmes in the workplace and the community that can maintain work participation. Timing of interventions is important; although we know that being off work for a longer period increases the risk of long-term absence, more information is needed about the timing of interventions to ensure optimal outcomes. Much is known about ergonomic factors and the role of types of work and workplace environment in predisposing to musculoskeletal disorders, but there are many unanswered questions about prevention, causation, treatment, and prognosis which must be addressed to ensure that the needs of those in work are being met. In particular there is a lack of good quality evidence to guide the preventive, therapeutic and rehabilitative arms of the response to the whole problem of musculoskeletal disorders and work in older adults.

Further research

The major concern with demographic change is the increasing number of older workers and the impact they will have. Most research on work and musculoskeletal conditions has not focused on older workers. Further work is required to assess if extended working life is good for all older workers who have musculoskeletal disorders. How will extensions to working life affect musculoskeletal

disorders? Will this exacerbate their development? What will be the impact of prolonged working life on future health and well-being? What are the best methods to maximize opportunities for making employment-related choices, which promote health, safety, and life satisfaction in later years? If staying in work exacerbates musculoskeletal disorders, what is the additional cost to society in terms of health and social care costs? Investigation of the health and economic impact is required to provide further direction for policy on older workers.

Conclusion

Musculoskeletal disorders are the most frequently cited reason for absence from work and there is a need for new approaches and attitudes to assess and reduce the burden. The cumulative burden of non-inflammatory arthropathies and disorders such as back pain, OA, and limb pain as a whole, results in a much greater economic and human cost to society than autoimmune disease. As the incidence of these conditions increases with age and as working lives extend, there will be many more employees with musculoskeletal problems in years to come. Significantly, new approaches impose the view that work loss does not need to be a consequence of a musculoskeletal disorder or disability. There are many opportunities to improve work participation; it presents an achievable challenge to everyone and underlines the importance of a biopsychosocial and interdisciplinary approach involving interaction between those with a musculoskeletal condition, clinicians, employers, and policy-makers.

Biologics registries

David Isenberg and Angela Zink

Introduction

Periodically a new treatment emerges for human diseases that carries the prospect of radically improving the outcome of a variety of conditions. Examples include the development of dialysis, transplantation, antibiotics and, most impressively for those with inflammatory musculoskeletal diseases, corticosteroids. Sixty years on from the introduction of corticosteroids it is very hard for today's rheumatologists to imagine what life was like without the availability of, say, low-dose oral steroids to manage polymyalgia rheumatica, high-dose oral steroids to treat giant cell arteritis and vasculitis, intramuscular or intravenous steroids to manage acute rheumatoid flares, or intra-articular steroids to help resolve localized knee inflammation.

The modern equivalent of the introduction of corticosteroids is of course the advent of the era of biologic therapy. There are significant lessons to be learnt from the introduction of corticosteroids. Too little attention was paid initially to the potentially serious side effects of steroids, especially when given for long periods in doses exceeding 10 mg/day. It took a long time before the major problems of osteoporosis, increased risk of infection, diabetes, and hypertension were linked unequivocally to steroid use. It is at least arguable that these problems would have been appreciated far sooner had today's warning systems and instruments such as drug registries been developed 60 years ago.

A registry is invariably prospective in nature, enrolling patients to capture the full side-effect profile of a particular drug (or other therapeutic intervention). Most registries will also assess the effectiveness of a new drug, since safety and effectiveness are often interrelated. Registries reflect the experience of 'real life' patients, which is not the case even in large double-blind controlled trials. Such trials invariably 'cherry pick' patients deemed most suitable by virtue of their having more straightforward disease without confounding comorbidities and often excluding the more serious manifestations of a given disease.

The establishment of many European and some North American registries in rheumatic diseases has been a success story in the past decade, as several recent reviews attest.[1–3] In this chapter we briefly describe how registries are established and run, and summarize the most important findings on effectiveness and safety. We focus on registries for patients with rheumatoid arthritis (RA). Some countries have also established registries for ankylosing spondylitis, psoriatic arthritis, and more recently systemic lupus erythematosus, but there are little published data.

Establishment and management of biologic registries

Ideally a wholly independent funding source, such as a national Department of Health, should fund a register in order to obviate any accusation of bias (which would inevitably be the concern were the register solely to be funded by a major pharmaceutical company) and to ensure academic independence. We are unaware of any such arrangement or of its likely development. On the other hand, since it is the companies' responsibility to ensure the safety of their products, it is reasonable for them to support independent, well-managed registries. In order to ensure unbiased assessment of risks and benefits, all drugs of a certain class (such as biologic agents) should be observed in parallel and all companies producing these drugs should jointly support the register. Independence is crucial and can be ensured by setting a filter and/or by appropriate contracts.

The funding of the British Society for Rheumatology Rheumatoid Arthritis Register (BSRBR-RA) is a case is in point. In the United Kingdom those companies whose drugs are being studied provide substantial funds to the British Society for Rheumatology who pass the vast majority of this support to the Arthritis Research UK Epidemiology Unit based at the University of Manchester. In this model (which is strongly supported by the National Institute of Health and Clinical Excellence) pharmaceutical companies receive long-term safety data both on their own product and from a contemporary control group with active RA not being treated with a biological agent. The group in Manchester is free to design its own research agenda and to publish what it wishes. There are, however, two caveats. Firstly, the British Society for Rheumatology has established a Biologics Register Committee whose function is to oversee and approve the arrangements both with the pharmaceutical companies and with the University of Manchester. Secondly, before submission, any papers or abstracts are sent (approximately 2 weeks for an abstract and a month for a full manuscript) both to the Committee and to nominated individuals within the pharmaceutical companies. Any comments are passed back to the Epidemiology Unit by the Chairman of the Biologics Register Committee. Although in theory these comments may be ignored, the researchers often find

the questions helpful and will often amend their abstract or manuscript accordingly. This system provides a necessary set of checks and balances and works principally because it provides an arrangement in which each party derives benefit.

Registries in other countries are funded and organized in a variety of ways, but a general principle is that long-term funding is provided jointly by several companies and that conduct, analysis, and publication of results remain in the hands of academia. In Germany, the state-owned Rheumatism Research Centre has one single seven-sided contract with all companies who own licensed biologics for the treatment of RA. Full academic freedom is guaranteed for the principal investigators running the register, which includes a procedure of feedback on publications similar to that described for the BSRBR. The contract ensures that funds are provided for long-term observation, i.e. for at least 6 years after the last patient has been enrolled. In Sweden, in addition to private money, it has been possible to get funds from public sources.

In some countries, registries specific to individual drugs have been set up in the last few years. Although it is still possible that these registries are independent of company influence, it is much more difficult to guarantee their independence. Thus we strongly recommend joint funding concepts with different companies involved.

Day-to-day management of registries

Invariably each registry employs a varying number of permanent staff to collect, monitor, analyse, and publish the data. Most registries started with the goal of collecting data over a minimum period of 5 years, and equally most have come to accept that a much longer period of time is necessary partly to help establish the really long-term benefit of biologic drugs and partly to capture the long-term side effects they may have (by analogy, even heavy smoking may take many years before its serious deleterious effects become evident). Most of the registries started by collecting paper-based information both from physicians and patients. With the passage of time electronic capture of data has become much more popular and in some instances, for example in Denmark, the amount of data entered via the internet now greatly exceeds that captured on paper.

Registries—similarities and difference

Much information on this topic has, as alluded to above, been published elsewhere but a summary of some of the main European and United States registries is shown in Table 34.1. It is vital when making comparisons between results obtained from registries to appreciate that there are some quite significant differences in terms of which patients may be prescribed biological agents in different countries. For example, in the United Kingdom biologic therapies may only be prescribed to patients with RA with a DAS28 score greater than 5.1 who are deemed to have failed two previously prescribed disease-modifying anti-rheumatic disease agents (DMARDs), one of which is invariably methotrexate. In Germany, although there are no strict guidelines about the use of biological agents, it is generally recommended that they will not be started until patients have demonstrated high disease activity with the failure of least one conventional DMARD. In Sweden the authorities do not restrict the use of biologics and this probably explains why around 20% of patients with RA on the population level are prescribed these drugs, probably close to twice as many as in the United Kingdom and Germany.

Although, as explained above, some differences exist in terms of when patients with RA (or other diseases) are started on biological agents, it clearly makes sense for biologics registries to standardize their data collection methods, observation periods, and types of analysis as far as possible. It is particularly important to help establish the real prevalence of less common adverse events and, eventually, to ascertain whether the prevalence of side effects varies significantly with respect to e.g. age of onset, gender, disease duration, ethnicity, comorbidity and comedication and, increasingly importantly, with the use of multiple biologic agents.

The European registries, in particular those run in the United Kingdom, Sweden, and Germany have worked closely together during the past decade and, as detailed elsewhere,[1,3] share a number of features. They include all biological agents given to patients with RA from the day of first licensing. They provide each funding company with regular, usually semi-annual, reports on adverse events that have occurred in patients treated with this company's drug (or in the comparator group), which helps the companies to fulfil the requirements of their periodical safety update reporting to the European Medicines Agency. In order to coordinate reporting and data analysis and interpretation, the registries have held regular meetings which were either open to all registries or held only among those with reporting commitments. All registries use comparator cohorts to put the results into perspective. These cohorts vary from register to register. In the United Kingdom the comparator cohort consists of patients with active RA whose DAS28 score at inclusion exceeds 4.2 but who are not taking a biologic therapy and are treated in the many collaborating rheumatologic units. In contrast, in Germany previous DMARD failure and the start of a new DMARD therapy is an inclusion criterion for the control group which is observed under the same protocol and in the same rheumatology units as the patients on biologics. Switching of therapies can then be followed easily. In other counties historical cohorts are used as comparators (e.g. the EMECAR cohort in Spain). Some countries, like Sweden, Denmark, and the United Kingdom, can link the data from their biologic cohorts to national population databases recording deaths, hospitalizations, and/or cancer. There are also some differences in the coding of adverse events. Whereas the British, Spanish, and German registries utilize the coding system known as MedDRA, the Swedish registry uses ICD-10 in order to be comparable to the national registries.

Do the biologic registries prove that biologic drugs work?

Given the careful selection of cases entered into double-blind controlled trials it was always likely that 'real life' results using tumour necrosis factor alpha (TNFα) blockade in RA would not be as impressive. Two studies comparing the effectiveness of TNFα blocking treatment from biologic registries with results of major clinical trials have confirmed that this is the case. However, if the strict inclusion criteria of the major trials had applied to the patients followed up in the registries, a very similar clinical response would have been found.[4,5]

The south Swedish registry, which contributes to the national biologics registry ARTIS, reported that 45% of patients treated with etanercept and 40% treated with infliximab had sustained ACR 50 responses at 12 months.[6] Encouragingly, the national Danish registry reporting ACR 20/50/70 response rates in their 2000/2001

Table 34.1 Overview of European registries with published data used in this chapter

Acronym	Country	Year established	Comparator group	Key features
ARTIS	Sweden	1999	No true comparator group but linkage with national registries for mortality, cancer, inpatient and outpatient care	Patients are documented at routine clinical visits, registry is part of clinical care
Biobadaser	Spain	2000	Contemporary cohort of non-biologic treated RA patients has been used (EMECAR)	Initially (2000–2006) ~50% of all musculoskeletal patients on biologics were included. Subsequently fewer patients have been studied, but with greater intensity
BSRBR	UK	2001	A contemporary group of just under 4000 patients with RA on DMARDs	4000 patients each with RA on Enbrel, infliximab, and adalimumab recruited; minimum follow-up was 5 yrs, now planned to increase to 10 yrs. Plus 1100 on rituximab recruited and aiming to collect 2000 on certolizumab and 1000 on tocilizumab. Data collection has been paper based
DANBIO	Denmark		Contemporary control groups (early RA and RA on DMARDs) now established	All 26 rheumatology units contribute. Patients with RA (>4500), AS, psoriatic arthritis and other diseases are included
DREAM	Netherlands	2003	Use of contemporary inception cohort of early RA not given DMARDs (Nijmegen)	11 collaborating rheumatology centres, >1000 patients enrolled
RABBIT	Germany	2001	Patients at onset of DMARD therapy after failure of at least one other	7000 patients enrolled at start of a biologic, 3000 controls. Patients are followed at 3, 6, and 12 months after commencing treatment and bi-annually thereafter
RATIO	France	2004–2006	No comparator group	National registry for lymphomas and opportunistic infections, event-based, now closed
SCQM	Switzerland	1997	Controls are taken from the quality management database	Not originally a biologics registry. Patients are enrolled at regular visits, at least once a year
SSATG	South Sweden	1999	See ARTIS	90% of all prescriptions of biologics in South Sweden are included, regular follow-up

AS, ankylosing spondylitis; DMARD, disease-modifying anti-rheumatic drug; RA, rheumatoid arthritis.

cohort compared to the 2005 cohort showed an increase from 53%/31%/13% to 69%/51%/30% respectively.[7]

Another way of judging the effectiveness of TNFα therapies is determining the percentage of patients who remain on these drugs over time. As detailed elsewhere,[2] approximately 70% of patients on etanercept, infliximab, or adalimumab being treated for RA will remain on these drugs a year after starting though several analyses have shown that adding methotrexate (or another DMARD) tends to increase treatment continuation.[8–12] Thus the BSRBR[8] reported that a combination of etanercept and methotrexate was still being used in 84% of patients 6 months after starting treatment, compared to 78% on the etanercept treatment only. The comparative figures for infliximab were 79% vs 70%. In the RABBIT register[11] at 12 months the survival rates for etanercept and methotrexate were 82% compared to 71% for etanercept-only therapy, with comparable figures for infliximab being 77% and 67%.

Switching biologic therapies

Given the increasing availability of biologic drugs including those blocking TNFα, CD20, and the interleukin (IL)-6 receptor (among others) and as significant numbers of patients stop their first such

agent because of side effects or lack of efficacy, the desire to try a second (or even third or fourth) biologic agent is increasing. Reports from the British registry have indicated that the likely survival of a second agent was broadly comparable to the first. The reasons for stopping a second TNF inhibitor (lack of efficacy or adverse events) were related to those for stopping the first one, indicating that there are patients more prone to adverse events or to ineffectiveness.[12] It could be further shown that patients who switched to a second TNF inhibitor had better functional outcomes after 1 year than those who continued anti-TNF treatment despite non-response.[13]

The Spanish BIOBADASER register showed higher age to be a risk factor for discontinuation due to adverse events whereas switching because of inefficacy was more frequent in younger patients. Patients with ankylosing spondylitis had longer retention rates than those with RA.[14]

In the Swiss Clinical Quality Management Cohort, the major cause of switching was adverse events, with 56% of cases.[15] Data from the same register showed that switching to rituximab after failure of a first anti-TNF treatment was more successful than trying a second anti-TNF agent if the reason for switching was

ineffectiveness. In other cases of switching there was no difference in response to the second treatment.[16,17]

Adverse events associated with TNFα blockage

Cancer risk

Given that the initial estimates for the numbers of patients that were studied in biologic registries were predicated on the risk of cancer, specifically lymphoma, links between TNFα blockade and neoplasia are being carefully scrutinized. A potential confounding factor is that in patients with RA the risk of non-Hodgkin's lymphoma is increased (reviewed in detail recently[18]). The French RATIO registry,[19] which is different from the other registries described so far, was designed to collect cases with lymphoma or tuberculosis in patients receiving anti-TNF treatment between 2004 and 2006 on a national basis. The denominator can therefore only be estimated. RATIO reported a two- to threefold increase of lymphoma in patients receiving anti-TNF therapy but also confirmed that this is similar to that expected for such patients with severe inflammatory diseases. Furthermore, a study linking data from the Swedish biologics registry, the Swedish RA registry, and the Swedish cancer registry identified and analysed cancer in a national cohort of 6366 patients with RA who started their TNF therapy between 1999 and 2006.[20] As a comparative cohorts they used a national biologics-naive RA cohort (n = 61 160), a cohort of patients with RA newly starting methotrexate (n = 5999), a cohort of patients with RA newly starting DMARD combination therapy (n = 1838), and the general population of Sweden. The conclusion was that during the first 6 years following the start of anti-TNFα therapy in routine care no overall increase of cancer risk was noted.

In the RABBIT registry, the risk of incident malignancies was assessed with a nested case-control study in 5120 RA patients. The incidence was 6.0 per 1000 patient-years, and there was no difference between patients exposed or not to anti-TNF agents.[21] In the Spanish BIOBADASER registry the age- and sex-adjusted incidence rate for cancer was 3.0 per 1000 patient-years in patients exposed to biologics and 5.6 in those unexposed (EMECAR cohort), compared to 4.6 in the general population.[22]

Recently the BSRBR[23] as well as the RABBIT registery[24] considered the question of whether patients with previous malignancies were at increased risk of having a recurrence if they were treated with TNFα blockade. In the BSRBR, 177 patients treated with anti-TNFα and 117 patients treated with DMARDs had a history of malignancy: 13 recurrent tumours occurred in the anti-TNF group and 9 in the DMARD group. This resulted in a recurrence rate of 25.3/1000 person years and 38.3/1000 patient-years, respectively. In RABBIT 14 recurrent tumours were observed in 122 patients, resulting in a recurrence rate of 45.5 per 1000 patient-years in patients treated with anti-TNF agents and 31.4 in those treated with conventional DMARDs. The recurrence rate ratios between anti-TNF and DMARD were thus 0.6 in the BSRBR and 1.4 in RABBIT, neither of which is significant. However, reasons for the discrepant results may be that the DMARD group in the BSRBR had a shorter observation time and shorter time since the last tumour than the anti-TNF group. In addition the British rheumatologists had waited significantly longer than those in Germany before starting an anti-TNF treatment after a previous tumour (58% of anti-TNF treated patients in the BSRBR but only 23% in RABBIT had gone more than 10 years since the last tumour at the start of anti-TNF

treatment). Therefore, further observation and comparison with data from other countries are needed.

By linking data from the Swedish biologics register ARTIS and clinical RA registries with national registries on cancer, hospitalization, and outpatient care it was shown that cancers occurring in patients treated with TNF inhibitors had a similar stage at cancer diagnosis and similar post-cancer survival rates to biologics-naive patients.[24]

To summarize the evidence, the data available so far are reassuring concerning the overall risk of cancer. However, it must be emphasized that site-specific increases in risk (especially skin cancer) cannot be ruled out yet.[25]

Further observation should also consider potentially increased risks in subgroups of patients such as older patients or those undergoing specific additional treatments.

Infections

Because of its mode of action, the risk of serious infections was a major concern at initiation of anti-TNF therapy. An increased incidence of tuberculosis reactivation is well established, in particular for the monoclonal antibodies,[22,26,27] and systematic screening has turned out to be an effective method of prevention.[28] Further, there seems to be an increased risk of viral infection, in particular herpes zoster, in patients treated with monoclonal antibodies.[29] An increased risk of septic arthritis in anti-TNF treatment was found in the BSRBR.[30]

Several registries have addressed the important question of whether TNFα blockade is linked to an overall increased risk of serious bacterial infection. Compared to conventionally treated patients, odds ratios ranging from 1.3 to 2.1 were reported.[31–33] The overall risk of serious infection under TNF blockade has been reported as between 4 and 6 per 100 patient-years.

There was a consistent observation that the risk of serious infection was highest in the first 3–6 months after start of treatment and declined thereafter.[30,34,35] The question is whether this decline on the cohort level is equivalent to a risk reduction in the individual patient. The German registry recently showed that about two-thirds of this decline in risk can be explained by 'depletion of susceptibles' (patients who experience an infection early on are taken off the drug, leaving those less susceptible on treatment), whereas about one-third of the decline can be attributed to improvement of the disease and reduction in the glucocorticoid dosage over time.[36] Taking all these factors into account, the incidence rate ratio for anti-TNF treatment compared to conventional DMARDs was 1.8. The data allow a calculation of individual patients' risk of experiencing a serious infection in the light of their risk profile. Thus, according to these data, a patient without any further risk factors has a very low 12-month risk of serious infection of 1% under conventional DMARDs and 2% under TNF inhibition. However, if a patient is older than 60 years, has a chronic renal disease, and is treated with glucocorticoids at 15 mg/day or above, the expected risk is 12% for conventional DMARDs and 21% for TNF inhibition. Switching such a patient from conventional DMARDs to anti-TNF and simultaneously reducing the glucocorticoid dose to less than 7.5 mg/day results in an overall risk of 5%. Thus, the infection risk conferred by anti-TNF treatment must be seen in the light of a patient's overall risk profile and must be balanced against the risks of alternative treatments and the clinical benefits.

Cardiovascular events and mortality

RA patients have a twofold increased risk of having a myocardial infarct.[37,38] The reasons for this seem to be linked to the role of inflammation in the development of atherosclerosis. The encouraging news from the BSRBR-RA treated with anti-TNFα therapy was that those who responded to the treatment within 6 months had a significantly lower rate of myocardial infarct compared to those who did not. Results from the Spanish registry supported this useful role for TNFα blockade,[39] reporting a decrease in mortality from cardiovascular events in TNFα-treated patients compared to that of a clinical cohort of conventionally treated patients. They also noted that the mortality of patients treated with these biologic agents was similar to that in the general population when matched for age and gender. No increase in overall mortality was also found in the BSRBR when comparing 12 672 patients on biologics and 3,522 DMARD-continue patients with a total of more than 60 000 patient-years of observation.[40]

Pregnancy

The BSRBR reported on 120 pregnancies with exposure to anti-TNF treatment at or prior to conception and 10 in women never exposed.[41] The rates of spontaneous abortion were higher in patients exposed to anti-TNF (with or without further DMARDs) at conception compared to those never exposed or exposed before conception. There was no further difference in the rates of pregnancy complications or the proportion of live births. Four congenital malformations were observed, two in both of the groups with exposure at or prior to conception. The German RABBIT registry has published a preliminary report on 42 pregnancies in 31 women.[2] In 24 pregnancies the mother was exposed to anti-TNF treatment during the first trimester. There was no difference in the rates of spontaneous abortion between women exposed or unexposed to anti-TNF at conception. No congenital malformation was reported. However, a large proportion of those women who had stopped anti-TNF treatment at conception or shortly thereafter experienced severe flares of the disease during pregnancy. These results are still too limited to allow firm conclusions. There is more information from inflammatory bowel disease suggesting that TNF blockers are safe during the first trimester of pregnancy and can be used in patients with highly active disease.[42]

The future for biologic registries—thoughts and expectations

There is no doubt that the development of biologic registries has been enormously helpful in our attempts to understand the long-term benefits and adverse effects of this new therapeutic modality. We know about the increased risk of serious infection, and we are able to act on it clinically. Concerns regarding incident skin cancer and recurrence of melanoma remain. The only unexpected adverse event reported so far was the development of psoriasis in some rheumatoid patients treated with TNFα blockade.[43] Some initial concerns about an increase in the development of diseases such as lupus or demyelinization have not materialized. However, it is essential to remember that it is still relatively early days with these drugs and we simply have no idea whether continuous immunosuppression by cytokine blockade or depletion of cells for 10, 20, or 30 years will not be followed by a host of serious or unpleasant side effects or simply failure of these drugs to work effectively

beyond a finite period. On the other hand, it is likely that further positive long-term effects of anti-TNF blockade will be detected. As shown for myocardial infarction and bacterial infections, the risk for comorbidity resulting from the disease itself or from current comedication may be reduced by effective control of the disease activity.

As more new registries are set up in various countries with various indications, it is vital to ensure that the best scientific benefit is gained from them. The European League against Rheumatism (EULAR) has recently decided to set up a Subcommittee on Biologics Registries within its Standing Committee on Epidemiology, which builds upon the work of a previous task force.[44] The aim is to coordinate the efforts throughout Europe, to ensure a high quality of conduct by exchange of methodologies and to further enhance our knowledge by making use of all available evidence.

CHAPTER 35

Outcomes of paediatric rheumatic disease

Kirsten Minden

Introduction

Paediatric rheumatic diseases (PRD) influence all aspects of a child's and their family's life, and may have multidimensional consequences. This chapter describes the instruments that have been developed to assess these consequences and the outcomes that have been reported for patients with PRD, with an emphasis on measures and outcomes in juvenile idiopathic arthritis (JIA), juvenile systemic lupus erythematosus (JSLE), and juvenile dermatomyositis (JDM).

Outcome measures

A methodology and standardization is required for measuring and valuing the range of health states associated with PRD.

Therapeutic response measures

A variety of instruments are available for measuring disease activity in JIA, JSLE, and JDM. However, due to the high variability in the clinical presentation and outcome of PRD, no single measure can reliably capture disease activity in all patients. To achieve a standardized approach, core sets of variables have been established (Table 35.1).[1,2] Beyond the core sets, there are other parameters that have yet to be incorporated into standard outcome assessment, but allow for a more sensitive assessment of disease activity, such as biomarkers (e.g. serum cytokine profiles, S100 proteins) or new imaging modalities (e.g. ultrasound coupled with power Doppler [USPW], MRI).

Using the core sets of disease activity measures, response criteria for use in therapeutic trials and in standard clinical care in JIA, JSLE, and JDM have been created.[1,3,4] These criteria enable determination of whether individual patients demonstrate clinically important improvement at a defined point in time. In JIA the definition of improvement is equivalent to the so-called American College of Rheumatology (ACR) paediatric 30 response (Box 35.1). Given the increasing demand of higher response levels, ACR paediatric 50, 70, 90, and 100 levels of response were defined. The ACR paediatric response criteria do not make it possible to quantify the absolute level of disease activity. For this, a composite disease activity score for JIA, the Juvenile Arthritis Disease Activity Score (JADAS) is

available, which is also based on the core set criteria (Box 35.2). In addition, criteria were developed by Wallace et al. in order to define a state of inactive disease or remission (Box 35.2).

Disease status measures

Physician-reported outcomes

Traditional disease status measures comprise clinically measurable signs or symptoms of the disease assessed by the physician, such as current disease activity and organ system damage. Standardized definitions of disease activity states (e.g. inactive disease, clinical remission, and minimal disease activity state) have been developed for JIA (Box 35.2).[5,6]

Validated, standardized, clinical measures aimed at assessing damage or permanent alterations in joint structures or extra-articular organ/systems as a result of disease or its treatment are available for JIA, JSLE, and JDM.[7–9] These instruments differ somewhat from damage instruments applied in adult-onset diseases, because they also consider the potential reversibility of some damage items in children and include assessment of growth retardation and pubertal delay.

In JIA, imaging has been of particular importance to assess structural joint damage. The reference standard method for assessing joint damage is plane radiography. Several radiographic scoring systems have been developed that allow for a standardized quantification of radiographic joint changes (e.g. Poznanski score, Dijkstra composite score, adapted Sharp/van der Heijde score, Childhood Arthritis Radiographic Score of the Hip). The newer imaging methods, MRI and USPD, for which corresponding scoring systems are in development, are even more sensitive for joint damage assessment.[10]

Patient-reported outcomes

The patients' perspective on outcome is equally important as the physician-based outcomes. This includes the direct effect of illness with subjectively perceived signs and symptoms: pain, fatigue, adverse effects from therapy, and disability. Given the current inability to prevent or cure rheumatic diseases, the primary aim of care is to ensure the best possible lifelong functioning and quality of life. This necessitates formal methods for measuring patient's experience

Table 35.1 Core sets of disease activity measures for juvenile idiopathic arthritis (JIA), juvenile systemic lupus erythematosus (JSLE), and juvenile dermatomyositis (JDM)

	JIA	JSLE	JDM
Generic domains			
Global assessment by physician	Physician global assessment of disease activity (VAS, NRS)	Physician global assessment of disease activity (VAS, NRS)	Physician global assessment (VAS, NRS)
Global assessment by parents/patients	Patient/parent global assessment of overall well-being (VAS, NRS)	Patient/parent global assessment of overall well-being (VAS, NRS)	Patient/parent global assessment of overall well-being (VAS, NRS)
Disability or health-related quality of life	Functional ability (e.g. CHAQ)	Health-related quality of life (e.g., CHQ-Physical summary score)	Functional ability (e.g. CHAQ) Health-related quality of life (e.g. CHQ-Physical summary score)
Disease-specific domains			
Disease-specific measures	Active joint count Restricted joint count		Muscle strength (e.g. MMT, CMAS)
Global disease activity		Global disease activity tool (e.g. ECLAM, SLEDAI, BILAG, SLAM)	Global disease activity tool (e.g. DAS, MDAA)
Laboratory measures	Acute-phase reactant (ESR or CRP)	Renal involvement (urine protein: creatinine ratio, 24-hour proteinuria)	Muscle enzymes (CK, LDH, ALT, AST, aldolase)
Additional	Spiking fever (to be used for systemic JIA)		

ALT, alanine aminotransferase; AST, aspartate aminotransferase; BILAG, British Isles Lupus Assessment Group; CHAQ, Childhood Health Assessment Questionnaire; CHQ, child health questionnaire; CK, creatine kinase; CMAS, childhood myositis assessment scale; CRP, C-reactive protein; DAS, disease activity score; ECLAM, European consensus lupus activity measurement; ESR, erythrocyte sedimentation ratio; LDH, lactate dehydrogenase; MDAA, myositis disease activity assessment tool; MMT, manual muscle testing; NRS, numeric rating scale; SLAM, systemic lupus activity measure; SLEDAI, SLE disease activity index; VAS, visual analogue scale.

Box 35.1 Definition of improvement in JIA

◆ **ACR paediatric 30 response:** 3 of any 6 of the core set variables (see Table 35.1) improved by ≥30%, with no more than 1 of the remaining variables worsening by >30%. For systemic JIA, absence of spiking fever (≤38 °C during the week preceding the evaluation) is also required.

◆ **ACR paediatric 50/70/90 response:** 3 of any 6 of the core set variables improved by ≥50/70/90%, with no more than 1 of the remaining variables worsening by >30%.

---

of disease. An accepted means of describing the health and functioning of an individual is the WHO International Classification of Functioning, Disability and Health (ICF). According to the ICF, 'functioning' comprises all different aspects of the way in which a specific health condition affects life and thus includes body functions and structures, activities, and participation related to environmental and personal factors.[11]

Instruments developed to measure patients' functioning and health are summarized in Table 35.2. Of the function-oriented health status measures, the Childhood Health Assessment Questionnaire (CHAQ) in childhood or the Health Assessment Questionnaire (HAQ) in adulthood are the most widely used, mainly because of their ease of use and their validation in long-term outcome studies. Health-related quality of life (HRQoL) can be measured by different approaches. So-called generic measures allow for the valuation and

---

Box 35.2 Criteria for defining clinical inactive disease and remission in selected categories of juvenile idiopathic arthritis (JIA)—persistent and extended oligoarthritis, rheumatoid factor positive and negative polyarthritis, and systemic JIA[5]

All of the following criteria must be met in order to consider a patient to be in a state of inactive disease:

◆ No joints with active arthritis.

◆ No fever, rash, serositis, splenomegaly, or generalized lymphadenopathy attributable to JIA.

◆ No active uveitis (according to the SUN Working Group: 'grade zero cells,' indicating <1 cell in field sizes of 1 mm by a 1 mm slit beam).

◆ ESR or CRP level within normal limits in the laboratory where tested or, if elevated, not attributable to JIA.

◆ Physician's global assessment of disease activity score of best possible on the scale used.

◆ Duration of morning stiffness of ≤15 minutes.

Clinical remission on medication: the criteria for inactive disease must be met for a minimum of 6 continuous months while the patient is on medication.

Clinical remission off medication: the criteria for inactive disease must be met for a minimum of 12 continuous months while off all anti-arthritis and anti-uveitis medications.

CRP, C-reactive protein, ESR, erythrocyte sedimentation rate.

Table 35.2 Patient-reported outcomes in juvenile idiopathic arthritis (JIA), juvenile systemic lupus erythematosus (JSLE), and juvenile dermatomyositis (JDM)

	JIA	JSLE	JDM
Function-oriented health status measures	Childhood Health Assessment Questionnaire (CHAQ) in childhood or Health Assessment Questionnaire (HAQ) in adulthood Juvenile Arthritis Functionality Scale (JAFS) Juvenile Arthritis Functional Assessment Report (JAFAR) Juvenile Arthritis Self-Report Index (JASI) Childhood Arthritis Impact Measurement Scales (CHAIMS)

comparisons of HRQoL of healthy people versus that of patients with different diagnoses. Conversely, disease-specific measures value the health of patients with a specific disease and are therefore thought to better capture changes in the degree of health.

Health outcomes

Given the substantial improvement in outcomes for patients with PRD over the past several decades, there has been a shift from measuring short-term mortality and morbidity to examining long-term outcomes and preventing the adult consequences of childhood-onset disease. However, many of the long-term outcome studies published have inconsistent case definitions. Studies often include patients from tertiary referral clinics, meaning they may reflect only those who have a disease severe enough to come to and remain at special healthcare facilities. Studies also vary substantially in years of follow-up and in whether they are prospective or retrospective. These factors help to explain both the variability and the limitations associated with outcome studies which are presented in the following. Yet, further variability is likely to be seen in future estimates associated with variations in availability and uptake of new treatments.

Physical consequences of juvenile rheumatic diseases for the individual

Mortality

Juvenile-onset inflammatory rheumatic diseases are associated with increased mortality rates compared with the general population.

However, mortality rates have considerably decreased over the past decades. Mortality rates among children with chronic arthritis were 4–7% in the 1970s, which represented a 10-fold increase over the general population. In 2010, Hashkes reported a global mortality rate of 0.2 for children with JIA, which did not differ significantly from the mortality rate of the general population.[12] JIA patients are still at increased risk of mortality in their young adult years.[13,14] Two population-based studies demonstrated that adult patients with childhood-onset arthritis have a roughly fourfold higher overall mortality than the general population. Elaine Thomas and colleagues estimated standardized mortality ratios (SMR) of 5 for women and 3 for men with childhood-onset arthritis, twice as high as those calculated for men and women with rheumatoid arthritis.

Children with systemic connective tissue diseases, such as JSLE and JDM, and primary vasculitis (except for Kawasaki's disease and Henoch–Schönlein purpura) still have a significantly higher mortality risk than the general population. Patients with primary vasculitis carry the highest risk, with a mortality rate of 1.9% and a SMR of 4.71 according to the study by Hashkes.[12] Patients with JSLE follow, with a rate of 1.2% and a SMR of 3.06. A cohort study from the United States noted a particularly high SMR of 20 for JSLE in the age category 19–34 years.[15] Of course, the lifespan of JSLE patients has improved dramatically. While global survival at 5 and 10 years follow-up was 42–72% and 40–70% for the patients studied in the 1980s, respectively, these values reached 88–100% at 5 years and 86–90% at 10 years follow-up in the studies published after the year 2000.[12,15–18] A marked improvement in prognosis was also demonstrated for patients with JDM, for whom mortality rates of almost

40% were reported in the presteroid era as compared to 0.8%–3.1% in the year 2010.[12,19]

Knowledge about specific causes of death in the various PRD is very limited. In the 1970s, the major causes of death in patients with childhood-onset chronic arthritis were renal failure (in one-half of the cases due to amyloidosis) and infections. Amyloidosis accounted for more than 40% of all causes of death, but is no longer a relevant cause of death in these patients. Systemic-onset JIA still accounts for two-thirds of the mortality seen in JIA, with macrophage activation syndrome (MAS) being the leading cause for mortality. Approximately 10% of patients with systemic-onset JIA are diagnosed with MAS which has a mortality of 8–22%.[20] To what extent cardiovascular diseases, infections, or even hematopoietic malignancies attribute to the increase in SMR, especially later in life, is unidentified. With regard to the risk of cancer occurrence, preliminary data point to an increased risk of malignancies (particularly of the lymphoproliferative type) in patients with JIA which cannot be explained by the introduction of biological therapies.[21] The relevance of this for early mortality seems insignificant. Causes

of death later in life among JSLE patients are better known. They include cardiovascular disease or infection, which account for approximately one-half of the deaths in adulthood.[15] Death in JDM most often results from respiratory insufficiency or interstitial lung disease, myocarditis, or from gastrointestinal ulceration with intestinal perforation and bleeding. Information about causes of death in adult JDM is missing.

Disease activity

Persisting disease activity is a significant consequence of disease for patients because it is closely linked to important symptoms such as pain, fatigue, and functional limitations. Outcome studies published since the year 2000 show that rheumatic diseases beginning in childhood frequently continue into adulthood (Table 35.3).

In JIA most remissions occur in the first 5 years after disease onset. After more than 10 years of disease duration 40–60% of the patients still have an active arthritis. The probability of remission varies significantly with disease-onset type, being best for oligoarticular JIA,

Table 35.3 Outcome studies of juvenile idiopathic arthritis (JIA), juvenile systemic lupus erythematosus (JSLE), and juvenile dermatomyositis (JDM) which comprised at least 20 patients with a specific disease, had a follow-up of at least 10 years, published since the year 2000

Study (year, country)	Number of patients assessed	Median or mean disease duration (years)	Patients (in %) with

at approximately 50%, and worst for polyarticular JIA, in which it approaches 15%.[25,32] The probability of remission decreases progressively after 10 years. If remission does not occur within 10 years of disease onset, it is unlikely to occur at all.

Similar results have been reported in JSLE, with over one-half of patients having active disease after a mean follow-up period of 13 years.[17] and over two-thirds of patients receiving oral corticosteroids at a mean follow-up of 16.5 years.[30] The median time to remission in JDM was estimated to be 4.7 years. In other words, one-half of patients with JDM will have achieved remission 4.5 years after diagnosis.[33] A similar percentage was found in studies with a follow-up of 8 and 17 years.[19,31]

Organ system damage

Cumulative disease activity over time has been shown to be a highly significant predictor of disease damage in children with inflammatory rheumatic diseases.[34] Five years after disease onset, damage has occurred in approximately one-half of the patients. Table 35.4 summarizes those studies on damage in JIA, JSLE, and JDM which used standardized damage instruments. In JIA, articular damage is the most important component of global damage, representing almost 80% of the total JADI (juvenile arthritis damage index) score in the study by Russo.[35] Ocular damage, growth failure, and muscle atrophy are the most frequent extra-articular damage components in JIA. Renal, neuropsychiatric, musculoskeletal, and ocular systems are the most commonly damaged organ systems in JSLE. In JDM, the skin leads the list of the most frequently affected organs, followed by the musculoskeletal and endocrine organ systems.

Articular damage

In JIA, articular damage is most common in hip, wrist, and temporomandibular joints.[35] Ten years after disease onset, at least one in four JIA patients has developed radiographic joint changes with erosions, joint space narrowing, or even destruction (Figure 35.1). Depending on the patient collective studied, between 2% and 50% of the 20–35 year old JIA patients have already been supplied with

endoprostheses.[23,24,28,32] Patients with systemic-onset show the highest frequency of joint replacements, and the hip is the most frequently replaced joint. As a result of change in treatment strategies, i.e. the early use of intra-articular steroids and immunomodulatory drugs, such as methotrexate and biological agents, joint damage is decreasing. In JSLE and JDM articular damage is rarely seen; however, joint contractures are seen in about 20% of JDM patients.

Extra-articular damage

Linear growth failure occurs in about 10% of children with PRD, with a decreasing trend over the past decades. Total body inflammation and corticosteroid therapy are strongly implicated as causes of growth failure. In view of the whole JIA group, growth failure is therefore more likely to develop in patients with systemic and polyarticular JIA. Simon and colleagues.[43] found a mean final height standard deviation score of –2.0 in 24 patients with systemic JIA, with 41% of subjects' height more than 2 SD below the mean. The prevalence of short stature (final height below the 3rd percentile) in 65 adult JIA patients was reported to be nearly 11% in a long-term follow-up study from Denmark, with all of the severely growth-retarded patients having polyarticular JIA.[44]

Local growth disturbances

In JIA local growth disturbances mainly occur at sites of inflammation and can take the form of overgrowth or undergrowth (Figure 35.2). There is a tendency to accelerated maturation of epiphyses, leading for example to increased leg length, or overcrowding and fusion of the joint in wrists and ankles. Limb length discrepancies and micrognathia (Figure 35.3) are the most frequently observed local growth disturbances in up to one-quarter of adult patients.[23,24]

Abnormal body composition

Abnormalities in body composition, i.e. a decreased lean body mass, an increased fat mass, and a reduced bone mineral density have been documented in patients with PRD. Up to 50% of adolescents and young adults with JIA, JSLE, and JDM experience

Table 35.4 Summary of studies on cumulative organ damage after more than 5 years of disease, assessed by JADI in juvenile idiopathic arthritis (JIA), SDI in juvenile systemic lupus erythematosus (JSLE), and MDI in juvenile dermatomyositis (JDM)

Ocular sequelae

Apart from musculoskeletal system damage, ocular sequelae are of major concern in JIA. They develop as consequences of uveitis in at least one-third of affected patients within the first 7 years of disease, and most frequently consist of cataract, posterior synechiae, glaucoma, and band keratopathy. The ocular complications result in a permanent, significant visual loss (<0.5) in 10–20% of patients. Blindness (20/200 or worse) due to uveitis in at least one eye still occurs in 5–10% of uveitis patients.[47] Most complications and reduction of visual acuity occur within the first 7 years of disease, but their prevalence increases with longer follow-up. More than 15 years after disease onset, uveitis is still active in almost one-half of the patients.

Atherosclerosis and cardiovascular disease

Patients with chronic inflammatory rheumatic diseases are probably at increased risk of premature atherosclerosis and early-onset cardiovascular disease. The aetiology may be multifactorial, attributable to manifestations of the disease itself (such as chronic inflammation, chronic hypertension, renal disease, or abnormal lipid profiles), adverse effects of medication (such as steroids and non-steroidal anti-inflammatory drugs) and lifestyle issues (such as decreased physical activity due to disease-related disability). Impaired vascular function has been shown in JIA and carotid intima-media thickness in JSLE, but the exact extent of the increased cardiovascular risk is unknown.

Fertility problems

Fertility disorder is of particular concern to patients. Fertility is not impaired in females with JIA, but fecundity was found to be reduced.[48] Also, pregnancy outcome was less successful in these women, with a significantly increased rate of miscarriage. Patients with systemic connective tissue disorders or vasculitides may even be at higher risk for decreased reproductive fitness than JIA patients as a consequence of their chronic inflammatory condition or the medications used to treat it (e.g. alkylating agents such as cyclophosphamide). Their true risk of infertility or low follicular/ovarian reserve is not known, however.

decreased bone mass at lumbar spine or femoral neck, and up to 10% osteoporosis.[45,46] The abnormalities in the amount and the geometric distribution of bone mass are of concern as both determine bone strength and the fracture threshold and put the patients at increased risk of osteoporosis and fractures later in life.

Muscle loss

Muscle loss, which is critically responsible for the bone loss, occurs in all forms of PRD. Muscle mass and force are reduced in JIA patients; about 10% demonstrate persistent muscle atrophy on clinical examination. In patients with longstanding JDM muscle weakness has been found in 31–42% of patients in three series after more than 10 years of follow-up, whereas MRI-detected muscular damage was found in one-half of the patients.[31]

Consequences of juvenile rheumatic diseases

Functional consequences

Treatment for PRD has improved dramatically, accompanied by a steady and significant reduction in disability rates. In the 1970s the frequency of patients in Steinbrocker functional class I (i.e. no functional limitation) ranged from 25% to 40% and that of patients with serious functional disability (corresponding to Steinbrocker functional classes III and IV) from 17% to 22%, but higher frequencies of patients with no functional limitation (60%) and lower frequencies of patients in Steinbrocker classes III and IV (10%) were recorded in the 1990s. Most recent outcome studies used a more sensitive functional measure, the HAQ, for the assessment of the patients' physical disability. According to the HAQ, approximately 40% of patients with PRD are somehow limited in their functional capacity in their young adult years (see Table 35.3). Approximately 10% of them are in need of assistance and/or aids in order to manage their activities of daily living, which corresponds well with the percentage of patients being in Steinbrocker functional class III or IV. Severe disability is most frequently seen in patients with rheumatoid factor positive polyarthritis and systemic onset of JIA, followed by patients with rheumatoid factor-negative polyarthritis and extended oligoarthritis. In contrast, patients with persistent oligoarthritis hardly ever report functional disability in early adulthood.[23,32,49]

Societal consequences

Symptoms associated with PRD, such as fatigue, pain, stiffness, and physical disability, may lead to reduced participation in daily school and social activities. However, children and adolescents with PRD more frequently cut back on participation in social activities rather than school activities. Patients with PRD miss on average 1–2 days of school per month due to their illness. Nevertheless, their academic achievement is comparable to that of the general population, or even better. However, entering the labour force is difficult for young people with PRD. JIA patients have lower employment rates compared to age-matched local controls.[23,24,28,49] The lower employment rates result from significantly higher rates of unemployment in JIA patients in comparison with controls, extended training periods, or early retirement. As compared to JIA patients, young adults with JSLE have an even lower employment rate. At a mean age of 24 years, only 40% worked full time.[17]

PRD have consequences not only for the individual, but also for their friends and family and for the whole of society. Parents may miss days at work and experience financial burdens. Klein-Gitelman and colleagues reported that one in five guardians of children with JIA, JSLE, and JDM reported having taken time off work, and 3% had stopped work in order to care for problems related to their child's rheumatic disease. Of families queried, 24% reported having lost income, with 14% having lost over $500 within the survey period of 3 or 6 months.[50] The economic burden of PRD is difficult to measure. The total costs of illness (both medical and societal costs) depend on the patient collective studied and the medical care delivery system. The few estimated direct costs of JIA range from €1800 to €27 700 per patient per year.[50] The main cost driver in JIA is medication, in particular biological agents. However, costs incurred in childhood have to be seen in view of lifetime pain, disability, and patient impairment. In adulthood, indirect costs due to work disability and sick leave account for most of the total cost in the active JIA population. Those costs incurred in adulthood might decline in the future as a result of new treatment strategies which have improved the prognosis of PRD. Long-term cost effectiveness studies are needed to prove this.

Quality of life

The impact of disease and its treatment on bodily, functional, and social level is reflected in impairments of patient's health status or perceived quality of life. How adolescents and young adults with PRD value their health has been repeatedly analysed using quality of life measures, such as the SF-36. Controlled outcome studies showed that patients with PRD judge their quality of life lower than age- and sex-matched controls.[17,19,28] They feel particularly impaired in their physical health (e.g. physical functioning, vitality, and bodily pain). Worse HRQoL is related to greater pain, fatigue, disease activity, damage, and functional disability. The effect size of JIA on HRQoL seems to be similar to that of JSLE and JDM. In general, a very high percentage of patients with PRD classify themselves as having a high quality of life in adulthood.

Outcome prediction

A variety of studies have investigated factors that will predict the course of PRD, to guide a risk-adapted and cost-effective treatment. Some indicators of poor health were identified, e.g. for JIA female gender, polyarticular and symmetrical joint involvement, elevated inflammatory markers, and rheumatoid factor positivity. Today, however, it cannot be predicted at disease onset which children will go on to have an unremitting disease and experience poor outcome or quality of life. Most interesting so far has been the prediction of prognosis based upon early treatment response, with outcomes at 3–12 months predicting response at later points in time.

Conclusion

The recent outcome studies are a testament that rheumatic diseases beginning in childhood are not benign. After 5–10 years of disease duration, approximately one-half of patients will have active disease, and will have developed damage due to the disease itself or to the adverse effects of treatment. Patients face a considerable morbidity in adulthood and lower life expectancy compared to their peers. Control of disease activity is important in order to decrease the damage. Owing to improved management, including early recognition and more-sophisticated treatment options, the outlook for children with juvenile rheumatic diseases has dramatically improved. In particular, functional outcomes have improved tremendously, with most patients exhibiting no or mild disability and able to lead a normal life.

Recently established large inception-cohort studies, with follow-up into adulthood, are expected to better characterize the multidimensional outcomes of patients with PRD. The data from these studies will lead to a better understanding of the disease prognosis, and could potentially form the basis of tailor-made treatment strategies for these illnesses presenting during childhood.

CHAPTER 36

Assessment of paediatric rheumatic disease

Loren A. Matheson and Ciarán M. Duffy

Outcome measures: rationale and development

Today, most paediatric rheumatic diseases are not life threatening. However, they impact children and their families by interfering with normal health, and they may negatively influence a child's happiness. Generally, the goals of paediatric rheumatology interventions are to alleviate the patient's subjective disease symptoms and minimize inflammation in order to avoid permanent damage and ameliorate their overall quality of life (QoL). Improvements in functional outcomes have heightened QoL expectations, which in turn have become increasingly important to assess. QoL outcome measures are of direct interest and importance to patients because they provide effective measurements of patient status. Not only are QoL assessments predictive of patient functional outcome, they also produce reliable and effective measures of treatment impact, side effects, and comorbidities.[1]

The development and validation approaches for outcome measures that are used to assess the state of health-related (HR) QoL in the paediatric rheumatic diseases have been well established.[2] The development of a new instrument requires a number of lengthy steps including rationale justification, item generation, and reduction, and a description of the instrument in terms of reproducibility, consistency (reliability), and validity (accuracy). The process used to develop and validate health outcome measurement instruments, specifically focused on children with rheumatic diseases, has been detailed elsewhere.[2] This chapter describes a number of these instruments and provides an overview of relevant information around usage and popularity.

Instruments for juvenile idiopathic arthritis

Many tools have been developed for the assessment of children with juvenile idiopathic arthritis, including disease-specific measures of functional status and HRQoL. In addition, there are a number of generic instruments used to assess HRQoL in children with juvenile idiopathic arthritis (JIA) that have received widespread use. A number of the most popular instruments are

discussed briefly here. Table 36.1 summarizes these instruments and provides details relating to usage, age range, and applicability. A relative comparison of the tools, including functional properties and QoL measures is presented in Table 36.2.

Childhood Health Assessment Questionnaire (CHAQ)

The adult Health Assessment Questionnaire formed the basis for the CHAQ (reviewed in [3]). The Disability Index within CHAQ assesses function in eight areas: dressing and grooming, arising, eating, walking, hygiene, reach, grip, and activities, for a total of 30 items. Discomfort is determined by the presence of pain, as measured by a visual analogue scale (VAS). In addition, a VAS measures patient or parent global assessment of arthritis. In the original validation study, reliability and convergent validity were very good, with excellent correlations with Steinbrocker functional class, active joint count, disease activity index, and degree of morning stiffness (reviewed in [3]). CHAQ has been successfully used for outcome evaluation in longitudinal studies.[4,5] It has also been used in a variety of settings, translated into many different languages, and undergone modifications in attempts to improve it while still maintaining excellent reliability and validity. Although many studies report good parent–child correlations, one study indicates that proxy and adolescent dyads who completed the CHAQ are more likely to disagree in those with severe disease as well as in those adolescents who report depressive symptoms.[6] Good responsiveness has been shown in other studies, including several longitudinal studies of etanercept.[7,8] Several studies have shown its usefulness in the evaluation of rehabilitative interventions.[9,10] It has also been suggested that the CHAQ is predictive of the presence of significant pain, as well as short-term outcomes, in a large cohort of Canadian children.[11] A digital form of the CHAQ has been developed and validated.[12] Although it took longer to complete than the paper version, the digital form was preferred by the majority of patients.

A recent study examined whether the CHAQ Disability Index scoring system and its responsiveness to change differed when calculated with and without the aids/devices and help sections of the questionnaire.[13] These components have been questioned because of their possible misinterpretation by the parent or child. The aids/devices and help items should only be completed if the need is

Table 36.1 Commonly used instruments for assessing juvenile idiopathic arthritis outcomes

Instrument	Usage	Age range	Proxy report	Applicability
JADAS	New	Children of all ages	No	Clinical and research
CHAQ	Widespread	Children of all ages	Yes	Research
JAQQ	Moderate	Children of all ages	Yes	Research
PedsQL	Widespread	2–18 years	Yes, 2–18 years	Research
PRQL	New	7–18 years	Yes, 7–18 years	Clinical
JAMAR	New	7–18 years	Yes, 2–18 years	Clinical and research
KIDSCREEN	Moderate	8–18 years	Yes, 8–18 years	Research
CHQ	Widespread	5–18 years	Yes	Research

Child Health Questionnaire (CHQ); Childhood Health Assessment Questionnaire (CHAQ); Juvenile Arthritis Disease Activity Score (JADAS); Juvenile Arthritis Multidimensional Assessment Report (JAMAR); Juvenile Arthritis Quality of Life Questionnaire (JAQQ); Pediatric Quality of Life Inventory (Peds QL); Rheumatology Quality of Life Scale (PRQL).

Table 36.2 Validation parameters for instruments commonly used for assessing outcomes in juvenile idiopathic arthritis

Parameter	JADAS	CHAQ	JAQQ	PedsQL	PRQL	JAMAR	KIDSCREEN
Clinical evaluation	Very strong	No	No		No	Very strong	No
Physical function measure	No	Moderate	Strong	Moderate	No	Very strong	Strong
Quality of Life measure	No	No	Strong	Strong	Strong	Very strong	Very strong
Pain measurement	Moderate	Moderate	Strong	Moderate	No	Very strong	No

Applicable to a heterogenous population	Strong	Very strong	Very strong	Strong	Very strong	Strong	Very strong
Tested widely	Moderate	Very strong	Strong	Strong	No	No	Strong
Easy to use	Strong	Strong	Strong	Strong	Very strong	Strong	Strong

Child Health Questionnaire (CHQ); Childhood Health Assessment Questionnaire (CHAQ); Juvenile Arthritis Disease Activity Score (JADAS); Juvenile Arthritis Multidimensional Assessment Report (JAMAR); Juvenile Arthritis Quality of Life Questionnaire (JAQQ); Pediatric Quality of Life Inventory (Peds QL); Rheumatology Quality of Life Scale (PRQL); TBD, to be determined.

due to the disease and not age-related limitations. The Paediatric Rheumatology International Trials Organization suggests that the removal of the aids/devices and help from the CHAQ does not alter the interpretation of the Disability Index. They report that the simplified questionnaire is a more effective alternative when assessing disability in patients with JIA.

Both with and without modifications, CHAQ has excellent reliability and validity and reasonable responsiveness. It also has good discriminative properties, can be administered to children of all ages, and is of great use in the clinical setting for long-term follow-up of children with JIA. It is valuable for longitudinal studies and clinical trials and has become the preferred measure in both settings. For these reasons, the CHAQ is the functional status measure most used as one of the six core variables for the assessment of change in JIA.

Juvenile Arthritis Quality of Life Questionnaire (JAQQ)

The JAQQ was designed to measure physical and psychosocial function as well as an array of general symptoms (reviewed in[3]). The instrument contained items across four dimensions: gross motor function, fine motor function, psychosocial function, and general symptoms. The initial validation study demonstrated good construct validity, moderate correlations with measures of disease activity and excellent correlations with pain. Responsiveness was shown by correlations of change scores, as well as by the ability of JAQQ to discriminate among patients based on physician global assessment of change.

A second iteration of the JAQQ saw the item number reduced to 74. A pain dimension, added as a supplement to JAQQ, included a VAS, a five-point ordinal scale, and, for children younger than

10 years, a five-point happy/sad face model. Twenty paediatric rheumatologists and therapists confirmed face and content validity of this version. Construct validity and responsiveness were established. Responsiveness was also shown to be maintained over time and to be at least as good as responsiveness of CHAQ, CHQ, or Peds QL. Enhancement of responsiveness was shown by a reduction in the number of items scored.

JAQQ has been translated into different languages and used in different cultural settings while maintaining its measurement properties (reviewed in[3]). A Canadian study showed that JAQQ was highly predictive of several short-term outcomes in a large cohort of children with JIA.[11] JAQQ has been developed in a detailed fashion, resulting in excellent reliability, validity, and responsiveness. It can be administered to children of all ages and disease onset types in a reasonable time with minimal assistance, and it can be scored quickly by hand; this makes it practical for use in both clinical and research settings.

Quality of My Life Questionnaire (QoMLQ)

The QoMLQ was developed to measure overall quality of life separate from health status or HRQoL. The instrument is made up of two separate 100 mm VAS, with the descriptors 'worst' and 'best,' that direct respondents to indicate their QoL. This is meant to assess problems caused by the disease itself and those caused by overall difficulties not directly related to the disease. This approach demonstrated clear differences between the scales, indicating that separation of the two factors is important. The QoMLQ demonstrated fair parent–child agreement and good convergent construct validity.[14] The minimal clinically important difference for improvement in QoL and HRQoL were given scores that enables clinicians to interpret QoMLQ results in a clinically meaningful way. QoMLQ is a short and easy-to-use generic instrument that is highly reliable and valid.

In further work from the same group, a novel approach was used in an attempt to measure the gap between one's current situation and one's expectations. The Gap Study quantified these gaps for a whole series of domains in children with rheumatic diseases.[15] The result was the development of a measure with 72 items distributed among five-gap scales (GapS). The GapS is currently undergoing further development.

Child Health Questionnaire (CHQ)

The CHQ is a family of generic quality-of-life instruments that have been designed for children 5–18 years of age. The CHQ measures 14 unique physical and psychosocial concepts. The parent form is available in two lengths (50 or 28 items) distributed in several dimensions: global health, physical activities, everyday activities, pain, behaviour, well-being, self-esteem, general health, and family. Scores can be analysed separately, the CHQ Profile Scores, or combined to derive an overall physical and psychosocial score, the CHQ Summary Scores.

The Paediatric Rheumatology International Trials Organization (PRINTO) has validated CHQ for use in 32 countries (reviewed in [3]). In one study that included 6639 participants (one-half had JIA, and one-half were healthy), mean scores for physical and psychosocial summary scores were significantly lower for JIA patients relative to controls. In a further study that included three distinct geographical regions (eastern Europe, western Europe, and Latin America), determinants of poor HRQoL were similar across all regions, with physical well-being affected by the level of disability and psychosocial well-being affected by the intensity of pain.[16] A study on improvements in HRQoL with abatacept used the CHQ to demonstrate tangible benefits of the drug.[17] CHQ was used in combination with CHAQ in a trial of etanercept, where it was shown to be highly responsive[7]; a comparable trial of methotrexate came to the same conclusion.[18] It has been suggested that JAQQ may be at least as responsive as CHQ for studies in JIA,[1] although CHQ has become the preferred measure of QoL for JIA trials because of its general nature.

Paediatric Quality of Life Inventory (PedsQL)

PedsQL is a modular instrument, containing generic and disease-specific cores, designed to measure HRQoL in children and adolescents 2–18 years old. Since 1999, the generic core has undergone various iterations and translations, the most recent of which, the PedsQL 4.0 Generic Core Scales, contains 23 items distributed in four scales: physical, emotional, social, and school functioning. A Rheumatology Module was developed for the PedsQL and it contains 22 disease-specific items distributed over five scales: pain, daily activities, treatment, worry, and communication.[19] It is completed by children and their parents and consists of versions appropriate for either children or teenagers and parents of children or teenagers. When it is completed separately, parent–child concordance has been good. This instrument was shown to have excellent reliability, validity, and responsiveness in a study of 271 children with various rheumatic diseases, 91 of whom had JIA, and their parents. Reliability varied with the age of the child, being less for younger children. In addition, a PedsQL Multidimensional Fatigue Scale was developed and validated in conjunction with the core scales and rheumatology modules.[20] The results of that initial study confirmed the initial reliability and validity of the PedsQL Multidimensional Fatigue Scale in paediatric rheumatology.

PedsQL remains an instrument that is in widespread use[21,22] and has been an important addition to the outcome measures available for use in JIA.

KIDSCREEN

The KIDSCREEN project set out to develop and validate the first European cross-cultural family of HRQoL instruments for children and adolescents, including self-reported and proxy-rated versions. The 10 dimensions examined on the KIDSCREEN instrument are: physical well-being, psychological well-being, mood and emotions, social support and peers relation, parents relation and home life, self-perception, autonomy, cognitive and school functioning, bullying and social rejection, and perceived financial opportunities. In the initial validation study, 2526 child/proxy pairs (aged 8–18 years) from 7 different European countries completed the questionnaire. The results demonstrated that the initial 52 item KIDSCREEN instrument proved to be a valid measure to assess relationships between youth and proxy reports.[23]

Since its initial validation, KIDSCREEN-52 has undergone psychometric property assessment. The questionnaire was administered to 22 827 children and adolescents in 13 European countries, which demonstrated acceptable levels of sensitivity and validity.[24] The instrument has also been shortened to 27 and 10 items and translated into many languages, with accompanying validation

studies for each version. This is a promising tool for use in clinical and epidemiological studies. Of particular interest is a study that used the KIDSCREEN-52 questionnaire to measure the outcome effectiveness of a psychosocial rehabilitation programme by assessing HRQoL of children living with different chronic diseases, including JIA.[21]

Paediatric Rheumatology Quality of Life Scale (PRQL)

The PRQL is a recently developed, simple, 10-item questionnaire that focuses on HRQoL in both physical health and psychosocial health.[25] Although there are a number of HRQoL scales available for use in children with JIA, it has been suggested that there is a need for an instrument that is simple, easy to administer, quick, and can be used in patients across different paediatric rheumatic diseases. The PRQL aims to fill that void by targeting incorporation into regular clinical care. The short questionnaire is intended for use as a proxy and self-report with a proposed age range of 7–18 years. The PRQL underwent preliminary validation in approximately 470 children with JIA and 800 healthy children in one study at one Italian centre.[25]

The PRQL was found to have good measurement properties and is reported as a valid instrument for clinical and research assessments of HRQoL in children with JIA. Further study with this instrument is needed to determine if the validity holds across multiple rheumatological diseases and in different cultural environments.

Juvenile Arthritis Multidimensional Assessment Report (JAMAR)

JAMAR was recently developed as an instrument that combines the traditional patient-reported outcomes used in clinical evaluation of children with JIA with other outcomes measures not addressed by conventional instruments.[26] There are a total of 15 measurements on the JAMAR, including assessments of overall well-being, pain, functional ability and HRQoL, as well as an evaluation of morning stiffness, overall level of disease activity, rating of disease activity and course, proxy or self-assessment of joint involvement and extra-articular symptoms, description of side effects from medications, and assessment of therapeutic compliance and satisfaction with the outcome of the illness. The JAMAR is proposed for use as both a proxy report for parents of patients aged 2–18 and a patient self-report with the suggested age range of 7–18 years old. The JAMAR is the first questionnaire to include a proxy or self-report assessment of articular symptoms.

In a validation study of 332 children and 618 parents of children with JIA over 2563 visits, the JAMAR was found to be feasible and to possess face and content validity.[26] The report indicates that parents and patients found that the JAMAR was user-friendly, easy to understand, and quick to complete (<15 minutes). Scoring of the various elements can be achieved in less than 5 minutes. The JAMAR was designed to be completed in a clinical setting and focuses on information needed for care, therefore only two straightforward measures were selected for assessment of physical function and HRQoL. The VAS for pain, well-being, and disease activity are presented as 21 numbered circles, instead of the conventional 10 cm horizontal line, to facilitate scoring without a ruler. A study by the same group determined that the simpler 21 numbered circles increases the precision of the parent/patient ratings.[27]

The main limitation to the validation study of the JAMAR is that the instrument was tested in Italian parents and patients at only one centre. In addition, the JAMAR may not provide sufficient detail regarding patient-reported outcomes of sleep disturbances, fatigue, coping, and family life, because of the short nature of the questionnaire. Research with this report is ongoing and will be followed with interest given its multidisciplinary nature.

Composite disease activity scores for juvenile idiopathic arthritis

The paediatric response criteria and American College of Rheumatology (ACR) JIA core set focus on change in disease state and assess improvement or worsening of disease activity. Currently, the ACR Pedi 30, representing a 30% change from baseline, is the measure of disease activity used to demonstrate efficacy of biologic therapy in JIA.[28] The Juvenile Arthritis Disease Activity Score (JADAS) was recently developed as a composite disease activity score for JIA. This instrument includes four of the measures from the core set: active joint count, physician's global assessment of disease activity, patient and parent global assessment of overall well-being, and erythrocyte sedimentation rate(ESR). Joint count is modified based on evaluation of 10, 27, or 71 joints in three different versions of the instrument. JADAS has been shown to have good measurement properties, including reliability and responsiveness to clinical change; however, a recent study has shown that there are properties of the JADAS-27 that may hamper its feasibility.[29] In addition, JADAS cut-off values for remission, minimal disease activity, and parent- and child-acceptable symptom state in JIA have been developed.[30] In cross-validation analyses, the JADAS proved to have good construct and discriminant validity and ability to predict disease outcome; however, misclassification of active disease versus inactive disease by JADAS scores was not uncommon.[31] A number of recent research studies have used the JADAS-27 and JADAS-71 as their disease activity measurement.[32,33]

Instruments for use in other rheumatic diseases

In recent years, rheumatic diseases other than JIA have been brought to international attention where a number of instruments have been developed and validated for use in both adults and children. Specifically, both juvenile dermatomyositis (JDM) and juvenile systemic lupus erythematosus (JSLE) have measures of disease activity and damage for both adult- and childhood-onset disease.

Two different groups developed similar core sets of measures for the juvenile idiopathic inflammatory myopathies. The International Myositis Assessment Clinical Studies Group (IMACS) used consensus methods to develop a core set that is applicable to both adult and paediatric idiopathic inflammatory myopathy. The PRINTO and the Paediatric Rheumatology Collaborative Study Group (PRCSG) also developed core set measures for JDM and JSLE. There are elements of each core that are common to both sets: the physician and patient global assessments, muscle strength, physical function, and muscle enzymes. PRINTO and PRCSG recently provided a definition of JDM improvement that reflects the consensus rating of experienced clinicians. They have incorporated clinically meaningful change in core set variables for the evaluation of global response to therapy in JDM.[34] The IMACS group has also published their

efforts to provide a definition of improvement in the juvenile idiopathic inflammatory myopathies.[35] The agreed-upon improvement definition involves three of the six core set measures bettered by more than 25%; however, this definition awaits further validation.

There are three validated tools for the assessment of strength, physical function, and endurance in children with JDM.[36] First, muscle strength has been assessed with the Manual Muscle Testing (MMT), where several variations exist depending on the number of muscles assessed and how muscle strength is scored.[37] Although the 8-muscle MMT performed similarly to the 26-muscle MMT score and demonstrated good reliability, construct validity and responsiveness, there are concerns about inter-rater reliability and application standardization. At least one study has made use of this test in conjunction with additional tools to demonstrate a greater severity of proximal weakness in polymyositis in comparison with dermatomyositis.[38]

CHAQ has also been validated for use in children with JDM in two separate studies where construct validity, reliability and responsiveness were demonstrated (reviewed in[3]). The Childhood Myositis Assessment Scale (CMAS) is an alternate assessment of physical function. This instrument is a 14-item observational performance-based tool that includes assessment of proximal, distal, and axial strength and upper and lower extremity strength and also includes timed endurance items. This instrument has good inter-rater reliability, construct validity and responsiveness. In addition, age-related norms have been published.[39] The drawback to the CMAS is that it is therapist administered and requires significant time to complete. One long-term outcomes study in JDM has determined that chronic course was the strongest predictor of poor prognosis.[40] This report makes good use of a combination of the three available instruments to study JDM: MMT, CHAQ, and CMAS.

As discussed earlier, the development of disease activity measures for JSLE was undertaken at the same time as the JDM initiative. Ultimately, the measures for JSLE included specific immunologic tests and renal function measures, as well as physician and parent global assessments, a measure of growth and development and a measure of HRQoL. The Systemic Lupus Erythematosus Disease Activity Index (SLEDAI), British Isles Lupus Assessment Group Index (BILAG), and Systemic Lupus Activity Measure (SLAM) were tested in the assessment of JSLE and were all shown to be highly sensitive to clinical change. The same group showed the responsiveness of European Consensus Lupus Activity Measurement (ECLAM) for juvenile SLE and suggested that it might be more sensitive than SLEDAI in this population. A recent study has described preliminary criteria for global flares in juvenile SLE and are based around absolute changes in the SLEDAI and BILAG.[41]

The CHQ, PedsQL, and CHAQ have been used as HRQoL measures in juvenile SLE patients[42–44]; however, there was a need for a new HRQoL instrument designed specifically for JSLE. The Simple Measure of Impact of Lupus Erythematosus in Youngsters (SMILEY) is a brief questionnaire that includes parallel child and parent versions with a 5-faces scale for responses. It includes four domains: effect on self, limitations, social, and burden of SLE. A multicentre validation study demonstrated face, content, construct, and concurrent validity, test–retest reliability, and internal consistency.[45] Further work with this instrument has been an international effort to provide a cross-cultural adaptation with translation to 13 different languages.[46] Studies to validate the translated and adapted versions of SMILEY are ongoing and will be of interest to achieve widespread use. There have been recent reports of studies on SLE patients that make use of the English version of SMILEY.[47]

Instrument usage and applicability

The majority of instruments discussed here, and HRQoL assessments in general, have been used mainly within a clinical research setting. However, the use of patient-reported outcomes in daily clinical practice has been the topic of much discussion in recent years. This encompasses self-assessment of functional status, as well as symptoms or other concerns, such as patient needs and satisfaction with care. The use of these instruments in a clinical setting may be of use in the early detection of HRQoL problems and may allow for a tailored intervention prior to an escalation of the issue. In particular, children with a chronic disease are at greater risk of HRQoL problems than their healthy peers.[48] For example, the effects of childhood disease and its treatment often increase the child's dependence on adults and decrease the child's participation in peer- and school-based activities. This could have an adverse effect on the accomplishment of developmental tasks, resulting in an impaired QoL. A questionnaire designed to capture pertinent information given to the clinician prior to or at the time of consultation might be of use to identify, monitor, and discuss particular HRQoL issues faced by children with JIA.

The choice of instrument is dependent upon the extent, impact, and type of paediatric rheumatic disease. For example, there are some instruments that focus on measuring the impact of physical function alone and others that assess physical function as a part of overall health status or QoL.

A survey conducted by one of us in 2005 determined that while paediatric rheumatologists are aware of this form of measurement and have participated in studies that have included such measures, in general, clinicians tend not to use them in clinical practice (unpublished data). It is possible that these instruments have been slow to infiltrate the clinical picture as a result of logistical issues around completing the forms and having the information available to the clinician in a timely fashion. New technology and the availability of web-based platforms (see 'Electronic applications') may facilitate the usage of HRQoL assessments in clinical practice by allowing the clinician to access the data at the time of a clinic visit. In the future, these instruments could potentially become an integral part of complete patient care.

Electronic applications

The concept of using technology to make clinical assessment of HRQoL more efficient is expected to gain momentum across all fields in the coming years. For example, the general HRQoL survey, KIDSCREEN-27, was recently translated into an online version, and consistency as well as reliability scores were comparable to those reported in the literature for the paper version.[49]

To overcome the practical issues around completing HRQoL forms in the clinic for clinical assessment, a group based in the Netherlands has developed a novel and innovative web-based application (KLIK PROfile) for patient-reported outcome measures. This program is tailored to general daily paediatric clinical practice, and specifically targets children with chronic diseases.[50] The authors envision parents and children completing the HRQoL at home up to 3 days before the consultation, and clinicians retrieving

the patient-reported outcomes directly from the website. It will be of interest to follow the KLIK PROfile and its evaluation for ease of implementation and use. This type of program may promote the widespread use of HRQoL instruments in daily clinical practice, as well as facilitating collaborative research between centres.

Conclusion

QoL, HRQoL, physical function, and health status instruments are often used as outcome measures in children with significant musculoskeletal involvement, but mostly for research purposes. These tools allow healthcare providers and researchers to account for varying degrees of patient-perceived states of ability as well as the impact of disability on overall well-being. When used at regular intervals during a disease course, the instruments are also able to account for changes in HRQoL perceptions, and many longitudinal research studies take patient-reported outcome measurements every 6 months. There are now many instruments available and it is important that when one is determining which instrument to use that the specific purpose of measurement be considered. If one is considering a measurement of physical function, the CHAQ is adequate for most purposes for most diseases. If one is considering a measurement of HRQoL in children with JIA, the JAQQ or Peds QL would be appropriate. The JADAS is an excellent measure of disease activity and could be adopted as an instrument to help plan disease management. Several newer measures including the KIDSCREEN and JAMAR are now available and it will be interesting to monitor their use over time. In addition, the SMILEY looks like an excellent tool for the assessment of HRQoL in childhood SLE.

Despite a broad range of available instruments, concern persists around the utility of these measures for clinical practice. However, availability of electronic and web-based versions of these instruments will, in all likelihood, enhance their use in the clinical setting. Whether this proves to be the case in practice remains to be determined.

CHAPTER 37

Basics of genetics

Anne Barton

Why should we be interested in genetics?

Human beings are more than 99% genetically identical to one another but it is the differences in the genetic code between individuals that account for differences in characteristics such as hair colour, eye colour, and height. These genetic differences also contribute to the risk of developing many diseases, including musculoskeletal diseases. An individual's genetic make-up does not change during life; therefore, the genetic changes exist before disease onset and may *cause* disease as opposed to being a *result* of disease. Thus, understanding which genetic changes are involved in disease has the potential to identify important biological pathways that could be targeted by the development of new drugs. Patients vary in the severity of their disease and response to treatment; again, genetic variation may be important and could be used to select the best drugs to use in particular patient groups.

How do we know if a disease has a genetic component?

Twin, family, migration, and adoption studies can all be used to determine whether there is a strong contribution from genetic factors to a particular disease. Twin studies assume that monozygotic (MZ) twins are genetically identical, whereas dizygotic (DZ) twins share only 50% of their genetic code. If a disease is more common in MZ than DZ twins, that is strong supporting evidence for a genetic component to risk. For rarer diseases, where it is more difficult to identify MZ and DZ twins, family studies can provide support for a role for genetics. The **sibling recurrence risk ratio**, λ_s, measures the ratio of disease in the siblings of patients with disease compared to the general population:

$$\text{Sibling Recurrence risk } (\lambda_s) = \frac{\text{risk of disease in sibling}}{\text{risk of disease in general population}}$$

The higher the value of λ_s, the stronger the genetic contribution to disease. Table 37.1 shows the estimated λ_s values for a number of autoimmune and musculoskeletal diseases.

What is genetics?

Genetic information is carried by DNA, which is located within the nucleus of cells. The total genetic code for an individual is called

Table 37.1 The sibling recurrence risk (λ_s) for a number of common musculoskeletal diseases

Disease	Estimated λ_s
Rheumatoid arthritis	2–11
Systemic lupus erythematosus	20–40
Psoriatic arthritis	20–40
Juvenile idiopathic arthritis	10–20
Systemic sclerosis	10–150
Osteoarthritis	1–9
Ankylosing spondylitis	30–40

the genome and can be thought of as a book. Within this book, the information is divided into chapters (chromosomes). Each cell carries all the genetic information but not all of it is used in every cell. For example, genes that code for enzymes important in the processing of alcohol, are only used (expressed) in liver cells. This is analogous to highlighting sections of a book pertinent to different readers. DNA is made up of four nucleotides: adenine (A), guanine (G), cytosine (C), and thymidine (T), similar to letters in our alphabet. Different combinations of three nucleotides result in amino acids, which are arranged into **exons**, and these exons can be thought of as words. As in language, different words make up different sentences and in this analogy, it is the sentence that is the equivalent of a gene. Different genes code for different protein products. The spaces in between the exons are the **introns** and, although they are not involved in the structure of the final protein product, a sentence would not make sense without these spaces.

Genetic variation

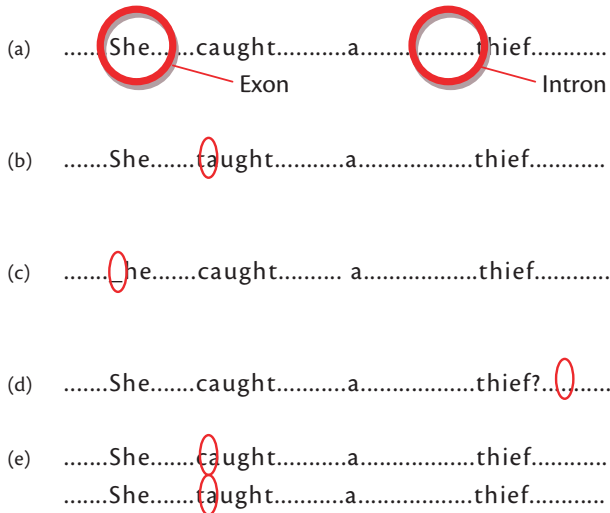
Many books contain typographical errors and the same is true of the genome. The simplest type of variation is where one nucleotide is replaced by another and this is called a **single nucleotide polymorphism (SNP)** (Figure 37.1). As we inherit two copies of the genome (one from our mother and one from our father), the change in the DNA sequence may be present on none, one, or both strands of DNA. Each version of the DNA sequence at that point is called an **allele**. For example, suppose that at a given point in the


Fig. 37.1 Variation in the DNA sequence is analogous to typographical errors in a book. (a) Genes are like sentences with the words being exons and the spaces between being introns. Note that the introns in a gene are larger than the spaces between words in a sentence. Note also that in the genome sequence, introns are also letters but do not make words. There are more letters in the English alphabet than in the genetic alphabet, which consists of just A, C, G, and T. (b) A change in a single letter (equivalent to a C to T single nucleotide polymorphism (SNP)) in an exon can change the meaning of the sentence. This is analogous to a non-synonymous amino acid substitution that changes the function of a protein. (c) An example of a deletion that changes the meaning of the sentence/protein. (d) In the genome, most changes occur in introns or in the DNA between genes but this can still affect the function of the protein. (e) Individuals inherit two copies of each gene. If a C/T SNP occurs at the position shown, for an individual, the genotype could be CC, CT, or TT depending on whether the nucleotide is changed in none, one or both versions of the gene.

DNA sequence, some people in the population carry an A nucleotide but some people carry a G, the A version is called the **A allele** and vice versa. The allele that is less common in the population is called the **minor allele**. International efforts have resulted in a catalogue of these variants being made; each is assigned an **rs number** so that researchers across the world will know what variant is being analysed if it is called by its rs number. It is like saying Chapter 3, page 4, paragraph 2, line 7, letter 18. If the SNP occurs in an exon, it may result in a change in the amino acid coded for, which may in turn affect the function of the protein. However, most SNPs occur in the introns of genes and in the DNA between genes. Other types of variation occur in the genome such as insertions or deletions, copy number variants, and other types of repeat sequences. However, SNPs are the most abundant type of variation and are easy to accurately genotype using modern technologies, so they have become the marker of choice for testing in genetic studies.

Linkage disequilibrium

Linkage disequilibrium (LD) is the non-random inheritance of alleles. During meiosis, recombination occurs on average once per chromosome arm. Therefore, variants that are close together on a chromosome are unlikely to become separated by recombination and are said to be in LD (Figure 37.2). In the general population, a lot of meiotic events separate individuals but, as recombination tends to occur at specific points in the genome (recombination hot spots), there are still blocks of DNA which are always inherited together and the variants within those blocks will always be in LD

with each other. This means that it is not necessary to genotype every variant across the genome to find which occur more frequently in people with a disease; because of LD, genotyping one variant will provide information on the other variants that segregate with it. The r^2 value measures the degree of correlation between variants. An r^2 value of 1 between two variants means that the genotype at one will perfectly predict the genotype at the second variant. For two variants to be perfectly correlated, they must have identical allele frequencies. If the allele frequencies are different, the r^2 value will be less than 1. The down side of LD is that if a genetic variant is found to occur more frequently in cases with disease, it may be acting as a marker for another variant which is the one causing disease, rather than being the causal variant itself.

Association studies

The most common study design in genetic studies is the **case–control association study**. The frequency of alleles at different locations across the genome is compared between cases with disease and those without (controls). The observed genotype and/or allele frequency in cases is compared with the expected frequency seen in controls using a basic χ^2 test, which can be translated into a significance (p) value. Alleles that occur at significantly different frequencies between cases and controls are said to be associated with disease. A common study design is the **candidate gene** approach in which variants in particular genes or genetic regions are selected for investigation. This approach requires a prior hypothesis about the role of the locus in disease, based on knowledge about the disease or results of previous studies of the same locus. There are approximately 30 000 genes and 10 million SNPs in the genome, so selecting the right variants in the right gene requires considerable luck. In recent years, a more systematic, hypothesis-free approach has been adopted in which hundreds of thousands of SNPs spanning the genome are tested for association, the **genome-wide association study** (GWAS). This has proved to be more successful in identifying variants associated with many musculoskeletal diseases.

Genome-wide association study: basic principles

As technology has improved, chip-based genotyping methods have developed and evolved to allow genotyping of ever-increasing numbers of SNPs, ranging from hundreds of thousands to millions of variants, dependent on the type of chip purchased. Allele frequencies of the SNPs are compared between cases and controls and if significant differences are found, the locus is said to be associated with disease. However, this simply provides an indication that the region is important. Given that there are estimated to be 10 million SNPs in the genome, the chance that the causal variant for a particular disease has been included on the SNP chip is low and association more commonly arises due to LD with the causal variant. Hence, fine mapping of the region and, ultimately, functional studies are required to identify the variant that causes the disease.

'Common disease, common variant' hypothesis

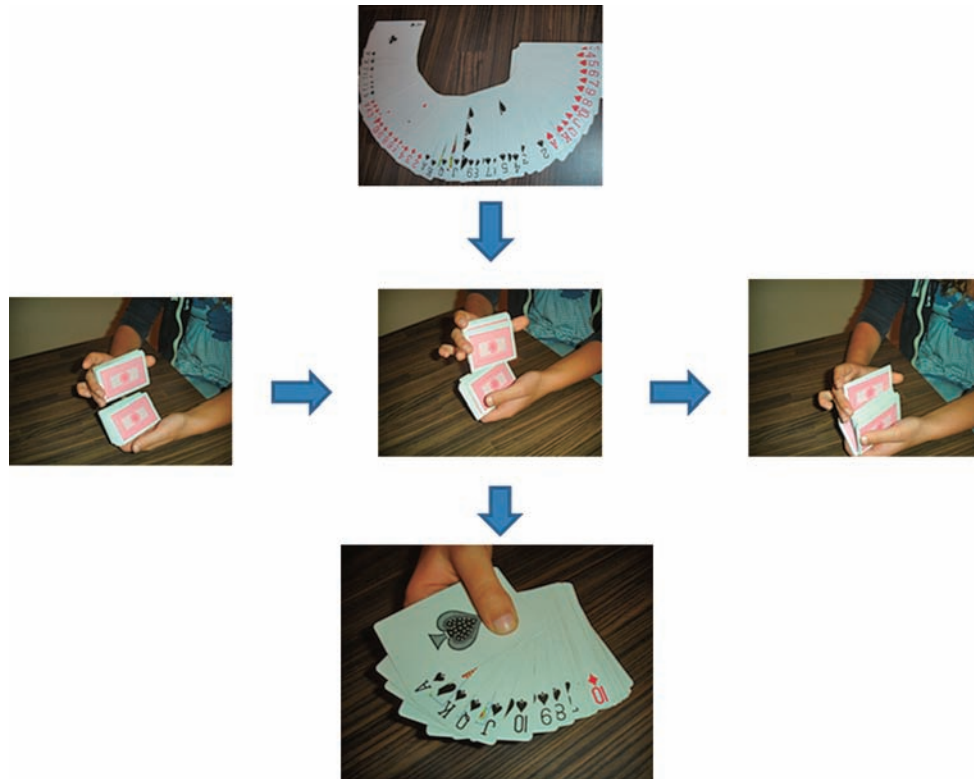
Common musculoskeletal diseases are complex; that is, both genetic and environmental factors contribute to susceptibility. In different individuals with disease, different combinations of genetic and environmental factors cause the same disease, so identifying the effect of a single genetic variant is diluted because not all cases will carry that variant. The 'common disease, common variant'


Fig. 37.2 Linkage disequilibrium (LD) is like shuffling a pack of cards. If a new pack of cards is shuffled, there will still be runs of the same suit that occur together because shuffling has not separated them. This is analogous to LD where chunks of DNA are inherited together so the genotype at one position can predict the genotype at another. Shuffling occurs during meisosis in the genome by recombination. Two unrelated individuals from the same ethnic group are likely to have been descended from a few common ancestors. Therefore, even though many generations has passed and many shuffling opportunities have occurred, there are still runs of nucleotides in the genome that are inherited together and are similar between individuals.

hypothesis assumes that complex diseases, particularly those that present later in life, will be caused by variants that are common in the population. Thus, if a mutation occurs in the DNA sequence that has a major effect on health, that individual will be unlikely to reproduce and the mutation will die out with the individual. However, if the variant produces only a small detrimental effect on health, the individual will be able to reproduce and the mutation will be passed on through successive generations until the allele is common in the population. For late-onset diseases, disease-causing alleles will not affect reproductive health and so it is expected that they will be common in the population and individually will have modest effects on disease risk. Indeed, this has proved to be true for many of the variants found to be associated with musculoskeletal diseases.

Effect sizes and power

The effect size of a variant refers to its contribution to disease risk; for diseases that are relatively uncommon in the population, such as most of the inflammatory musculoskeletal diseases, the effect size is equivalent to the odds ratio (OR) from a case–control study. For example, an OR of 3 (equivalent to the largest genetic effect contributing to rheumatoid arthritis (RA)) means that an individual is three times more likely to develop disease compared to the general population. This must be set into the context of the risk of disease in a population. Thus, if the risk of RA in the general population is 1%, then carrying the major risk allele only increases the risk

to 3%. For complex diseases, many genetic variants contribute to risk but each has only a modest effect. For example, many of the risk variants have OR of 1.1 to 1.2, equating to a 10–20% increased risk of developing disease. The **power** of the study relates to the ability to detect these effect sizes at a given significance threshold. Power is directly related to sample size; the bigger the sample size, the greater the power to detect associated variants. The power is also influenced by the allele frequency of associated variants; if the minor allele is uncommon in the population (<5%, for example) even larger sample sizes are required to have sufficient power to detect the effect. It is conventional to describe the test statistics in relation to the minor allele. Thus, an OR of 0.8 with confidence intervals that do not include 1 means that the minor allele protects against disease, or that the more common major allele increases risk. Whereas alleles contributing to the risk of diseases may only have modest effect sizes, side effects from drugs can be caused by alleles with very large effect sizes. For example, the OR of developing liver toxicity after using the antibiotic flucloxacillin is increased over 80-fold if patients carry the HLA-B*5701 allele. The sample size required to detect such effects is much lower because power is also determined by the effect size that is expected.

Assessing the quality of a case–control association study

When reading articles reporting findings of case–control association studies, there are several points worth bearing in mind. First,

as described above, the power of the study is related to sample size and the larger the sample size, the better the power. The studies that have been most successful in identifying associated variants for common, complex diseases have tested thousands of case and control samples. Small sample sizes are more likely to lead to both false-positive and false-negative findings. A false-positive finding may arise because, by chance, the small numbers of cases tested happen to contain more individuals with a particular allele but that allele is not associated with disease (Figure 37.3). Where sample sizes are small, validation of the association findings in another case control sample is therefore recommended, as it is unlikely that the second set of cases will also have a higher frequency of the allele simply by chance. False-negative findings can arise in small sample sizes because the study is underpowered to detect the effect size expected.

Second, it is important to check what quality control measures have been undertaken. Samples that have poor-quality DNA will not be reliably genotyped and this can lead to bias. Similarly, the assays for SNP genotyping can vary and may mean that certain SNPs only produce high quality data in a proportion of samples. An important quality control measure, therefore, is to remove samples and SNPs with genotyping success rates below an arbitrary threshold.

Third, SNPs where the allele proportions differ significantly from Hardy–Weinberg expectations in control samples should be removed from analysis. **Hardy–Weinberg equilibrium** occurs when two alleles (p and q) in a population that is randomly mating result in frequencies that satisfy the formula:

$$p^2 + q^2 + 2pq = 1$$

The most common reason for deviation from Hardy–Weinberg equilibrium is genotyping error. However, it is possible that disease is only caused in cases if two copies of the minor allele are present and, in that situation, Hardy–Weinberg expectations would not be met in the cases. For that reason, exclusion of SNPs from analysis is generally based on the Hardy–Weinberg results in the control sample.

Fourth, it is important to consider whether population stratification could have resulted in a false-positive finding. Population stratification refers to populations of different ancestral or ethnic backgrounds being included in the case and/or control samples. For example, if all the cases are recruited from Scotland and all the controls from Italy, associations with the gene encoding red hair

or the gene encoding height (both of which differ significantly across Europe) may be detected, but those genes are not associated with disease. Population stratification is more of a problem in North American studies where there has been Hispanic and Afro-Caribbean admixture. Population stratification can be corrected for statistically, if found to be present.

Finally, the issue of multiple testing should be considered. In a GWAS, 1 million SNPs may be simultaneously tested for association. If the significance threshold is set at p = 0.05, 1 in 20 (50 000) SNPs will show association by chance alone. Therefore, strict significance thresholds of $p < 5 \times 10^{-8}$ are generally required before a variant is considered to be confirmed as being associated with disease. If a variant is associated at $p < 0.05$ but $> 5 \times 10^{-8}$, the association may be considered possible or suggestive but further validation is required before it can be confirmed.

Follow-up of association findings

Once association has been identified with a disease, the next stage is to try to identify the causal variant in the region. As described above, association may arise due to LD with the true causal variant at the locus. Fine mapping describes the process of interrogating the surrounding region by testing multiple markers to identify the most associated variant. Resequencing of the surrounding region is emerging as an alternative approach as the cost of the technology reduces. In most cases, this will still leave a group of variants with equal evidence for association, but bioinformatics approaches can be used to determine which are most likely to affect the function of the DNA and, therefore, which are most likely to play a role in disease causation. Ultimately, proof that a particular variant causes disease requires functional studies to explore how and why that particular genetic variation predisposes to disease.

Other study designs

In the early part of this century, linkage studies remained a popular choice of study design for investigating complex diseases. Linkage studies are performed in families and, for late-onset diseases like the musculoskeletal diseases, families in which two affected siblings were identified were studied. At a particular marker in the genome with two alleles, *A* and *a*, the siblings have a 25% chance of both having the genotype *AA*, a 50% chance of *Aa*, and a 25% chance of *aa*. If both siblings have the disease and the marker is linked with disease, then the siblings will show a deviation from the expected allele sharing so that they share the allele linked with disease more often. Linkage studies in complex diseases have been largely disappointing and so genetic researchers now undertake association studies. Although the focus in this chapter has been on case control association studies, the **transmission disequilibrium test (TDT)** is an alternative association study design that can be undertaken in families. The test assesses the inheritance of alleles from heterozygous parents (for example, genotype *Aa*) to offspring affected with disease. For a locus not linked or associated with disease, the *A* allele would be expected to be transmitted to the offspring 50% of the time and the *a* allele 50%. The TDT examines large number of families and tests for a deviation from the expected 50:50 transmission of alleles. An allele that is transmitted more than 50% of the time is linked and associated with disease. For equivalent power, more samples need to be tested in a TDT (2 parents and 1 offspring) compared with a case control study (1 case and 1 control) so most researchers now undertake case–control association studies.

H H T H H H H T T H   T H H H T T T T H T
1st attempt   2nd attempt
7 H, 3 T   4H, 6T

Fig. 37.3 The influence of chance on results from case–control studies when sample sizes are small. I flicked a 2p coin 10 times and the results are shown, where H = heads and tails = T. If I did this a large number of times, I would expect 50% H and 50% T. Indeed, overall, there were 11H and 9T, almost 50:50. In this small sample, however, by chance, there were 7 H and 3 T at the first attempt but more T than H the second time. If the first attempt was cases and the second attempt controls, one might conclude that H is more common in cases and T more common in controls, i.e. that H is associated with being a case rather than a control. Although this is an extreme example and such small sample sizes would never be published for a genetic association study, it illustrates the point that small sample sizes can bias findings; the larger the sample size, the more robust the estimates of true allele frequency are.

Case–control association studies remain the most popular and effective way of identifying loci that increase susceptibility to musculoskeletal diseases, but other designs are required to address important clinical questions. For example, patients vary in their response to treatment and, in extreme cases, can develop serious side effects. **Nested case control** or **cohort study** designs can be used to identify genetic contributions. For example, if response to therapy is measured using a continuous scale such as the 28 joint count disease activity score (DAS28) used in RA, then the sample will consist only of cases with RA treated with the drug of interest and on whom the DAS28 at specific time points is recorded. Logistic regression analysis can be used to correlate changes in the DAS28 over time with genotype. Similarly, investigation of genetic variants influencing other outcome measures, such as the development of erosions in RA, require prospectively recruited cohorts of patients in which some will develop erosions and others will not, by specified time points.

Clinical applications of genetics

Currently, the only routine genetic test performed in musculoskeletal settings is testing of thiopurine S-methyltransferase (TPMT) polymorphisms in patients starting azathioprine. Variations in the gene have a large effect on the activity of the enzyme and metabolism of azathioprine. Hence, knowledge about the genotype can inform clinical decisions about whether to start azathioprine and at what dose. Although a huge number of genetic associations have been discovered in the past 5 years for a range of musculoskeletal diseases, it is too soon for these breakthroughs to translate into the development of new drugs, but that aim is actively being pursued by many research groups. In coming years, the breakthroughs in identifying genetic variations increasing the risk of common musculoskeletal conditions should lead to a better understanding of how these diseases occur and how they can be better treated or prevented.

CHAPTER 38

Environment

Christopher R. Holroyd, Nicholas C. Harvey,
Mark H. Edwards, and Cyrus Cooper

Introduction

Musculoskeletal disease covers a broad spectrum of conditions, the aetiology of many of which remains poorly understood. It is generally accepted that most chronic diseases result from both genetic predisposition and environmental exposures, and there is increasing evidence that the interaction between the two plays a major role. Recent attention has focused primarily on identifying possible genetic risk factors, and although this has provided clues regarding disease pathogenesis, it is becoming clear from genome-wide association studies (GWAS) that fixed genetic variation leaves a substantial part of disease variability unexplained. Environmental factors and their interaction with the genome may account for a greater proportion of chronic disease risk than previously thought, and thus represent a large missing piece of the puzzle. Attention might sensibly be focused on developing methods to assess an individual's environmental exposure with the same precision currently employed in the characterization of fixed genetic variation.

In this chapter we discuss the importance of evaluating environmental exposure and describe the evidence that disease pathogenesis may be partly determined by the interplay of environment and genotype, through mechanisms such epigenetics. We then describe the environmental influences on musculoskeletal disease across the whole life course, using three examples: osteoarthritis (OA), osteoporosis, and rheumatoid arthritis (RA).

Gene–environment interactions

It has long been proposed that many musculoskeletal diseases have a large genetic component. Advances in genotyping technologies over recent years, such as the introduction of the polymerase chain reaction and the completion of the Human Genome project, have made it possible to perform association studies on a genome-wide basis by analysing large numbers of single nucleotide polymorphisms (SNPs) spread at close intervals across the genome, rather than focusing in on one gene at a time. These GWAS have been applied to many rheumatic diseases, and have identified numerous potential genes involved in their pathogenesis. Interestingly, the effect size of most of the polymorphic variants identified has been small and variants identified in one study may not be consistently reproduced in others.

Although future studies employing more detailed assessment of the genome may yet delineate a substantial fixed genetic component of disease pathogenesis, it is likely that non-genetic 'environmental factors' and subsequent gene–environment interaction contributes to a substantial proportion of risk. Gene–environment interactions are thought to be involved in most complex diseases and explain how a specific genotype may result in several different phenotypes depending on environmental factors. This concept underlies the phenomenon of developmental plasticity, ubiquitous in the natural world.

If the interplay of complex environmental and genetic factors is to be elucidated, it is important that both genetic variation and environmental exposures are reliably measured. While GWAS techniques continue to be refined, there has been a relative paucity in the effort to accurately assess the other half of the gene–environment equation. It is essential that modern methods are developed to assess an individual's environmental exposure with the same precision as is possible for the individual's genome.

The exposome

The concept of the 'exposome' was first proposed in a 2005 editorial.[1] It is defined as a record of all environmental exposures, both internal and external, that an individual receives over their lifetime, from conception through to childhood, early and late adulthood, and finally death. These exposures are numerous and include environmental chemicals, radiation, diet, drugs, behaviour and lifestyle, infections, and psychological stress (Figure 38.1). Unlike the genome, which is fixed at conception, an individual's chemical environment is dynamic and varies over the life course due to changes in internal and external exposures. Thus, characterizing the human exposome is likely to be extremely challenging and would require longitudinal sampling, especially during critical time points such as fetal development, puberty, and early adulthood. Generally long-term exposures are not assessed and often any environmental exposure data that is collected in studies is via questionnaire-based methods which may be limited in their capacity to capture comprehensive and accurate data. This is particularly common in dietary assessment, which is particularly prone to measurement error, and highlights the need to improve the tools used for quantitative exposure assessment.

Two approaches have been suggested by epidemiologists to characterize the exposome: a 'bottom-up' or 'top-down' strategy (Figure 38.2).[2] A top-down approach measures both exogenous and endogenous chemicals such as protein adducts, metals, and metabolites as well as gene expression using repeated blood samples collected during the life of an individual. This would identify all potentially important exposures, but would provide no information regarding source. The bottom-up approach would involve

sampling water, dietary sources, and air, with subsequent quantification of chemicals in the samples. This would identify potential exogenous exposures and their sources, but would miss any endogenous exposures such as gender, obesity, and psychological stress. It is currently not possible to measure all chemicals in blood, so it has been suggested that the focus should be on classes of substances that are known to be biologically active.[2] Although challenging, the exposome could promote discovery of key exposures responsible for chronic disease and potentially pave the way for personalized medicine.

Epigenetic mechanisms

Key times in the potential influence of the exposome on adult chronic disease are the period in utero and early infancy. There is increasing evidence that epigenetic mechanisms are central to the process by which early environmental exposure affects health and disease in later life. Epigenetics literally means 'above genes' and refers to changes in phenotype, usually mediated by altered gene expression, caused by mechanisms other than changes in the underlying DNA sequence. These changes are stable and heritable, and may last through multiple generations.[3] The most studied epigenetic mechanism is DNA methylation, which involves the addition of a methyl group to DNA mainly at CpG sites. Methylation within the promoter area of genes generally leads to gene repression. Thus, there is usually an inverse relationship between the extent of CpG methylation and gene expression. At the single-cell level, a gene is either methylated or not (i.e. 0 or 100%), but across a tissue, some cells will contain a methylated gene and some an unmethylated gene. This balance of methylation and non-methylation across the whole tissue allows a continuous range of methylation (0–100%) at the tissue level, and thus a graded relationship between environment and gene expression.

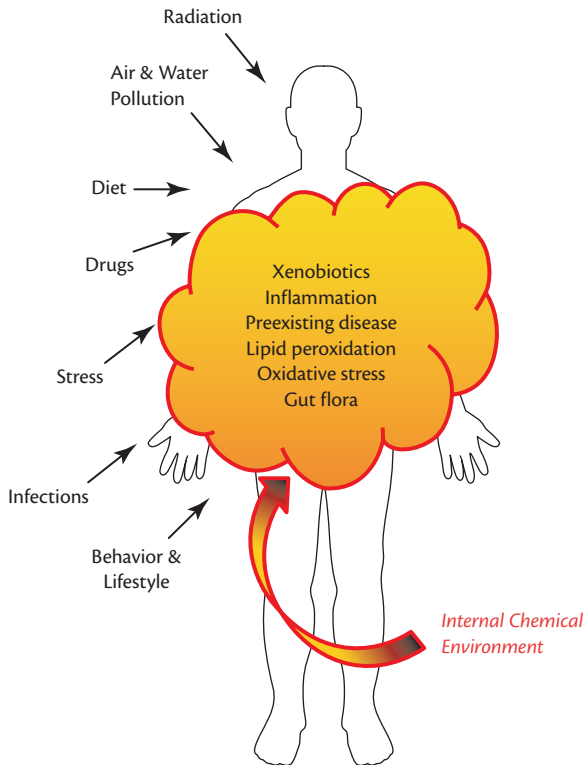
Histone modification is a second epigenetic pathway and involves post-translational changes of the amino acids that make up histones. Histones are small proteins involved in packaging of DNA into chromatin. If the amino acids in the chain are changed, the shape of the histone will be modified and consequently the way that DNA is wrapped around the histones may also change, leading to


Fig. 38.1 The exposome represents the combined exposures from all sources that reach the internal chemical environment.

alterations in gene expression. The two types of epigenetic modification are mechanistically linked and work together to determine which gene or gene set is transcribed.

DNA methylation is an essential process for normal development in higher organisms. Patterns of methylation differ through the phases of development: after conception, and with the exception of imprinted genes, gamete methylation patterns are erased during early blastocyst formation. During embryonic and fetal development, maternal or environmental factors can disrupt the patterns of DNA methylation; examples of this process have been shown in animal models. Abnormal DNA methylation during development may permit specific genes to undergo inappropriate expression during adult life, resulting in disease development.[4]

The first example of an association between a periconceptional exposure and DNA methylation in humans was shown in Dutch subjects prenatally exposed to famine during the Dutch Hunger Winter in 1944–1945.[5] Exposed subjects showed persistent epigenetic differences in a variety of genes compared to their unexposed, same-sex siblings. Epigenetic mechanisms are now well established in the development and progression of a variety of cancer types,[6] and there is increasing evidence that they may have a role in the development of musculoskeletal disease.

The remainder of this chapter focuses on the environmental influences on three musculoskeletal diseases: osteoporosis, RA, and OA.

Osteoporosis

Genetic factors

Although it has been estimated that between 50% and 85% of the variance in bone mineral density (BMD) is genetically determined,[7] genes identified by over 10 GWAS only account for 4–5% of the genetic variance in BMD. Genetic regulation of bone mass is likely to be determined by numerous genes, all with a small effect size.[8] Of the genes identified, many encode proteins known to influence bone mass, such as oestrogen receptor 1 (ESR1), vitamin D receptor (VDR), lipoprotein receptor-related protein 5 (LRP5), and the tumour necrosis factor (TNF) receptor superfamily (TNFSF). The mechanisms by which other identified genes affect bone mass remains unknown. Examples include microtubule-regulating kinase 3 (MARK3) and the major histocompatability complex (MHC).

Early environmental factors

There is evidence that the risk of osteoporosis might be modified by early environmental factors. Retrospective studies of adults aged 60–75 years have shown that there is a significant relationship between low weight at 1 year and reduced adult bone mineral content (BMC) at the spine and hip in late adulthood.[9] Similarly, poor growth in utero and during the first year of life, using the same cohort, was associated with alterations in bone architecture, cortical size and geometry, with a reduction in BMC, resulting in increased fracture in later life.

Prospective studies of mother–offspring cohorts have shown that certain maternal lifestyle factors during pregnancy and body composition are associated with offspring bone mass at birth and in later childhood.[10–12] Independent predictors of greater neonatal BMC include greater maternal birth weight, height, parity, fat stores (triceps skinfold thickness), and lower physical activity in late pregnancy. Maternal smoking is associated with lower neonatal bone mass. Maternal serum 25(OH)-vitamin D concentration has also been associated with reduced offspring bone mass at birth and in later childhood.[12]

Late environmental factors

Lifestyle factors associated with low bone mass include excess alcohol, smoking, low calcium intake, low body weight, physical inactivity, and vitamin D deficiency.

Smoking is directly toxic to bone cells and is associated with reduced BMD and increased fracture risk. In a large prospective study of 116 229 women, current smokers were seen to have an increased risk for hip fracture compared to those who have never smoked (relative risk = 1.3).[13] These findings have been consolidated in a meta-analysis which estimated that smoking increases lifetime hip and vertebral fracture risk by 31% and 13% in women and 40% and 32% in men respectively.[14] Most studies have reported a dose–response relationship, with increasing fracture risk with increasing amounts smoked. Cessation of smoking is associated with a reduction in fracture risk over time.

Alcohol in moderation may have a positive effect on BMD and has been shown to reduce markers of bone turnover and parathyroid hormone levels.[15] However, excess consumption is associated with an increased fracture risk. A recent meta-analysis concluded that compared to non-drinkers, individuals who consume up to 1 drink per day have a lower risk of hip fracture (relative risk 0.8) and those who consume more than two alcoholic drinks per day have a higher risk.[16] There is some evidence that drinking beer increases fracture risk more than wine and spirits.

Calcium and vitamin D deficiencies are associated with bone loss. In the United States NHANES III survey, greater calcium intake was associated with higher BMD in women but not in men.[17] Supplementation with calcium alone has been associated with gains in BMD compared with placebo, but may be insufficient to prevent postmenopausal bone loss and fracture. Combining calcium supplementation with vitamin D may be more effective; a recent systematic review of randomized trials in which calcium or calcium in combination with vitamin D supplementation was administered to adults aged over 50 year concluded that supplementation was associated with a modest (12%) risk reduction for fracture of all types and a reduced rate of bone loss at the hip and spine.[18]

Regular weightbearing activity has been shown to increase or preserve BMD in young and middle-aged individuals, but appears insufficient alone to prevent postmenopausal bone loss.[19]

Gene–environment interactions

Two potential gene–environment interactions have been described in the pathogenesis of osteoporosis. Polymorphisms in the IL-6 gene have been associated with hip BMD in women who were more than 15 years post menopause and in those with inadequate calcium intake or without oestrogen replacement therapy.[20] Similarly, the interaction between lumbar spine BMD and VDR genotype has been shown to vary with birthweight.[21,22] Among individuals in the lowest third for birth weight, spine BMD was higher in individuals with genotype *BB* and in contrast, spine BMD was reduced in individuals with the same genotype in the upper third of birth weight distribution. This suggests that genetic effects on BMD may be modified by the uterine environment.

Epigenetic mechanisms

Epigenetic mechanisms may play a role in the pathogenesis of osteoporosis, although exact mechanisms remain to be elucidated. Epigenetic modifications may underlie the association between low maternal vitamin D, low umbilical cord calcium concentration, and reduced offspring bone mass. Vitamin D mediates its effects by acting upon vitamin D response elements in the promoter region of target genes, and in animal studies has been shown to influence genes encoding calcium transporters.[23] One study has demonstrated that the expression of the placental calcium transporter PMCA3 gene predicts neonatal BMC.[24] Modified expression of the genes encoding placental calcium transporters, by epigenetic regulation, might represent the means whereby maternal vitamin D status could influence neonatal bone mineral accrual.

Epigenetic modulation of the hypothalamic–pituitary–adrenal (HPA) axis may represent a second mechanism whereby poor maternal environment can impair offspring bone mineral accrual. Elevated levels of circulating cortisol in adult life have been associated with reduced BMD and increased rates of bone loss.[25] Animal studies have confirmed that protein restriction during pregnancy is associated with reduced methylation of key CpG-rich islands in the promoter region of the glucocorticoid receptor (GR) gene, and this results in elevated GR expression and features of hypercortisolism.[26]

Rheumatoid arthritis

Genetic factors

Candidate gene analysis and GWAS have identified numerous genes implicated in the pathogenesis of RA. Although the shared epitope of HLA DRB1 remains the strongest genetic risk factor, polymorphisms in other genes have been identified and replicated in different populations, such as the protein tyrosine phosphatase gene (*PTPN22*), which has a role in B- and T-cell regulation. The peptidyl arginine gene (*PAD14*) has also been implicated, but findings have not been consistently replicated across different populations. Recent work has focused on other genes such as CTLA4, FCRL3, and the major histocompatability complex 2A (MHC2A), and the possibility that certain polymorphisms may predict a patient's response to treatment.

Early environmental factors

There is limited evidence regarding the developmental origins of RA or the effect of exposures during early life. Data from the prospective Nurses' Health Study of 87 077 white women has suggested that increased birthweight may be associated with a twofold increase in the risk of adult onset RA, compared with those of average birthweight, even after adjustment for confounders and other potential risk factors.[27] One explanation for this finding is that individuals with a higher birthweight have lower serum cortisol levels, as do patients with RA, and may be unable to increase cortisol production in response to chronic inflammation and stress. These findings need replication before any firm conclusions can be made.

Late environmental factors

Most studies investigating potential environmental factors in the development of RA have focused on smoking, hormonal factors, and diet. Caffeine intake has also been investigated in some studies, yielding mixed and often inconclusive results.[28,29] Smoking has been consistently linked with RA, in terms of both disease risk and severity. Current smokers and those who have quit within 10 years appear to have a moderately increased risk of RA especially if the individual is male or seropositive.[30,31] Both duration of smoking and intensity appear to be risk factors, with heavy smokers having over a 13-fold increased risk.[30] After 10 years post-cessation of smoking, risk of RA appears to return to that of the normal population. Some studies have not implicated smoking as a risk factor for seronegative RA.[32]

High consumption of olive oil, fruit and vegetables, oily fish, or vitamin D (a 'Mediterranean diet')[33,34] have been suggested as playing a possible protective role in the development of RA. Red meat consumption has been implicated as moderately increasing the risk of inflammatory arthritis,[35] but this has not been confirmed in a more recent study.[36]

Other environmental factors that have been associated with RA include exposure to viruses (Epstein–Barr and parvovirus), blood transfusion, stress, and obesity; alcohol consumption and breastfeeding may have a protective role.

Gene–environment interactions

There is increasing evidence highlighting potential gene-environmental interactions in RA. A recent population-based case control study of 858 RA cases and 1048 controls suggested a potential interaction between smoking and the HLA DRB1 shared isotope.[37] The risk of developing seropositive RA was increased in individuals who smoked and carried double copies of the HLA DRB1 isotope compared to smokers with no copies of HLA DRB1. There is also evidence to suggest an interaction between smoking and the *PTPN22* gene.

Epigenetics

RA patients are generally considered to have a Th1-based phenotype; histone modification, particularly histone deacetylation, has been implicated in epigenetically regulating T helper cell differentiation.[38,39] Similarly smoking, which is associated with an increased risk for RA and a more severe disease outcome, has been shown to reduce the expression of the histone deacetylases (HDAC) SIRT1 and 2 in the lungs of rats.[40] Furthermore, pretreatment of macrophages with the SIRT1 activator significantly inhibited the smoke-induced production on proinflammatory cytokines. This has led to the development of HDAC inhibitors as therapeutic agents, which have been used with beneficial effects in vitro or in experimental models of RA.[41]

DNA methylation may represent a second epigenetic pathway. For example, methylation of genomic DNA of T cells derived from RA patients has been shown to be globally lower than that of T cells from healthy controls.[42] Areas of hypomethylation in the IL-6 gene have been identified in the peripheral blood mononuclear cells in RA patients compared to healthy donors.[43] It has been postulated that this hypomethylation may lead to increased expression of the proinflammatory cytokine IL-6.

Osteoarthritis

Genetic factors

It has been estimated from studies in twins that 58% of OA is genetic and it appears that different genes may influence the development of

OA at different sites. For example, the IL-1 gene cluster may confer susceptibility for knee OA but not hip OA.[44] Other potential genetic influences for the development of knee OA include the oestrogen receptor-alpha (*ESR1*) gene, the metalloproteinase gene (*ADAM12*), *GDF5*, and *PTGS2*, which encodes the enzyme cyclooxygenase 2. The frizzled-related protein-3 (*FRZB*) gene has been associated with hip OA in females. There appears to be greater genetic effects on OA of the hand compared to other sites, possibly due to the relatively weaker environmental role in the pathogenesis of hand OA. There is a moderately increased risk of familial clustering of hand OA, especially amongst sisters of women severely affected by hand OA. Genes associated with hand OA include *VDR* and *MATN3*, which encodes the extracellular matrix protein, matrilin-3.

Early environmental factors

A few studies have described a relationship between birthweight and the development of OA. In the MRC National Study of Health and Development, a prospective study of 2986 men and women, low weight at birth was associated with the development of hand OA in men, but not in women, at age 53 years.[45] Similarly, in a separate United Kingdom cohort, the Hertfordshire Cohort, low birthweight and weight at 1 year was associated with an increased prevalence of lumbar spine OA in men aged 65 years.[22]

Late environmental factors

Major cohort studies of OA, such as the Framingham Study,[46] the Chingford 1000 Women Study,[47] and the Bristol OA500 Study[48] have identified several environmental risk factors associated with OA. Of these, obesity, prior joint surgery, and physical activity are most frequently reported. Obesity, which is the main preventable risk factor, has been repeatedly shown to significantly increase the risk of knee OA in both sexes. In addition, high body mass index (BMI) is more strongly associated with bilateral rather than unilateral knee osteoarthritis. Results from the Framingham Osteoarthritis Study and other cohorts suggest that weight loss reduces the risk of developing knee OA. Individuals who lost weight in the 10-year period prior to their baseline radiograph had a 50% reduction in the odds of having radiographic knee OA for every 2 kg/m^2 decrease in BMI.[49] There is also a positive association between obesity and hip OA; however, this appears to be of lower strength than that observed with knee OA. Some authors have reported an association between obesity and hand OA but results have been conflicting and the relationship remains controversial.

Individuals with a history of regular sports participation or who have abnormal or injured joints are also at an increased risk of OA. Data again from the Framingham cohort have shown that the number of hours per day of heavy physical activity was associated with the risk of incident radiographic knee osteoarthritis (odds ratio = 1.3 per hour) after adjustments were made for confounding factors.[50] Risk was greatest among individuals in the upper tertile of BMI who performed more than 3 hours/day of heavy physical activity. No association was seen from moderate and light physical activity, number of blocks walked, or number of flights of stairs climbed daily.

Gene–environment interactions

There is some evidence of a gene–environment interaction in the development of OA. Prevalence of lumbar spine OA has been shown to vary according to VDR genotype and birthweight.[21,22]

Among individuals in the lowest third for birth weight, individuals with genotype 'BB' had an increased prevalence of vertebral osteophytes; in contrast, prevalence of osteophytes was reduced in individuals of the same genotype in the highest third of birthweight distribution.

Epigenetics

Despite a relative paucity of data, early evidence points to a possible role of epigenetics in OA. Differences in the promoter methylation status of genes associated with OA have been observed in a few small studies. For example, 8 out of 9 patients with OA had at least one unmethylated site in the promoter region of the *MMP9* gene, whose expression is increased in OA, compared to 1 out of 5 controls. Further studies have reported differences in the methylation status in the MMP-3 and ADAM-TS4 gene promoter regions in chondrocytes from patients with OA compared to patients without OA. Although these studies have shown an association, there was considerable variation between patients and further work is needed to prove that hypomethylation results in the activation of degradative enzymes involved in OA.

Conclusion

It is likely that most chronic musculoskeletal disease results from a combination of genes, environmental factors, and an interaction between the two. There is increasing evidence for the role of the environment in early life, in addition to later environmental influences in osteoporosis, RA, and OA pathogenesis. Lifelong environmental influences (the exposome) are difficult to capture; however, addressing gene–environment interactions, with better assessment of the exposome, may lead to novel strategies to reduce the burden of chronic musculoskeletal disease in future generations.

CHAPTER 39

Epigenetics

Steffen Gay and Michel Neidhart

Introduction

Epigenetics is defined as the study of heritable changes in gene expression that are not due to changes in DNA sequences. The importance of environmental influences and epigenetic changes in the development of cancer and other diseases is increasingly being noticed. The involvement of factors such as drugs, UV light, infection, and diet, is reflected by the facts that the frequency of the consequential abnormalities differs from country to country and that geographic segregation of patients suffering from a given autoimmune disease has been identified.[1] The perplexing observation that concordance with respect to rheumatoid arthritis (RA) or systemic lupus erythematosus (SLE) is never 100% in monozygotic twins[2] raises the question as to what happens to the transcription and translation machineries between the genotype upstream and the phenotype downstream. The discordance results, at least in part, from epigenetics, which has been cited as a mechanism by which cells with as few as 30 000 genes differentiate into so many different cell types and vary so extensively at different developmental and functional stages. Epigenetics also plays a key role in the development of diseases associated with ageing. The molecular basis for epigenetics is in great part elucidated (Figure 39.1), involving chemical modifications of the DNA itself or to histones, which are proteins closely associated with DNA. In addition, a prominent role for microRNAs is also emerging.

Molecular basis of epigenetics

DNA methylation

DNA methylation is a crucial epigenetic modification of the genome that is involved in regulating many cellular processes (Figure 39.2). These include embryonic development, transcription, chromatin structure, X chromosome inactivation, genomic imprinting, and chromosome stability. The only known epigenetic modification of DNA in mammals is the methylation of cytosine at position C5 in CpG dinucleotides.[1,3] The most efficient way to silence gene transcription is to prevent the binding of transcription factors to DNA. To achieve this, DNA methyltransferases (DNMTs) convey a methyl group to the 5′ carbon position of cytosines of CpG dinucleotides. The mammalian DNA methylation machinery is composed of two components: the DNMTs, which establish and maintain DNA methylation patterns, and

the methyl-CpG binding proteins (MBDs), which are involved in 'reading' methylation marks.

Methylation of CpG dinucleotides

The methylation process is catalysed by the protein family of DNMTs, which uses the methyl donor S-adenosylmethionine (SAM) to specifically methylate the fifth carbon atom of the cytosine ring. In normal cells, DNA methylation occurs predominantly in repetitive genomic regions, including satellite DNA and parasitic elements such as long interspersed transposable elements (LINES), short interspersed transposable elements (SINES), and endogenous retroviruses.[3] DNA methylation is a potent mechanism for silencing gene expression and maintaining genome stability in the face of a vast quantity of repetitive DNA, which can otherwise mediate illegitimate recombination events and cause transcriptional deregulation of nearby genes. The silencing of genes allows cell differentiation and explains how, for example, a neuronal cell can be different form a muscle cell in spite of the same genetic background.[4] The methylation of CpG dinucleotides represses transcription directly, by inhibiting the binding of specific transcription factors, and indirectly, by recruiting MBDs.

DNA methyltransferases

DNA methylation is catalysed by a group of enzymes in mammals called DNMT1, DNMT3a, and DNMT3b. DNMT1, known as the 'maintenance methyltransferase', has been shown to have a 10-fold preference for hemimethylated DNA (only one of the two DNA strands is methylated) compared with an unmethylated strand, and is used mostly by the cell to maintain the DNA methylation status in a stable fashion through cell division.[5] DNMT3a and DNMT3b, known as 'de-novo' methyltransferases, are used by the mammalian cell to methylate previously unmethylated DNA.

In somatic cells, DNMT1 is the predominant DNA methyltransferase.[6,7] The direct interaction between DNMT1 and proliferating cell nuclear antigen ensures that patterns of methylation are faithfully preserved in DNA synthesis.[8,9] Reduction of DNMT1 levels leads to hypomethylation, genomic instability, and tumorigenesis.[10]

Methyl-CpG binding proteins

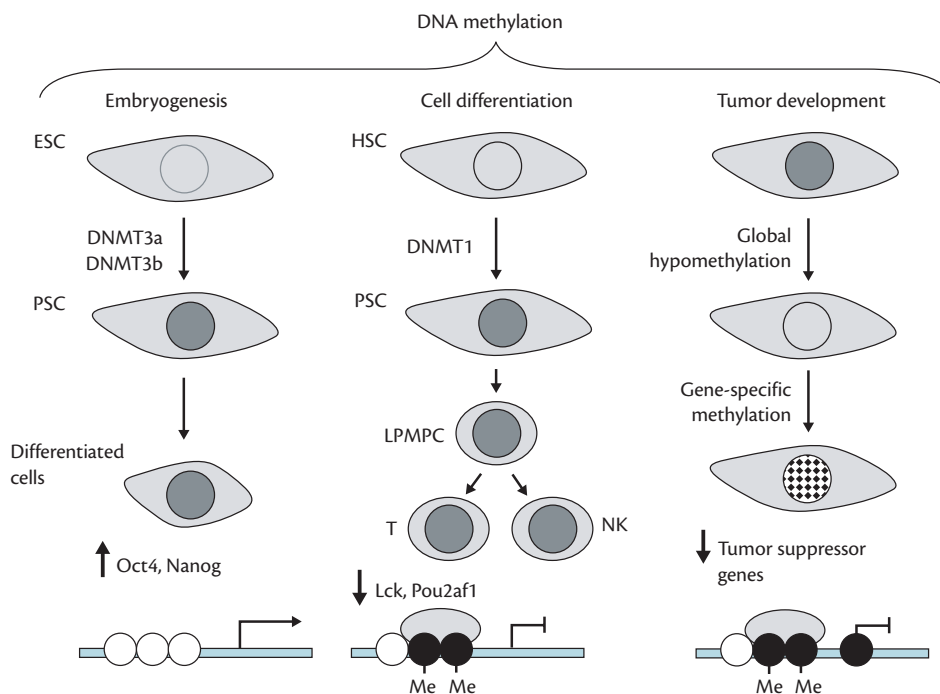
DNA methylation leads to silencing by direct inhibition of transcription factor binding to their relative sites and by recruitment
Fig. 39.1 Epigenetic mechanisms.


Fig. 39.2 Biological processes involving DNA methylation.

of methyl-binding domain proteins (MBDs),[11] for example MDB1, MeCP2, MBD3, and MBD4. These MBDs are present in transcription corepressor complexes involving several other members of the epigenetic machinery such as histone deacetylases and histone methyltransferases, resulting in chromatin reconfiguration and gene silencing.[12,13] The deletion of MeCP2 causes the neurodevelopmental disorder called Rett's syndrome.[14]

Histone modifications

The nucleosome is the basic subunit of chromatin. It consists of 146 base pairs (bp) of DNA wrapped around an octamer of two copies each of H2A, H2B, H3, and H4 classes of histones. Nucleosomes, of which there are an estimated 10 million per cell, are organized into regular arrays.[1] These structures present as small glomerular

proteins with a flexible N-terminal tail protruding from the nucleosome that is accessible to modifications that impart functional capacities to the histones. They are small globular proteins with flexible N-terminal tails that project from the nucleosome and hence are available for molecular interactions. The tails can be extensively modified.[15] The modifications include acetylation, methylation, ubiquitination, phosphorylation, sumoylation, deimination/citrullination, ADP-ribosylation, and proline isomerization. Each modification serves a specific purpose. Good examples of opposite effects are enhancement of transcription by histone H3K9 acetylation and repression of transcription by histone H3K9 methylation.

Histone acetylation

Histone acetylation is generally associated with regions of actively transcribed chromatin. The addition of an acetyl group to lysine residues within the histone tail neutralizes their positive charge, thereby disrupting the interaction with the negatively charged DNA which loosens up the chromatin structure. In addition, transcriptional activators are recruited by these acetyl-lysines via bromodomains and enhance gene activity.[16] The enzymes adding and removing acetyl groups from lysine residues in the histone tails are histone acetyltransferases (HATs) and histone deacetylases (HDACs), respectively.[17] The status of histone acetylation results from an intricate cross-talk between HATs and HDACs. HATs are separated according to their cellular location and function into two distinct groups: the cytoplasmic B-type HATs and the nuclear A-type HATs.[18] The latter are presumed to have more impact on gene transcription, whereas cytoplasmic HATs can catalyse acetylation of non-histone proteins.

Histone deacetylation

HDACs are a class of enzymes catalysing the opposite action to HATs. They influence a myriad of cellular processes including signal transduction, apoptosis, cell cycle regulation, and cell growth.[19] HDACs catalyse deacetylation of both histone and nonhistone proteins and, similar to HATs, can be either nuclear or cytoplasmic. This cytoplasmic deacetylase activity can lead to post-translational modifications of transcription factors and chaperone proteins, and can have major effects on several important pathways, such as the NF-κB pathway,[20] the APE1-Ref1 oxidative stress response pathway,[21] and the phosphatase and tensin homologue (*PTEN*) phosphatase gene.[22] Similarly to HATs, HDACs exert their catalytic activity through an association with protein complexes, such as the sirtuin 1 (SIRT1) protein deacetylase complex.[23]

Histone methylation

In contrast to acetylation, methylation of histone residues can either activate or repress gene expression. Methylation of histone 3 lysine 4, 36, and 79 (H3K4, H3K36, and H3K79) is found at active genes, methylation of histone 3 lysine 9 and 27 and histone 4 lysine 20 (H3K9, H3K27, and H4K20) at transcriptionally repressed genes.[15] Histone lysine methyltransferases catalyse the addition of up to three methyl groups in a site-specific manner, i.e. these enzymes can only recognize lysine residues within a very specific sequence of amino acids. Accordingly, also histone lysine demethylases act site-specific. The methylation of arginines is catalysed by protein arginine methyltransferases. Up to now there is only one report of a histone arginine demethylase.[24] Removal of the methyl group can also occur by demethylimination by peptidylarginine deiminase 4 (PAD4). The residue is thereby converted to citrulline.[25]

MicroRNAs

MicroRNAs (miRNAs) consist of 21–23 bp of RNA and function as post-translational regulators of gene expression.[26] One-third of the human transcriptome is regulated by about 1000 miRNAs. These oligonucleotides are first synthesized as long, non-coding RNAs that are processed by the RNA cleaving enzyme DROSHA in the nucleus, transported into the cytoplasm in the form of short hairpin RNAs, and further cleaved by the enzyme DICER into their final configuration of double-stranded miRNAs.[27] The miRNAs are then incorporated into the RNA-induced silencing complex. Through Watson–Crick base pairing, miRNAs bind to complementary sequences of mRNAs and induce either degradation or translational silencing of the target mRNAs. It is interesting to note that miRNAs are also themselves epigenetically regulated at their promoter level, and target many genes that play important roles in such processes as cell cycle progression, apoptosis, and differentiation.[28] A single miRNA can have hundreds of target mRNAs, highlighting the implication of this gene regulation system in cellular functions.[29] By controlling the accumulation of the target protein(s) in cells, these regulatory RNA molecules participate in key functions in many physiological networks and their deregulation has been implicated in the pathogenesis of serious human disorders.[30]

Epigenetics in health and disease

Epigenetics play a fundamental role in biological diversity such as phenotypic variation among genetically identical individuals.[31] It could also explain the phenotypic differences between monozotic twins, especially regarding the susceptibility to certain diseases.

Embryogenesis

The fact that all of the cells in a multicellular organism arise from a single original cell indicates that tremendous phenotypic variability can occur among cells that share a common genome. On the organism level, it has been shown that monozygotic twins can differ in disease susceptibility and many anthropomorphic features.[32] These phenotypic differences in the context of a common genome are attributed to epigenetic factors. During embryogenesis, disruption in epigenetic regulation, such as aberrant DNA methylation, can lead to malformation, disease, or death.[3,33] Embryonic lethality results if the normal DNA methylation patterns are disrupted by absence of DNMT1.[34] Experiments in conditional mutants have shown that offspring of female animals that lack DNMT3a specifically in germ cells, die in utero and have disrupted DNA methylation and allele-specific expression at multiple maternally imprinted loci.[35] DNA methylation is critical for differentiation, but not essential for maintenance of the undifferentiated state, as it has been observed that triple knockout (Dnmt1(−/−) / Dnmt3a(−/−) / Dnmt3b(−/−)) embryonal stem cells proliferated normally and continued to express known pluripotence-associated markers, such as Oct4 and Nanog.[36] These cells only showed evidence of impaired proliferation when they were induced to differentiate.

Cell differentiation

Haematopoeitic progenitor cells can differentiate into lymphoid-primed multipotent progenitor cells, and the common lymphoid progenitors derived from these cells give rise to lymphocytes and NK cells. They have a reduced ability to develop into cells of the megakaryocytic or erythroid lineages. The dynamic generation

of blood cells in the adult seems to be designed in a manner that allows each sub-branch of the system to operate autonomously.[37]

Many genes that are initially methylated in stem or precursor cells are found to undergo selective demethylation in a tissue- or lineage-specific manner. These genes include *Lck*, which undergoes demethylation in T cells and encodes a SRC family kinase that is responsible for initiating signalling downstream of the T-cell receptor, as well as POU domain class 2-associating factor 1 (*Pou2af1*), which encodes a B-cell-specific coactivator and undergoes demethylation in B cells.

Tumour development

Cancer cells have genome-wide aberrations at the epigenetic level, including global hypomethylation, promoter-specific hypermethylation, histone deacetylation, global down-regulation of miRNAs, and upregulation of certain actors of the epigenetic machinery such as EZH2. These aberrations confer a selective growth advantage to neoplastic cells. In various cancers, the 5-methylcytosine content was found to decrease by an average of 10%,[38] leading to apoptotic deficiency, uninhibited cellular proliferation, and tumorigenicity.[39]

Hypomethylation in cancer

Global DNA hypomethylation was the first epigenetic alteration noted in cancer cells.[40] Hypomethylation in tumor cells is primarily due to the loss of methylation from repetitive regions of the genome (LINE-1 and Alu),[41] and the resulting genomic instability is a hallmark of tumour cells.[42] This chromosomal instability can be associated with rearrangements and reactivation of transposon promoters.[43–49] Loss of genomic methylation correlates with disease severity and metastatic potential in many tumour types. This leads to the disruption of normal gene expression and potential activation of growth-promoting and anti-apoptotic pathways. Furthermore, promoter hypomethylation can lead to reactivation of miRNAs embedded in the coding regions of certain genes, resulting in silencing or aberrant expression of the corresponding protein.[28] Hypomethylation by genetic disruption of DNMT1 is

protective against carcinogenesis in some models,[50] but can also promote tumour formation in others.[43]

Promoter-specific methylation in cancer

DNA methylation is an alternative way of silencing tumour suppressor genes, in a manner equivalent to genetic mutations.[44,45] Examples of this mechanism of tumorigenesis are numerous, notably methylation of the mismatch repair gene human mutL homologue 1 (*MLH1*) in colorectal cancer, the DNA repair gene O-6-methylguanine-DNA methyltransferase (*MGMT*) in gliomas and colorectal cancer, and the cell cycle regulator *p16* (cyclin-dependent kinase inhibitor 2A, *CDKN2A*) in colorectal and other malignancies.[46] Similar to mutations, silencing of tumour suppressor genes confers a selective proliferative advantage to corresponding cells, mediates invasiveness, and facilitates metastasis.

Non-neoplastic diseases

Diseases such as cardiovascular, metabolic, musculoskeletal, and haematopoietic disorders, which can be attributed to the interaction between genetic and environmental factors as well as to processes of ageing, are highly prevalent in industrialized nations and can be associated with a large burden on healthcare resources.[47,48] They are influenced by environmental factors, as in the contribution of smoking to the development of rheumatic diseases and atherosclerosis.[49] Metabolic disorders (e.g. obesity and diabetes)[50] and neurodegenerative disorders such as Alzheimer's disease and dementia[51] can also have an epigenetic component (Figure 39.3).

Metabolic and cardiovascular diseases

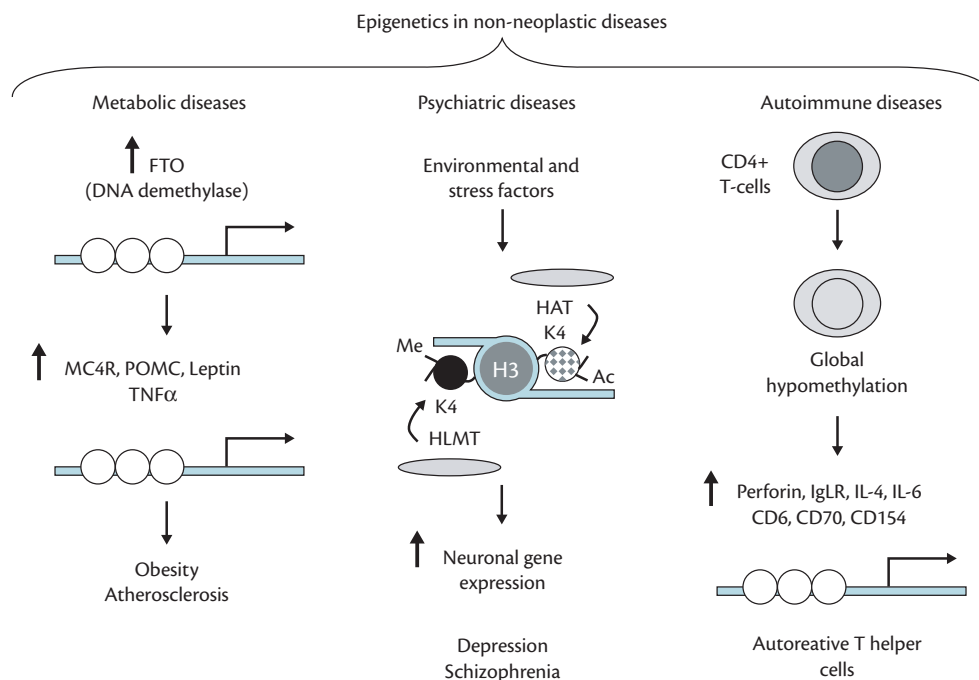
Obesity results from interactions between environmental and genetic factors. Known susceptibility variants do not fully explain the heritability of obesity and therefore other forms of variation, such as epigenetic marks, have been considered.[52] Failures in imprinting are known to cause extreme forms of obesity (e.g. Prader–Willi syndrome), but have also been associated with susceptibility to obesity. It


Fig. 39.3 Epigenetic imbalance in non-neoplastic diseases.

has been shown that obese mothers tend to have obese children and that clinical interventions causing maternal weight loss reduced risk of obesity in the offspring. Evidences indicate that the establishment of the epigenome can be affected by environmental factors during critical development periods. Possible disturbances of methylation may arise during fetal development due to a lack of availability of dietary methyl donors.[53] Potential interactions between the environment and DNA methylation mediating the expression of genes associated with increased body mass index and adiposity also has been suggested for the following loci: *FTO*,[5,53] *MC4R*,[54] *POMC*,[61] and leptin.[55] Interestingly, the *FTO* locus encodes for a DNA-demethylase enzyme,[59] and polymorphisms of this gene were associated with obesity in Pima Indians,[63] a population with increased incidence of RA.[56] Polymorphism in the *MC4R* gene also has been associated with RA.[57] In rats, hypermethylation of the proopiomelanocortin (POMC) promoter leading to decreased hypothalamic–adrenocortical activity has been associated with obesity.[61] Furthermore, in obese patients, tumour necrosis factor alpha (TNFα) promoter methylation is a predictive biomarker of hypocaloric diet-induced weight loss.[58] Thus, great similarities are found between metabolic and inflammatory diseases. Adiposity is a predisposing condition to atherosclerosis and RA accelerates the process. Endothelial dysfunction and carotid intima–media thickness, early preclinical markers of atherosclerosis which are the main determinants of cardiovascular morbidity and mortality, occur early on in RA.

Psychiatric diseases

Environmental factors signal to the neural stem cell genome to regulate cell fate decisions and neurogenesis.[59] Sequence-specific transcription factors work in concert with the chromatin machinery to direct the neuronal lineage programme within neural stem cells. In the stem cell state, repressive chromatin remodelling machinery maintains neuronal gene repression through one set of histone modifications, such as H3K9 methylation and DNA methylation. Stimulation by environmental factors and/or stress signals (during disease) can induce adult neurogenesis and survival/maturation of newborn neurons by derepressing or activating neuronal gene expression through the hyperacetylation and/or switch in histone modification to H3K4 methylation. Epigenetic modifications in various brain regions were linked to neuropsychiatric disorders, including depression[60] and schizophrenia.[73] In addition, a wealth of information is known to date about epigenetic modifications with regards to hippocampal function and dysfunction.[74–77]

Autoimmune diseases

Accumulation of autoreactive lymphocytes and production of antibodies against a wide range of self-antigens are the hallmarks of autoimmune diseases that damage kidneys, skin, lung, and other organs.[61] The role of genetics has been suggested by the observation that the incidence of SLE is fivefold higher in monozygotic twins than in dizygotic twins. However, the concordance rate between monozygotic twins can range from 5% to 75%, and these variations suggest the involvement of additional triggers from the environment.[61] The CD4+ lymphocytes of patients with SLE, but not their CD8+ T lymphocytes, manifest a defective capacity to methylate their DNA; the degree of this inhibition correlates with disease activity.[79] The consequence of this fault is that several methylation-sensitive autoreactivity-promoting genes are overexpressed in CD4+ T cells, including those for perforin, immunoglobulin (Ig)-like receptor, interleukin (IL)-4, IL-6, and the B-cell costimulatory molecules CD70, CD6, and CD154.[80–84]

Variations have also been described in histones of CD4+ T cells from patients with SLE.[85] In particular, H3 and H4 acetylation levels have been shown to correlate negatively with disease activity.

Ageing

In peripheral blood lymphocytes, the pattern of DNA methylation of the two members of a pair of monozygotic twins, as well as their H3 and H4 acetylation profile, diversifies increasingly with ageing (Figure 39.4).[32] One reason for this is that the total genomic
Fig. 39.4 Variables influencing epigenetics: ageing, gender, therapies.

5-methylcytosine content decreases with age, but at different rates in each twin. Similarly, in tissue culture, genomic DNA is demethylated in the long term, particularly DNA of those genes involved in cell differentiation.[62] A supplementary reason for increased diversity of H3/H4 acetylation with age is that environmental exposure is cumulative, so that there is every likelihood that small initial differences will become substantial with time.

Although DNA methylation patterns in adult cells are relatively stable, important changes have been described in ageing tissues. A global decrease in 5-methylcytosine content was reported in cultured human fibroblasts[63] and promoter-specific hypermethylation was observed in epithelial tissues.[88,89] Global profiling demonstrated several hundreds of gene promoters to acquire methylation in intestinal mucosae of ageing mice, whereas hundreds of others were found to have a parallel loss of DNA methylation.[64] This linear change of 5-methylcytosine content with ageing has a strong tissue specificity and has been shown to be common across mammals. Indeed, both the amount and pattern of DNA methylation have been found to diverge between human monozygotic twins as they age.[32] An age-related decline in chondrocyte production of osteogenic protein-1 (OP-1) (Bone Morphogenetic Protein-7) may contribute to cartilage loss in osteoarthritis. Age-related methylation of the OP-1 promoter may contribute to a decrease in OP-1 production in cartilage and a decrease in expression of OP-1 responsive genes such as IGF-1, the IGF-1R, and aggrecan.[65]

Gender

Autoimmune diseases demonstrate a gender bias and represent the fifth leading cause of death by disease among females of reproductive age.[66] Studies in SLE and systemic sclerosis indeed point to a skewed X inactivation.[67,68] Clinical and murine experimental studies indicate that the gender bias in autoimmunity may be influenced by sex hormones.[69] RA is more common in women than in men, whereas atherosclerosis shows the reverse pattern.[70] With ageing, these sex-related differences become less obvious. An interesting question is whether sex differences in disease prevalences in middle-aged adults could be associated with differential imprinting of the X chromosome—an epigenetic process—since one X chromosome in women should always be inactivated by DNA methylation. In women, *Xist*, a large regulatory RNA transcribed from the X inactivation centre (XiC) is produced by the future inactivated X chromosome (Xi) and initiates the silencing process.[71] In the Xi chromosome, DNA methylation at gene promoter CpG islands (CGIs) has been correlated with permanent expression silencing.[11] The recent observation that demethylation of the inactivated X chromosome in CD4+ T cells from female SLE patients is associated with overexpression of the B-cell-stimulating CD40 ligand points to a potential reason for the female sex predominance in this autoimmune disease.[67]

Drugs

A number of drugs have been suspected of causing SLE, most notably procainamide, hydralazine, and 5-azacytidine. There is evidence that these drugs inhibit DNA methylation.[72,73] The same group have reported data supporting an increase in lymphocyte function-associated antigen expression and the ensuing proliferation of autoreactive T cells in patients with SLE.[74]

Epigenetics in rheumatoid arthritis

RA is a chronic inflammatory disease of the joints affecting around 1% of the population worldwide.[75] One of the main characteristics of this autoimmune-related disorder is the hyperplastic synovial lining composed of infiltrating inflammatory cells and synovial fibroblasts (Figure 39.5).[76] Beside cytokines and chemokines that fuel the synovial inflammation, these resident cells produce matrix-degrading enzymes which lead to a progressive destruction of articular cartilage and bone.[77] Although our understanding of the cause of RA remains patchy it is generally accepted that it arises from an interplay of genetic predisposition (in particular HLA-DR allele subtypes and specific gene polymorphisms), immunological
Fig. 39.5 Differentiation of fibroblasts and development of the activated phenotype in rheumatoid arthritis is controlled by epigenetics.

deregulation (e.g. autoantibody production), and environmental factors (such as nutrition, smocking, or exposure to infectious agents).[78,79]

TNFα derived from monocytes/macrophages is involved in the pathogenesis of RA, as shown by the beneficial effect of anti-TNF therapies.[80] Interestingly, the expression of TNFα is regulated by epigenetic mechanisms.[81] Thus, a positive correlation has been reported between high expression levels of TNFα and low methylation status. In non-responders to the TNF blockade (these represent up to one-third of the patients receiving TNFα blockers), inhibiting of a single cytokine does not seem to be enough to alleviate the symptoms. Furthermore, in many cases the symptoms return when therapy is stopped. This could be due to inflammation-independent processes or an epigenetically imprinted disease phenotype.[79]

Autoreactive T cells

T-cell development

RA patients are considered to have a Th1-biased phenotype.[75] Paradoxically, in synovial fluid, high levels of IL-4 and IL-13 can be measured in patients with early RA and very low expression in established disease;[80] this would implicate a temporary Th2 disposition in early RA. However, it should be noted here that RA is an infiltrating disease and that paradox patterns of T-cell subpopulations are often observed in the periphery during active disease.[82]

DNA hypomethylation

T cells of patients with RA exhibit an aberrant DNA methylation pattern (Figure 39.6).[74] The global methylation of genomic DNA of T cells derived from patients is reduced, compared to T cells from healthy donors. CD4+ T cells treated with the DNMT1 inhibitor 5-azacytidine respond to autologous antigen-presenting cells and induce autologous B-cell differentiation without exogenous antigen or mitogen.[83] T cells treated with DNMT1 inhibitors and ERK

pathway inhibitors overexpress CD70,[84] a costimulatory molecule for B cells. DNMT1 inhibitors also cause LFA-1 overexpression directly by demethylating the CD11a promoter.[85] Taken together, these mechanisms could contribute to T-cell autoreactivity, and potentially to autoimmunity.

Aggressive synovial fibroblasts

Mesenchymal stem cell development

Mesenchymal stem cells are undifferentiated, multipotent cells that reside in various human tissues and have the potential to differentiate into osteoblasts, chondrocytes, adipocytes, fibroblasts, and other cells of mesenchymal origin. In the human body they can be regarded as readily available reservoirs of reparative cells that are capable of mobilizing, proliferating, and differentiating into the appropriate cell type in response to certain environmental signals.[86] During the normal differentiation of mesenchymal stem cells into fibroblasts, two key transition points are regulated by epigenetic processes: first, the development of mesenchymal stem cells into a transient fibroblastic phenotype, and, second, the termination of lineage expansion. Both of these transition points are tightly regulated in space and time.[87] The hypothesis is that synovial fibroblasts emerge from mesenchymal stem cells and develop into tissue-specific cells under the influence of the microenvironment and under epigenetic control.[88]

Fibroblasts and phenotypic plasticity

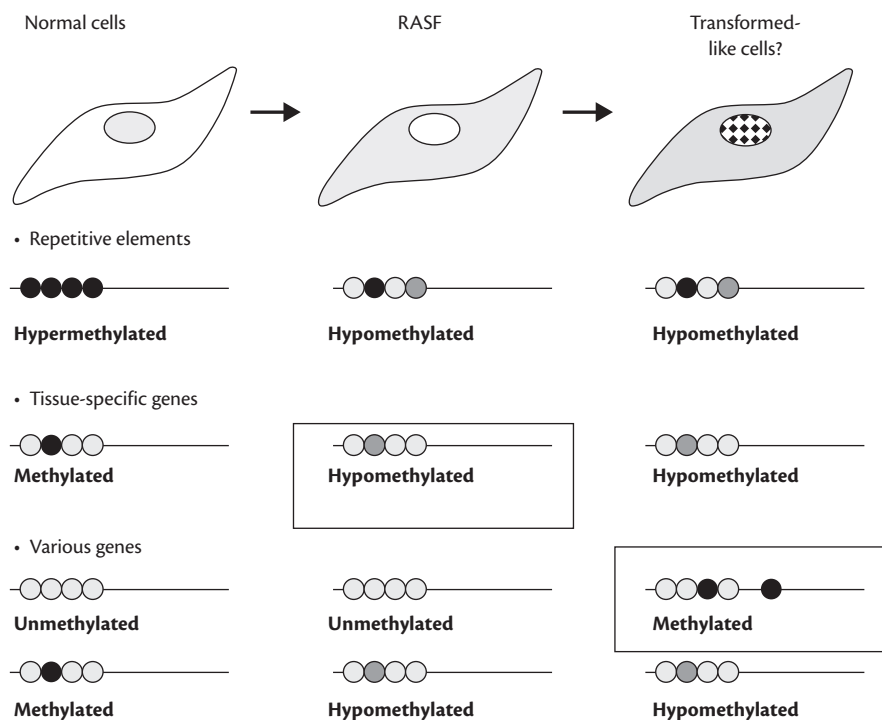
Fibroblasts are thought to develop specific characteristics in response to their microenvironment; for example, fibroblasts in the skin, spleen, kidney, lung, or synovium exhibit different patterns of growth factor release. To produce such characteristics, certain genes are silenced in fibroblasts in some tissues but expressed in those in other tissues. Specific patterns of gene expression are, in great part, under epigenetic control. Many diseases are associated


Fig. 39.6 Methylation in rheumatoid arthritis synovial fibroblasts (RASF).

with deregulation of the injury-repair response and fibroblast function, which leads to an increase or decrease in the deposition of extracellular matrix proteins, altered tissue architecture, impaired function, and, in some cases, substantial morbidity and mortality. In such cases, the fibroblasts are hypothesized to either not react or overreact to a given stimulus; this incorrect response can have different causes that include deregulated epigenetic controls.[78,88]

Rheumatoid arthritis synovial fibroblasts

In RA, a cytokine-independent pathway seems to be responsible for the ongoing joint destruction mediated by synovial fibroblasts.[78] The pathological changes associated with this process include excessive hyperplasia of the synovial tissue and an infiltration of inflammatory cells into it. The activated phenotype of RA synovial fibroblasts could be an intrinsic property of these cells, since these cells coimplanted with human cartilage into severe combined immunodeficient (SCID) mice are invasive even in the absence of other cells of the human immune system.[76] This concept is reflected in vitro by, for example, the increased production of matrix-degrading enzymes and adhesion molecules by these cells.[77] In contrast to normal synovial fibroblasts or those from patients with osteoarthritis, synovial fibroblasts from patients with RA show 'spontaneous' activities that are associated with an aggressive phenotype. For example, these cells show upregulated expression of proto-oncogenes,[76] specific matrix-degrading enzymes,[77] adhesion molecules,[89] and cytokines.[90] Histone acetylation is increased in RA synovial fibroblasts[88] and levels of specific miRNAs are changed,[91] suggesting that multiple epigenetic pathways in addition to genomic methylation[92] are altered.

DNA hypomethylation

The endogenous retroviral element LINE-1 is reactivated in the RA synovial lining and at sites of cartilage and bone invasion.[92–93] Most LINE-1 elements are retrotransposition-defective. The expression of LINE-1 proteins in RA synovial fibroblasts is associated with a partially hypomethylated promoter region.[92] The incorrect methylation patterns induce either cellular dedifferentiation or a completely new phenotype.[88] Genes normally silenced by methylation might contribute to the activated phenotype of rheumatoid arthritis synovial fibroblasts. For example, IL-6 could be upregulated due to demethylation of a single CpG site in the *IL6* promoter region.[94]

CXCL12 (SDF-1α) is differentially expressed in RA and osteoarthritis synovial tissues and isolated fibroblasts. Recently, the methylation status of the CXCL12 promoter has been examined.[95] A lower percentage of CpG methylation was found in the CXCL12 promoter of RA synovial fibroblasts.

Proinflammatory cytokines such as TNF, IL-1β, and IL-6

These proinflammatory molecules have multiple influences on the pathogenesis of RA; IL-1β and IL-6[96] can also affect genomic methylation. IL-6 stimulates translocation of DNMT1 to the nucleus. An important point to note is that proinflammatory cytokines and growth factors accelerate the cell cycle. During DNA replication, normal synovial fibroblasts recruit DNMT1,[93] which has been shown to interact with proliferating cell nuclear antigen at the DNA replication fork to ensure the correct setting of methylation markers.[9] In RA synovial fibroblasts, then, a relative deficiency of DNMT1could lead to loss of methylation markers in daughter cells, and induce the irreversible differentiation into an aggressive phenotype.

Histone modification

Studies of histone modifications in RA have mostly concentrated on histone acetylation and particularly on the use of histone deacetylase inhibitors as therapeutic agents. Paradoxically, in whole synovial tissue of patients with RA, the balance of HAT and HDAC activity is already shifted towards a loss of HDAC activity as compared to osteoarthritis and normal synovium.[88] In particular, the expression of HDAC1 and 2 was significantly reduced. Smoking is associated with an increased risk for developing RA and a more severe disease outcome.[97] Chronic exposure to cigarette smoke led to strongly reduced expression of the histone deacetylases SIRT1 and 2 in the lungs of rats. Pretreatment of macrophage cells with the SIRT1 activator resveratrol significantly inhibited the smoke-induced production of proinflammatory cytokines.

MicroRNA

Recent studies have uncovered dysregulated microRNA (MiR) expression in patients with RA, suggesting that abnormalities in MiR expression may contribute to the molecular mechanisms of the disease. The following MiRs are upregulated in peripheral blood mononuclear cells of patients with RA: MiR-16, MiR-132, MiR-146a, MiR-1555, and MiR-363.[98] In RA synovial fibroblasts, MiR-146a and MiR155 are also upregulated,[91] in addition to MiR-124a, MiR-203, MiR-223, and MiR-346.[91] The implication of miRNAs in immune-mediated disorders such as RA has recently emerged, suggesting that miRNA-based therapeutic approaches may have a promising potential in these diseases.[98]

Epigenetic therapies

Nutrients and epigenetics

Nutrients play essential roles in the following epigenetic events. First, folate, vitamin B_{12}, and methionine participate in the generation of SAM, which acts as a methyl donor in the methylation of cytosines in DNA. Second, covalent attachment of biotin to histones plays a role in gene silencing and in the cellular response to DNA damage.[99] Epigenetic mechanisms have recently been recognized as major contributors to nutrition-related longevity and ageing control. Studies of the comparison of DNA methylation levels in pancreatic acinar cells between caloric restriction-fed rats and control rats fed ad libitum suggest that it increases the methylation level of proto-oncogenes such as Ras.[100] Caloric restriction also induces a DNA hypermethylation of the p16INK4a promoter, blocking the access of E2F-1.[101] DNMT1 activity is significantly elevated in response to caloric restriction to correct the decreased methylation level during ageing.

The best-characterized of all animal models in which an epigenetic change in a gene is inherited and leads to well-defined pathological outcomes is the Avy mouse. The coat colour of these mice is governed by the expression of the *agouti* gene.[102] The agouti coat colour of wild-type mice results from a band of yellow pigmentation in the middle of the hair follicle, which is otherwise darkly pigmented. The expression of the *agouti* gene is under control of a promoter in the long terminal repeat (LTR) of an intracisternal A particle (IAP) proximal to the gene, whose ability to drive expression is correlated with the degree of IAP methylation. Most intriguingly, the addition of nutrients likely to enrich the pool of methyl donors and vitamin cofactors required for methylation to the diet of mothers increases methylation of the IAP promoter site, such that more offspring are pseudoagouti and less prone to the

yellow-obese syndrome.[53,103,104] Such experiments have made viable yellow mice a powerful model to study the relationship between epigenetics, maternal diet, the so-called metabolic syndrome, and disease prevention.[105]

DNA methylation is governed by a variety of dietary factors, including folate, vitamin B_2 (riboflavin), vitamin B_{12} (cobalamin), vitamin B_6 (pyridoxine), methionine, choline, and alcohol, that mediate one-carbon metabolism and thereby increase the amount of available SAM.[106] SAM serves as the primary donor to add methyl groups to a wide range of acceptors, including DNA, RNA, and histone proteins. The end result of this reaction is the production of S-adenosylhomocysteine (SAH) as a by-product of the reaction. SAM was effective in a dog model of osteoarthritis[107] and in human depression.[108]

Histone deacetylase inhibitors

There have been a number of reports of beneficial effects from the use of histone deacetylase (HDAC) inhibitors (HDI) in experimental models of RA or in in-vitro studies.[109] In a mouse model of autoantibody-mediated arthritis intravenous application of the HDI FK-228 rapidly reduced the symptoms of arthritis with a marked decrease in the expression of TNFα and IL-1β in the synovium. The expression of the cell cycle inhibitors p16[INK4a] and p21[WAF1/Cip1] was increased, which could be linked to an increased protein acetylation at the *p16INK4a* promoter after incubation of RA-FLS with the HDI in vitro.

Modulators of microRNAs

The function of most miRNA genes is still awaiting gain- and loss-of-function studies. Unfortunately, creating genetic knockouts to determine miRNA function through homologous recombination in murine models is difficult. Additionally, paralogous miRNA genes are often expressed from multiple genomic loci, posing redundant function that further hampers knockout studies. Presently, loss-of-function studies rely on introduction of chemically modified antisense oligonucleotides, which act as competitive inhibitors of miRNAs. To increase the stability of the antisense oligo backbone, a methyl group is added to the $2' o$ position on the nucleic acid.[110] Similarly, locked nucleic acid modifications are also commonly used. An effective miRNA inhibitor that has been demonstrated to spontaneously spread into organs, even in the context of whole organisms, is based on a cholesterol conjugate. This was originally developed by the Tuschl and Stoffel laboratories in collaboration with Rajewsky and Alnylam Pharmaceuticals Inc. and was dubbed antagomir.[111] Currently, these modified miRNAs are under investigation in cardiovascular[112] and chronic liver diseases.[113]

Conclusion

The RA synovium contains cells of various types that exhibit hypomethylated DNA. Among these, T cells[74] and synovial fibroblasts[92] contain fewer 5-methyl-cytosine residues than normal cells and in the case of RA synovial fibroblasts this difference is conserved over long-term culture in vitro. Furthermore, expression of LINE-1 mRNA and proteins are associated with hypomethylated promoters.[92,113] This characteristic reflects a global state of DNA hypomethylation, which has important consequences for RA synovial fibroblasts, since an important mechanism of epigenetic control seems to be defective. As a demonstration of the consequences of this loss of epigenetic control, inhibition of DNMT1 expression

in normal synovial fibroblasts is sufficient to produce an aggressive phenotype that includes upregulated expression of matrix-degrading enzymes and adhesion molecules. Indeed, the level of DNMT1 protein in proliferating RA synovial fibroblasts is lower than that in normal synovial fibroblasts. Thus, during DNA replication in RA synovial fibroblasts, the correct methylation patterns are not transmitted, or incorrect patterns could be transmitted, from mother cells to daughter cells. Consequently, genes in the daughter cells that should be silenced are expressed. This mechanism explains in great part the high number of transcripts that are upregulated in RA synovial fibroblasts. Several mechanisms can lead to the upregulation of gene transcripts as a consequence of DNA hypomethylation, either directly, through the loss of methylation markers in gene promoter regions, or indirectly, through the action of transcription factors or signalling pathways that are modulated by methylation. Since DNA methylation interacts with histone modifications and miRNA activity, these other epigenetic mechanisms could also be affected and could contribute to development of the aggressive phenotype. Two major questions remains: what is the cause of the DNA demethylation in RA (e.g. enhanced recycling of polyamines[114]) and how to interfere in this mechanism to render RA synovial fibroblasts less aggressive.

CHAPTER 40

Genetics of rheumatoid arthritis

Steve Eyre and Jane Worthington

Genetic contribution to rheumatoid arthritis

The observation of clustering of cases of rheumatoid arthritis (RA) within families provided the first evidence for a genetic basis to the disease. The increased risk to the sibling of a proband compared to the population prevalence, known as the sibling relative risk or λ_s, is estimated to be between 2 and 10. Studies in twins can also be used to quantify genetic risk. The concordance rates for monozygotic twins and dizygotic twins of 15% and 3.6% respectively indicates that both genetic and non-genetic factors determine susceptibility, and on the basis of these observations the heritability of RA is estimated to be about 60%. RA is thus defined as a complex disease in which both genetic and environmental risk factors determine susceptibility (Figure 40.1). The various attempts to quantify the size of the genetic component of susceptibility must be viewed as estimates, as they fail to account for the effect of the shared environmental exposures of those living together or for any interactions between genetic variants or between genetic and environmental risk factors.

RA is a heterogeneous disease with a range of clinical presentations, variable degrees of severity, rates of progression, and responses to therapies. It is now thought that the particular disease course followed by an individual patient is influenced at various stages by both genetic and environmental risk factors.

Most studies to date have focused on determining the risk factors for susceptibility to RA defined by the 1987 ACR criteria, failing to include in analyses milder cases with an inflammatory arthritis that may in fact satisfy the newly revised criteria for disease. Indeed the vast majority of data emerging in the postgenomic era is based on the analysis of autoantibody-positive cases. More refined investigations are now required, using carefully ascertained and longitudinally followed patient cohorts in well-powered studies to determine (1) whether there are genetically distinct subgroups of disease and (2) whether genetic markers can be used to classify patients at symptom onset in order to identify those likely to have the more severe phenotypes. Pharmacogenetic studies are also under way to identify genetic markers for the prediction of the efficacy of therapies and of risk of adverse events.

HLA and the shared epitope hypothesis

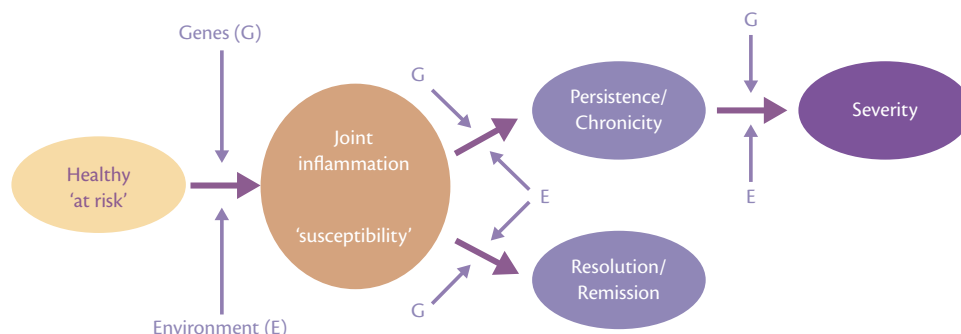
The association of RA with genes from within the major histocompatibility complex (MHC), along with the detection of autoantibodies (rheumatoid factor) in the serum of RA patients led to the classification of RA as an autoimmune condition. In 1976 Stastny[1] first reported association of the MHC class II antigen HLA DRw4 with RA. The introduction of DNA molecular typing methods, used in many studies across numerous populations, revealed


Fig. 40.1 Combinations of genetic and environmental risk factors act together over time to determine initial susceptibility to inflammatory arthritis and the subsequent disease course followed by an individual patient, leading to a spectrum of outcomes from natural remission through to rapidly progressing, treatment-resistant rheumatoid arthritis.

a complex picture with multiple *HLA DRB1* alleles associated with RA. In 1987 Gregersen et al.[2] described a unifying hypothesis based on the observation that all associated alleles had in common a 5-amino-acid sequence within the third hypervariable region of the *HLADRB1* gene. The so-called 'shared epitope' (SE) at positions 70–74 (amino acid sequence QRRAA) forms a critical part of the binding groove of the HLA DRB1 protein in which peptides are held and presented to the immune system. Although many of the RA-associated *HLA DRB1* alleles share the identical amino acid sequence at the SE there appears to be a hierarchy in terms of the risk they confer such that the association of *HLA DRB1*0401* is greater than *HLA DRB1*0101* and the genotype *0401/*0404* is associated with by far the highest risk for OR. The SE hypothesis has recently been refined by employing SNP genotyping in large cohorts of cases and controls and the statistical imputation of HLA alleles. These analyses suggest that the genetic association signal from the SE can be simplified to the amino acid at position 11, at the bottom of the DRB1 binding groove, and to amino acids at positions 71 and 74, also in the antigen-binding groove. The addition of two further independent genetic associations, for a single amino acid in HLA-B and one in HLA-DPB1, again both in the antigen-binding groove, explain fully the genetic association signal over the MHC region.[3]

The role of the HLA DRB1 protein is to present short peptides to T cells; a key step in the shaping of the immune response through deletion or positive selection of T-cell clones. The position of amino acids 11, 71, and 74 within the peptide-binding groove is assumed to have an influence on the nature and orientation of presented peptides, although the pathogenic mechanism, whether this is the presentation of self or foreign peptide, remains unknown. A number of alleles negatively associated with RA share a different amino acid region at positions 70–74 (DERAA) and have a very different shaped peptide-binding groove.

The effect size reported for the SE and RA varies considerably. The effect size is much greater in autoantibody-positive compared to autoantibody-negative disease. It is highest in patients with the most severe forms of RA such as those with erosive disease and extra-articular manifestations such as Felty's disease and lowest in cohorts with a broad spectrum of disease, such as those to be found in primary-based care. The question as to whether the SE determines susceptibly or persistence/severity remains a subject of debate.

Despite many unanswered questions, the importance of the HLA region in RA is undisputed. Estimated to account for between 40–60% of the genetic component of susceptibility, this locus is the major genetic influence on susceptibility to RA. This means that approximately one-half of the genetic susceptibility is determined by loci outside the MHC and in recent years much effort has focused on defining the non-HLA component of susceptibility, with the aim of gaining greater insight into the aetiology of disease, on the assumption that an understanding of genetic susceptibility is dependent on knowledge of *all* significant risk loci.

Protein tyrosine phosphatase N22 (PTPN22)

Even before the advent of genome-wide association studies (GWAS), major advances in technology facilitated the discovery of the second risk locus for RA. The first large-scale SNP-based candidate gene study, led by Begovich,[4] tested 16 000 potentially functional SNPs from immune-related genes. Large sample sizes and the use of both test and replication stages were strengths of the study which identified an association to the minor allele (C) of a SNP at position 1858 which resulted in an arginine to tryptophan change (R620W). In a parallel candidate gene study in type 1 diabetes targeting genes on T-cell signalling pathways, the same association was observed. Subsequently these results have been replicated many times and the same variant has been associated with many other autoimmune diseases.[5] This variant does not exist in Asian populations and no other associations within PTPN22 have been found in non-whites, providing strong evidence of genetic heterogeneity between populations for RA. The *PTPN22* gene encodes the protein Lyp and the disease-associated variant is thought to disrupt binding to Csk in the TCR-mediated negative regulatory signalling pathway. Recent studies indicate that the associated variant not only decreases binding to Csk, but may also increase binding to proteolytic enzymes, increasing degradation of the PTPN22 protein.[6] This could explain the reduction in PTPN22-mediated T-cell control, with a reduced amount of a less effective protein. Some studies suggest the association is restricted to autoantibody-positive RA, but in the largest study to date association was detected in seronegative RA, albeit with a lower effect size.

STAT4

The first hypothesis-free approach to searching the genome for susceptibility loci was non-parametric linkage analysis based on the analysis of polymorphic microsatellite markers in affected sibling pair families. A series of studies, each individually underpowered, largely served to confirm the importance of the MHC region. The exception was a SNP-based fine mapping study of one of the linkage peaks detected in a United States cohort, where 13 candidate genes were targeted in a well-powered study using over 7500 samples and significant association to a SNP in the gene *STAT4* was detected. The effect of *STAT4* (odds ratio = 1.2) is more modest than that of SE or *PTPN22*, but interestingly the strength of association is same in seronegative and seropositive RA and is also seen in other autoimmune diseases. Although the biological effect of the associated variant has not been determined, *STAT4* is a highly plausible candidate gene for RA as it encodes a transcription factor involved in cytokine-mediated signalling in T cells.

PADI4

Strong evidence of association to SNPs within the *PADI4* gene first emerged from studies in Asian populations.[7] Various hypotheses have emerged as to why RA patients develop antibodies to citrullinated peptides. To test the possibility of genetic variants influencing this process, a Japanese group investigated 100 SNPs in a region encoding a series of enzymes involved in citrullination. They found risk of RA associated with SNPs in non-coding regions of *PADI4*. This association has been replicated in a number of Asian populations and seems to represent the major non-MHC locus in these populations (odds ratio = 1.3). Association to this locus in white populations has subsequently been confirmed.

Genome-wide association studies

The impact of genome-wide associations on the identification of risk variants for a range of complex diseases, not least RA, has been

enormous. RA was one of seven diseases studied in the United Kingdom's Wellcome Trust Case Control Consortium (WTCCC) which performed a groundbreaking proof-of-principle study demonstrating that high-throughput genotyping of 500 000 SNPs in 2000 cases for each of 7 common diseases and a shared set of 3000 controls could detect associations to known and novel loci.[8] Although for RA, only associations to HLA and PTPN22 exceeded genome-wide levels of significance (p $< 5 \times 10^{-8}$), targeting nine loci (p $= 1 \times 10^{-5}$ to 5×10^{-7}) in a validation study led to the identification of the third-largest effect size locus for white RA at 6q23 (rs6920220, odds ratio = 1.2).[9]

In the same year, two additional GWAS for RA were published. The first was a small-scale study using an early-generation Affymetrix chip with just 100 000 SNPs and a two-stage study design with relatively small sample sizes. Only one SNP reached genome-wide significance, with the minor allele of rs13207033, at the same 6q23 locus identified in the United Kingdom study, being associated with protection from RA. Interestingly, both associated SNPs map over 180 kb from the nearest gene, lying between *OLIG3* and *TNFAIP3*. A fine mapping study of this region of the 6q23 region in United Kingdom samples has revealed further complexity, with a third independent association detected within intron 2 of the *TNFAIP3* gene (rs5029937).[10] This raises the possibility that effect sizes for a locus, based on the initial GWAS association, may be underestimates. The risk to an individual of carrying at least one risk allele at rs6920220 and rs5029937 and no protective allele at rs13207033 rises (odds ratio = 1.5). *TNFAIP3* is an attractive candidate gene for RA; the A20 (murine protein product of *TNFAIP3*) knockout mouse develops cachexia and systemic and joint inflammation. Recent studies in myeloid-specific A20 knockout mice resulted in the development of a phenotype including spontaneous erosive polyarthritis with many features of RA. TNFAIP3 is on the signalling pathway for tumour necrosis factor (TNF), the central cytokine driving inflammation in RA. It acts as a potent inhibitor of NFκB and is therefore a potent anti-inflammatory protein. Markers at the 6q23 locus have now been associated with RA in a number of populations and with other autoimmune diseases including systemic lupus erythematosus (SLE), coeliac disease and type 1 diabetes. Across these studies multiple SNPs have been implicated and further fine mapping studies will be required for each disease to discover whether the aetiological variants are the same for each disease.

The third GWAS of 2007 combined data from United States and Swedish studies (1500 seropositive cases and 1800 controls genotyped for 300 000 SNPs). After HLA and PTPN22, the strongest association in this study was to markers in the *TRAF-C5* locus. The association was validated within the original publication and subsequently in multiple independent studies.

Validation studies and meta-analyses

Initial results from GWAS in RA and other complex diseases revealed that the new and yet to be discovered loci were almost certainly numerous, but of small effect sizes (odds ratio <1.2). In turn this confirmed that a GWAS of 1000–2000 cases and similar numbers of controls had limited power to detect such effects. The GWAS data therefore harboured many genuine associations that did not reach statistical significance, and the challenge was to separate those from potential false-positive associations. One way to do this is to increase the power of studies by increasing the sample size

used. By this method, further loci (*PRKCQ*, *AFF3*, *KIF5A*) from the WTCCC were confirmed at genome-wide significance by expanding the number of controls to include the non-autoimmune disease cases.

As an increasing number of confirmed susceptibility loci were reported across autoimmune and chronic inflammatory diseases the overlap in terms of genetic susceptibility between these conditions became increasingly apparent. Replication studies in independent RA cohorts targeting loci from SLE, type 1 diabetes, and coeliac disease was highly successful in adding *AFF3*, *IL2/IL21*, *TAGAP*, *CTLA-4*, *UBE2L3*, and *BLK* as confirmed RA susceptibility loci.

Meta-analysis of GWAS data offers an attractive and relatively low-cost solution to increasing the power to detect small effects. Although each of the first three major GWAS studies used different SNP chips and hence generated genotypes for different sets of SNPs, the introduction of methods to impute the genotypes of missing SNPs, means that combination of the three studies was possible. The first RA meta-analysis, of 3929 cases and 5807 controls, led to the identification of association with rs4810485 in intron 2 of the *CD40* gene. To facilitate the selection of SNPs from GWAS to be targeted in validation studies, Raychaudhuri developed a bioinformatics programme (GRAIL) which screens potential loci against confirmed loci. This was used with great effect on the meta-GWAS data to prioritize 22 SNPs from 179 regions, from which 7 (*TAGAP*, *CD28*, *TRAF6*, *PTPRC*, *FCGR2A*, *PRDM1*, *CD2-CD58*) were confirmed as novel RA susceptibility loci through an international collaboration to genotype large validation sample sets.

In the United States a further independent RA GWAS identified *REL* as a novel RA susceptibility locus. Most recently, combination of this GWAS data with new data from United States and Canadian samples culminated in a meta-analysis of 5539 autoantibody-positive RA cases and 20 169 controls.[11] Following the use of GRAIL and findings from other autoimmune diseases, genotyping of 34 SNPs in a further 6768 cases and 8806 controls confirmed 10 additional novel associations, taking the number of RA susceptibility loci confirmed at genome-wide significance to 31.

More recently advantage was taken of the great overlap in the genetic association findings in autoimmune diseases to design a common genotyping array, Immunochip, containing over 200 000 SNPs across 186 associated loci. The RA community formed a consortium, RACI, to test over 11 000 RA cases and 15 000 controls with this array. Data from this experiment has increased the number of confirmed RA loci in white populations to over 45. Newly identified loci include *IL6R*, the target for a therapeutic intervention, *IRAK1*, the first locus located on the X chromosome associated with RA, and *IKZF3*, a region previously robustly associated with asthma. The fine mapping experiment also highlighted a number of potentially aetiologically causal, exonic variants and focused the signal in around half of the associated regions to encompass just a single, candidate gene.[12]

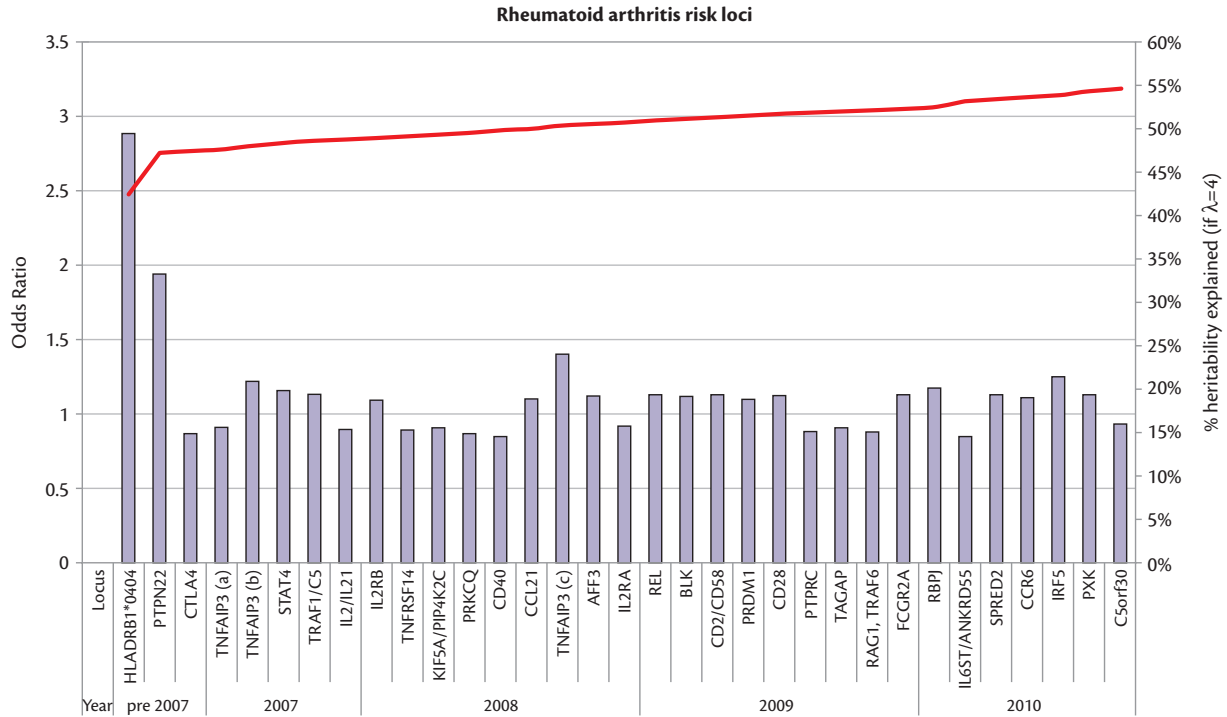
The current state of knowledge of RA susceptibility loci is summarized in Figure 40.2. GWAS have revolutionized our knowledge of non-HLA disease susceptibility loci, resulting in the identification of large numbers of risk loci with small effect sizes. Many challenges and questions remain. Despite this apparent success, the RA loci are estimated to explain only around 55% of the genetic heritability, with the majority of that accounted for by the SE.


Fig. 40.2 Current rheumatoid arthritis genetic risk loci, plotted in order of discovery. Odds ratio and confidence interval on the y-axis (left) and increase heritability explained on the y-axis (right), assuming $\lambda_s = 4$.

The same situation is seen in other complex diseases and has a fuelled a debate; the so-called 'missing heritability question'. Possible explanations to account for why GWAS have failed to capture the missing heritability include the following:

◆ Multiple additional loci remain to be identified: it is highly likely that analysis of sample sets of increasing size will continue to reveal new associations.

◆ Inaccurate estimate of odds ratios for individual loci from GWAS: fine mapping may reveal multiple effects, better identify the causal SNP, and produce more accurate estimates of odds ratios.

◆ Rare variants: these have not been well captured on the current generation of SNP chips. The challenge here will be assembling sufficiently powered studies to detect the associations.

◆ Structural variants such as copy number variations (CNVs) and insertion/deletions: A CNV GWAS failed to detect any significant associations with RA, it did however conclude that most simple CNV's are well captured by SNP chips, reducing the likelihood of this being a valid explanation.

◆ Gene–gene and gene–environment interactions: these have largely not been addressed due to lack of data (environmental risks) or lack of power.

Insights into pathogenesis

Although our understanding of the genetic basis of susceptibility to RA is far from complete, the new knowledge of genetic susceptibility loci gained in the post-GWAS era can add to our understanding of pathogenesis. One proviso that should be born in mind is that many of the associations arising from GWAS are to markers outside the traditionally defined boundaries of any genes,

or within gene-rich regions. Although loci tend to be 'named' according to the nearest recognizable relevant gene, fine mapping and functional studies will be required to more accurately map associations, before we can be certain of the genes implicated in the disease process.

With these limitations in mind, it is still tempting to look for clues about pathogenesis amongst the loci identified so far. Genetic studies have confirmed the central role that T cells play in the susceptibility to RA, which can be clearly seen in the associated genes highlighted in a T-cell priming pathway. In addition, most of the genes implicated are enriched in pathways associated with antigen processing and presentation or with the regulation of T-cell activation, regulation, and proliferation. It will be informative to determine whether these pathways, or a subset, need to be perturbed in all patients and whether genetic variants within specific pathways can predict the observed disease heterogeneity. Indeed, there is already preliminary evidence that certain genes associated with disease onset are also involved in the eventual outcome: for example, the same variants in *TRAF1* associated with susceptibility are also associated with the development of erosions.[13]

Ongoing work is also highlighting genes that may play a role in treatment response. Early studies indicate that *PTPRC*,[14] implicated in the susceptibility to RA, may also be involved in how well a patient responds to treatment. Well-powered GWAS, similar to the studies performed for susceptibility loci, will be needed to determine whether any novel loci are associated with response to treatment, in terms of disease outcome or adverse side effects. Genetic profiling of a patient at presentation in order to determine their probable disease course and make informed choices about the treatments is a goal for the future.

CHAPTER 41

Genetics of spondyloarthropathies

Matthew Brown

Introduction

The spondyloarthropathies (SpA) are a group of clinically and aetiologically related forms of inflammatory arthritis that include ankylosing spondylitis (AS); psoriatic arthritis (PsA); colitic arthritis, complicating inflammatory bowel disease (IBD); and reactive arthritis. AS is the prototypic disease. All are characterized histopathologically by the presence of enthesitis, and to a varying degree, all share genetic associations, notably with HLA B27. An increasing number of other genetic associations have been reported with these diseases, providing further information as to the immunopathogenic mechanisms underlying them.

Genetic epidemiology

As a group the spondyloarthropathies are very common; up to 2.4 million Americans suffer from SpA, compared with 1.3 million suffering from rheumatoid arthritis (RA).[1] The prevalence of AS is around 0.5% in people of white European ancestry. The disease has a global distribution, with the exception that it is uncommon in people of African or Australian Aboriginal descent, as HLA B27 is rare in these ethnicities. Psoriasis is even more common, with a prevalence of 2–3% in people of white European ancestry, with the disease being less common in people of Asian and African ancestry.[2,3]

The typical age of onset is in the early 20s, and onset over 45 years of age is uncommon. AS has a moderate male predominance (~2–3:1), whereas colitic arthritis and axial spondyloarthritis have a more balanced gender distribution.[4,5] Psoriatic spondyloarthritis, as with AS itself, has a strong male predominance.[6] The reason for the male predominance of AS and psoriatic spondyloarthritis is unknown.

AS runs very strongly in families, and most of the risk of developing AS is inherited, with heritability in excess of 90%.[7,8] Siblings or children of AS patients have about 12% likelihood of developing AS, and the likelihood of recurrent disease in more distant relatives is much lower (≤1%).[9,10] The recurrence risks of AS in relatives of AS patients are reported in Table 41.1. A major role for genetic factors in the risk of developing AS is supported by this strongly familiality, and by twin studies. These studies, although not large,

suggest that the heritability of the risk of developing the disease is over 90%.[7,8] Twin and family studies also indicate that the severity of AS is highly heritable, with the heritability of radiographic severity measures being 62%,[11] and family studies indicating significant heritability of disease activity and severity measures such as the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI) and Bath Ankylosing Spondylitis Functional Index (BASFI), as well as age of symptom onset.[12,13]

Psoriasis is also known to be highly heritable; the concordance rate in monozygotic (MZ) twins is significantly higher than in dizygotic (DZ) twins (35–72% vs 12–23%), indicating greater sharing of risk factors, most probably genetic (estimated heritability 80%).[14] PsA also runs strongly in families; sibling of a first-degree relative with PsA are 12–49 times more likely to develop the condition themselves than relatives of individuals without PsA, though only 4 times more frequently than in spouse controls, suggesting that there is a significant environmental component to PsA risk.[15,16] Concordance of pattern of PsA within families does not appear to be strong, suggesting that in psoriasis there is an underlying predisposition for synovitis/enthesitis rather than for a specific disease pattern.[15]

Histocompatibility antigen associations

The association of AS with HLA B27, the major gene involved in the disease, was made in the early 1970s,[17–19] yet it is still unclear as to how it causes the condition. Theories range from differences in its capacity to present antigens, to problems caused by the formation of homodimers of B27 itself, or by its propensity to misfold in the endoplasmic reticulum. The latter theory proposes that

Table 41.1 Risk of ankylosing spondylitis in relatives of cases, given HLA B27 status[9]

	B27 status unknown	B27-positive	B27-negative
Grandparent	1%	5%	0%
Parent/sibling	10%	15%	0%
Identical twin	60%	60%	—

accumulation of misfolded HLA B27 induces an endoplasmic reticulum stress response,[20] leading to secretion of proinflammatory cytokines such as interleukin (IL)-23,[21] which is considered a major driver of inflammation in the disease. It remains unclear exactly how HLA B27 induces AS, although recent genetic findings indicate that the mechanism involves aberrant peptide handling, narrowing the potential range of mechanisms significantly.[22]

There are now over 65 known subtypes of HLA B27 which are thought to have evolved from the common ancestor HLA B27 allele, *HLA B*2705*. Most subtypes are very rare, and in most populations worldwide, variation within HLA B27 makes no difference to the likelihood of these individuals developing the condition. In white European populations the two most common subtypes, *HLA B*2702* and *B*2705*, are equally disease associated.[23] Two other subtypes, *HLA B*2706* which is found in Asians[24] and *HLA B*2709* which is found in Sardinians,[25] appear to be protective or neutrally associated with disease. HLA B27 is rare in most African populations, where the development of seronegative arthritis such as AS appears more closely related to HIV infection than genetic risk factors. In Scandinavian countries and amongst the Inuit HLA B27 has a much higher prevalence(10–37%),[26] suggesting that either HLA B27 provides a survival advantage (perhaps through protection against an infectious disease) or that the high prevalence is due to a founder effect or genetic drift.

The strength of the association of HLA B27 with reactive arthritis is considerably lower than with primary AS, with most series reporting B27-carriage rates of 20–60%. In case series with axial spondyloarthritis, the prevalence of HLA B27 varies substantially, reflecting the lower specificity of the diagnostic criteria for axial spondyloarthritis compared with AS. There is no HLA B27 association with psoriasis (which is associated with HLA Cw6), but in patients with psoriatic spondyloarthritis there is a strong association with HLA B27. HLA B27 appears to act primarily as a dominant gene in AS, although there is some evidence that individuals carrying two copies of the gene have higher risk of AS, and may develop more severe AS, than heterozygotes.[27] HLA B27-negative patients have a later age of disease onset by about a decade than HLA B27-positive patients.[27,28]

There has been considerable research into the influence of HLA alleles other than HLA B27 with AS. Association of HLA B60 with AS is well established, having first been reported by Robinson et al. in 1989,[29] and subsequently confirmed in white Europeans[23] and in east Asians.[30] Considering the non-B27 alleles only in cases and controls, the association of HLA B60 carries an odds ratio of 3.5–3.6 in HLA B27-positive and -negative cases.[23] Whether this association is specifically due to HLA B60 or due to linkage disequilibrium with a nearby genetic variant is unclear, and to date no other major histocompatibility complex (MHC) genetic associations have been reported and confirmed with definitive statistical confidence.

Other genetic associations of spondyloarthropathies

Ankylosing spondylitis

Although *HLA B27* is clearly the major gene in AS, twin and family studies indicate that other genes must be involved. Rapid advances are being made in identifying further genetic loci associated with the disease (Table 41.2).[22,31]

Table 41.2 Genes with confirmed associations with ankylosing spondylitis

Gene	Locus	Likely function
HLA B27	6p21.3	Presentation of peptides to T cells, or misfolding leading to endoplasmic reticulum stress reaction
21q22	21q22	Unknown
2p15	2p15	Unknown
ANTXR2	4q21	Unknown
CARD9	9q34	Th17 activation after β-glucan exposure
ERAP1	5q15	Peptide trimming prior to HLA class I presentation
IL12B	5q33	Activation/differentiation of IL-23R expressing cells
IL1R2	2q11	Influence on IL-1 cytokine response
IL23R	1p31	Activation/differentiation of IL-23R expressing cells
KIF21B	1q32	Unknown
PTGER4	5p13	Induction of IL23 expression, in turn driving activation/differentiation of IL-23R expressing cells; bone anabolism
RUNX3	1p36	Reduction in CD8 lymphocyte counts
TBKBP1	17q21	TNF signalling
TNFR1/LTBR	12p13	TNF signalling

The first two genes identified as being associated with AS other than *HLA B27* are *ERAP1* (*ARTS-1*) and *IL23R*.[31] *ERAP1* encodes an aminopeptidase which is expressed in the endoplasmic reticulum, and which is involved in preparing peptides for HLA class I presentation to immune effector cells. Its association with AS is restricted to *HLA B27*-positive cases, the first confirmed human example of gene–gene interaction in any common human disease.[22] *ERAP1* has also recently been shown to be associated with psoriasis, and in this condition the association is restricted to *HLA Cw6*-positive cases.[32] This suggests that HLA B27 and HLA Cw6 operate in AS and psoriasis by similar mechanisms. The protective *ERAP1* variants prevent conformational changes in ERAP1 which are thought to be required for peptide cleavage,[33] and lead to less peptide presentation in the endoplasmic reticulum to HLA class I molecules. The restriction of the association of *ERAP1* with HLA B27-positive AS indicates that HLA B27 must operate in AS by a mechanism involving ERAP1, and thus through aberrant peptide handling.

IL23R encodes the receptor for the cytokine IL-23, which is involved in activation of a range of proinflammatory cells including Th17 lymphocytes, gamma-delta cells, mast cells, and others. Stimulated by the discovery of the association of *IL23R* with AS, trials of IL-17 blockade have been initiated in AS, and in a phase 2 study strong beneficial effects similar to those observed with TNF-antagonist medications have been reported.[34]

Other genetic associations with AS with effects on the IL-23 pathway include *IL12B*, *CARD9*, *PTGER4*, and *IL1R2*. *PTGER4* is of particular interest as it forms part of the mechanostat, linking physical stress at entheses with induction of IL-23 production and anabolic bone formation signals, thus identifying a mechanism by which inflammation leads to bone formation in AS. *IL12B* encodes IL-12p40, the shared subunit of IL-12 and IL-23. *CARD9* encodes a protein involved in signalling between the innate immunity receptor dectin-1 and the nucleus, leading to IL-23 production. This is of

particular interest given the recent demonstration in the Skg mouse model that dectin-1 stimulation by the fungal cell wall component beta-glucan induces spondyloarthritis, episodic unilateral uveitis, and colitis resembling Crohn's disease.[35] This shows a mechanism by which spondyloarthritis can develop in the absence of HLA B27 through innate immune pathways.

Psoriatic arthritis

Although there have been many large studies of psoriasis genetics, psoriatic arthritis is less well understood and fewer studies have been published. Distinguishing between associations of psoriasis and the arthritis complicating psoriasis is also challenging. It seems likely that genes will contribute to the development of arthritis in psoriasis cases. However, with the exception of the association of *HLA B27* with axial psoriatic arthritis, no gene has been convincingly shown to be associated with psoriatic arthritis independently of the skin disease.

Psoriasis is strongly associated with *HLA Cw6*.[36] The mechanism for this association is unknown but is presumed to relate to a predisposition to present particular antigenic peptides, in turn leading to an immune reaction in the skin. As mentioned above, the association of psoriasis with the same ERAP1 haplotypes associated with AS, and the restriction of this association to HLA Cw6-positive psoriasis[32], suggests that HLA Cw6 operates in psoriasis by a similar mechanism to that by which HLA B27 operates in AS. This most likely involves aberrant peptide presentation.

Genome-wide association studies (GWAS) have recently identified several genetic associations with psoriasis (see Table 41.3),

many of which overlap with both AS and IBD. As with AS and IBD, genes involved in the IL-23R pathway are over-represented in psoriasis associations, and include *IL23R, IL12B, TYK2,* and *IL23A*.[32,37] These findings have been important in stimulating clinical trials in psoriasis of cytokine-inhibition therapy targeting this pathway, with clear beneficial effects. For example, ustekinumab, an antibody treatment targeting IL-12p40, is now a licensed treatment for psoriasis in many countries, and is effective for both psoriatic skin and joint disease.[38] Anti-IL-17A antibody treatment has also been shown to be effective for both psoriasis and PsA.[39]

Several genes which can broadly be said to act through NFκB1 show association with psoriasis, something which is more a feature of seropositive diseases such as RA, perhaps explaining the clinical overlap of psoriatic arthritis with RA. These include *NFKB1A, REL, TRAF3IP2,* and *TNIP1*.[32,40]

A surprise finding from genetic studies has been the association of genes involved in interferon signalling pathways and psoriasis. *IL28RA* encodes a type III interferon receptor subunit. *IFIH1* encodes an innate immunity receptor, stimulation of which by microbes leads to a type 1 interferon response. *TYK2* encodes a tyrosine kinase involved in signalling from various cytokine receptors including IL-23R and interferon receptors. This suggests that interferon signalling induced by microbial infection may be important in psoriasis pathogenesis.

Conclusion

Genetic studies have confirmed significant overlaps between the genetic architecture of AS and psoriasis, particularly involving IL-23 signalling pathways, but also significant differences in HLA and other associations, which are likely to be important in determining the phenotype of spondyloarthritis that occurs in genetically predisposed individuals. These findings have greatly advanced research into the causes of spondyloarthritis and have already led to translational advances with new treatments entering clinical practice for these common conditions. Only a minority of the genetic risk of these conditions has yet been explained though, and many more genetic associations with these conditions remain to be discovered.

Table 41.3 Genetic associations of psoriasis

Gene	Locus	Likely function
HLA Cw6	6p21.3	Uncertain. ?Presentation of peptides to T cells
ERAP1	5q15	Peptide trimming prior to HLA class I presentation
IL12B	5q33	Activation/differentiation of IL-23R expressing cells
IL23R	1p31	Activation/differentiation of IL-23R expressing cells
LCE3B/C	1q21	Barrier protection
DEFB4	8p23.1	Barrier protection
IFIH1	2q24	Interferon signalling
IL28RA	1p36	Interferon signalling
IL4/IL13	5q31	Cytokine signalling, modulates Th2 lymphocyte activation
IL23A	12q13	Activation/differentiation of IL-23R expressing cells
TYK2	19p13	IL-23R signalling
NFKB1A	14q13	NFκB1 pathway
TNFAIP3	6q23	NFκB1 pathway
TNIP1	5q33	NFκB1 pathway
REL	2p16	NFκB1 pathway
RNF114	20q13	Unknown
FBXL19	16p11.2	? through NFκB1 pathway effects
NOS2	17q11.2	Inducible nitric oxide synthetase? Involved in microbial defence

CHAPTER 42

Genetics of connective tissue diseases

Myles Lewis and Tim Vyse

Genome-wide association scans in connective tissue diseases

The scale of genetics projects has increased dramatically in recent years. Technological advances mean that millions of single nucleotide polymorphisms (SNPs) and other genetic variants such as copy number variation (CNV) can be tested on a single chip. The realization that much larger cohorts are required to increase the power of genetic studies has meant that thousands rather than hundreds of patients are now recruited through international collaboration, even in uncommon diseases such as systemic sclerosis (SSc). Only recently has this begun to increase our understanding of disease pathogenesis. Early evidence of a genetic contribution to connective tissue diseases came from twin and familial studies in systemic lupus erythematosus (SLE): the concordance in monozygotic twins was 24% compared to 2% in dizygotic twins. The sibling recurrence risk ratio (λ_s) for SLE is estimated to be 29-fold higher than in the general population, compared to 5.3 for RA.[1]

To date, five genome-wide association studies (GWAS) have been conducted in SLE, two in SSc and two in Behçet's disease. In SLE, three GWAS[2–4] and a large replication study[5] of individuals of European ancestry, and two GWAS in East Asian populations[6,7] have provided convincing evidence for 31 susceptibility genes, which have reached genome-wide significance (p $<5\times10^{-8}$; Table 42.1). There is suggestive evidence for a further 10 loci, which require confirmation. In systemic sclerosis, a total of nine loci have been found with good evidence at the genome-wide level of significance, with a further four loci implicated (Table 42.2).[8–10] Two GWAS of Behçet's disease have confirmed an extremely strong association with *HLA B*51:01* and identified *IL10* and *IL23R-IL12RB2* regions as genetic risk loci.[11,12] Examining these lists of genes, it is clear that a substantial amount of overlap is seen between SLE and systemic sclerosis, and many of these genes also overlap with rheumatoid arthritis (RA). As ever more genes are identified, they can be functionally grouped into known pathogenic pathways, to help elucidate the links between the risk variants and disease itself.

Major histocompatibility complex

The importance of the MHC in human immunological responses has long been appreciated, but the strong association with MHC haplotypes and autoimmune diseases has been difficult to dissect because of (1) long-range linkage disequilibrium (LD) and (2) duplication of regions leading to CNV and pseudogenes. The strongest genetic associations identified in GWAS of SLE, systemic sclerosis, and Behçet's all lie within the MHC, although it is clear now that this is due to multiple genetic effects. The MHC is an extremely gene-dense region, with at least 250 genes across 3.6 Mb of the classical MHC, with linkage disequilibrium extending the region to 7.6 Mb in size.[13] Whereas gene clusters in other areas of the genome are inherited in clusters of the order of 20 kb long, at the MHC, LD can extend up to 2 Mb. This is a major confounding factor in MHC genetic association studies. Prior to the advent of more detailed mapping of the MHC region, the 8.1 MHC haplotype was associated with a strikingly large number of diverse autoimmune diseases (Table 42.3). The 8.1 haplotype extends to include *HLA-A1, B8, C4AQ0, C4B1, DRB1*03:01* and *DQA1*05:01, DQB1*02:01* (DQ2), encompassing two significant class III genes, complement C4A null as well as the *TNF-308A* allele. Only recently have genetic studies developed sufficient statistical power or employed techniques such as transancestral mapping to dissect which genes within the MHC are responsible for disease association, rather than merely find associations with the block as a whole. The IMAGEN study[14] examined 1472 tag SNPs in multiple autoimmune diseases including SLE, Crohn's disease, ulcerative colitis, and RA. It resolved three separate signals in class III loci: *SKIV2L*, a locus in between *TNXB-CREBL1* and *NOTCH4*. The highest HLA risk in IMAGEN was observed for *HLA-DRB1*03:01*, with a weaker effect observed for *HLA-DRB1*15:01*. The HLA region has not yet been fine-mapped in other CTD, but HLA typing has confirmed that the *HLA-DRB1*03-DQA1*05* haplotype is the strongest HLA association in the idiopathic inflammatory myopathies (IIM), including dermatomyositis, polymyositis, and CTD-overlap myositis.[15] The *DRB1*03/DPB1*01:01* haplotype was associated with anti-Jo-1 positive cases, predominantly due to *DRB1*03*. The strongest genetic effect so

far identified in Wegener's granulomatosis is from the MHC, with tagging SNPs identifying *HLA-DPB1* alleles, particularly *04:01*.[16] A possible second signal lies in the neighbouring *RXRB-RING1* locus, but finer mapping is required for confirmation. Evaluating the relationship between HLA associations and SNP associations at the MHC is a complex and challenging question: thus far, no firm conclusion can be reached, although it is likely that both HLA

molecules and non-HLA genes contribute to the genetics of the MHC associations in SLE and other CTD.

Interferon response genes

High levels of type I interferon have been linked to autoimmune pathogenesis in several connective tissues including SLE, systemic sclerosis, and inflammatory myopathies. Several genes along the interferon pathway are associated with increased risk of CTD, including *IRF5*, *STAT4*, *IRAK1*, and possibly *IRF7*. Interferon regulatory factor 5 (IRF5) is a transcription factor which plays a central role in induction of the type I interferon (IFN) response, downstream of Toll-like receptor (TLR) signalling and antiviral pathways. Candidate gene studies had already discovered a splice variant in exon 1B, but resequencing of SLE patients identified novel rare variants including a 30 bp insertion in exon 6 and a 3′ untranslated region (UTR) variant, which increased mRNA stability, strongly increasing IRF5 protein expression.[17] Combining all three variants showed the strongest risk of SLE and the highest levels of serum IFN-α activity in SLE patients. Signal transducer and activators of transcription-4 (STAT4) is a key transcription factor activated in response to type I IFN, and appears to act downstream of IRF5. The *STAT4* risk alleles increased sensitivity to IFN-α in peripheral blood mononuclear cells (PBMC) from SLE patients,[18] and in a combined genetic analysis of *IRF5* and *STAT4* four or more risk alleles were linked to a substantial risk of SLE (odds ratio = 5.83), suggesting a genetic interaction. STAT4 is activated in response to IL-12 and IL-23, and may be involved in other pathways such as directing Th1 and Th17 responses, and production of IFN-γ in antigen-presenting cells. The same *IRF5* and *STAT4* risk haplotypes are associated with systemic sclerosis.[19] Other interferon pathway genes with good evidence for their involvement in autoimmune diseases include *IFIH1*, *TYK2*, *IRF8*, while further confirmation is required for *IRF7*, *TRAF6*, and *IKBKE*.

Genes specific to lymphocyte function

Three key genes involved in B-cell receptor (BCR) signalling have been associated with SLE in GWAS: B-lymphoid tyrosine kinase (*BLK*), B-cell scaffold protein with ankyrin repeats (*BANK1*), and *LYN*, which phosphorylates Igα/β as a key signalling event following BCR stimulation.[3,4,20] Three SNPs with potential functional effects were identified in *BANK1*: the strongest evidence is for a branch point SNP (rs17266594), which affects transcription of different splice variants, increasing the level of the main transcript.[20] The same three SNPs in *BANK1* associated with SLE are also associated with diffuse SSc, particularly anti-topoisomerase I antibody positive individuals.[19] SNPs in the *BLK* promoter region were identified in the first SLE GWAS, and shown to reduce BLK expression.[4] BLK is a Src family tyrosine kinase, like Lyn. Although the B-cell functions of BLK are not understood, the genetic association with SLE has been reproduced across multiple studies,[2–5,7,21] while a weak association was seen in a meta-analysis of SSc patients.

Two well-replicated disease susceptibility genes in SLE affect T lymphocyte function: *PTPN22* and *TNFSF4*. *PTPN22* encodes lymphoid tyrosine phosphatase, with dual B- and T-cell functions. The non-synonymous SNP rs2476601 encodes an Arg620Trp substitution, leading to a more potent phosphatase, with impaired B-cell tolerance checkpoints and increased numbers of autoreactive B cells. The same variant is associated with RA, SLE, SSc, Crohn's disease, and type 1 diabetes, with less strong evidence that it may be associated with the inflammatory myopathies and ANCA-positive Wegener's granulomatosis. In addition to its B-cell effects, the 620Trp substitution has a paradoxical effect on T cells, leading to reduced T-cell receptor signalling. TNF ligand superfamily member 4 (*TNFSF4*) encodes OX40L, a costimulation cell surface ligand involved in T-cell activation during antigen presentation. Cross-linking of OX40L causes B-cell proliferation and increased immunoglobulin secretion. The risk haplotype identified in both SLE and SSc increases OX40L expression.[22]

An interesting gene found in both SSc GWAS is *CD247*, which encodes the T-cell receptor subunit zeta (CD3ζ).[8,10] An earlier candidate gene study in SLE suggested that SNPs in the 3′ UTR, which lowered CD3ζ expression, predisposed to SLE. The *TBX21* gene, which has so far only been found in association with SSc,[23] encodes T-bet, a major transcription factor critical for Th1 development and suppression of Th17 differentiation. T-bet deficiency increased skin fibrosis in a bleomycin-induced skin fibrosis mouse model.

Regulators of the NFκB inflammatory pathway

The protein encoded by *TNFAIP3* (TNFα induced protein 3) is better known as the deubiquitinating enzyme A20, which is involved in deactivating a number of NFκB pathway intermediates and preventing TNF-induced apoptosis, downstream of TLR signals. A20 deficiency in mice leads to a profound autoinflammatory phenotype with cachexia and early mortality due to hypersensitivity to TNF. A coding SNP (rs2230926) associated with SLE and RA has been shown to reduce A20-mediated inhibition of TNFα. Sequencing of A20 exons shows that the main genetic effect is on control of A20 expression through variants in the 5′ and 3′ UTR. Association with *TNIP1*, which interacts with A20, has been confirmed in GWAS of SLE, SSc, and psoriasis[5,6,8] Studies using *Tnip1*-deficient mice suggest that, unlike A20, *TNIP1* does not control NFκB activation, but is still critical for preventing TNF-induced apoptosis.

Genetics of complement deficiency in systemic lupus erythematosus

Homozygous deficiency of complement C1q, C2, and C4 is associated with the development of a SLE-like disease with surprisingly high penetrance. There is evidence of a hierarchy, with higher risk conferred by earlier components of the classical pathway: 93% of case reports of C1q deficiency were associated with a lupus-like illness,[24] 57% for C1r and C1s, 75% for C4, while for C2 deficiency the risk is estimated to be 10–30%. With C3 deficiency the most prominent clinical features are recurrent pyogenic infections and membranoproliferative glomerulonephritis, and around 13% of cases develop SLE. Attempts to explain the association between complement deficiencies and SLE have concentrated on key functions of complement: transport and processing of immune complexes via the liver and spleen; phagocytosis of apoptotic cells; and generation of tolerance signals during antigen presentation. The 'waste disposal hypothesis' proposes that complement deficiency leads to failed clearance of organ-damaging immune complexes, as well as overexposure of autoantigens due to impaired clearance of apoptotic cells. This theory is supported by evidence from C1q-deficient mice, which developed lupus autoantibodies and nephritis associated with defective phagocytosis of apoptotic cells.[25] However, the development of autoimmunity in these mice is critically dependent on the mixed 129×C57BL/6 genetic background,[26] although the phagocytic defect due to C1q deficiency is unaffected by these genetic factors. It must be remembered that inherited complete deficiencies of classical pathway complement components are extremely rare: only 41 cases of C1q deficiency have been reported. As part of a commonly duplicated RCCX module in the MHC class III region, the C4A and C4B genes are affected by CNV, which directly correlates with serum levels of C4. Recent evidence suggests that partial deficiency of C4 may not act as a susceptibility factor in SLE.[27]

Other genes involved in phagocytosis and immune complex processing

ITGAM has consistently appeared with strong association in recent GWAS. *ITGAM* encodes alpha-chain integrin α_M, which is part of the complement receptor 3 (CR3) cell surface receptor, also known as CD11b or Mac-1. CR3 is expressed on a wide variety of immune cells and is involved in uptake of immune complexes by binding iC3b or cell surface signalling through ligands such as intercellular adhesion molecule-1 (ICAM-1) and ICAM-2. Evidence is accumulating that the main functional variant in *ITGAM* is a non-synonymous rs1143679 polymorphism strongly associated with SLE,[28] but interestingly is not associated with RA or SSc. This variant causes a R77H substitution, whose functional effect is to severely reduce neutrophil adhesion via ICAM-1 and -2, and impair iC3b-mediated phagocytosis.

The low-affinity Fc receptor genes *FCGR2A*, *FCGR2B*, *FCGR3A*, and *FCGR3B* suffer from extensive sequence homology due to duplication of genetic segments. The non-synonymous SNP rs1801274 associated with SLE[3] causes a missense His131Arg substitution in the ligand binding domain of FcγRIIa, leading to inhibition of phagocytosis via reduced affinity for IgG2. Duplication of a segment between *FCGR3B* and *FCGR2C* is common, resulting in between zero and six copies in a typical diploid human genome. Low *FCGR3B* CNV (less than two copies) is a major predisposing factor to SLE, microscopic

polyangiitis, and Wegener's granulomatosis,[29] and predisposes to immune-mediated nephritis in rats. Expression of FcγRIIIb, which is restricted to neutrophils, correlates with copy number of *FCGR3B*, and the low CNV of *FCGR3B* seen in SLE is associated with decreased immune complex adhesion and uptake by neutrophils.[30] Another variant found in South-east Asian and white European SLE patients, whose function has been investigated, is the Ile232Thr substitution in the inhibitory Fc receptor FcγRIIb. This substitution leads to exclusion of FcγRIIb from signalling lipid rafts, preventing its inhibitory action on other activatory Fc receptors in B cells.[31]

Other important genes

In Behçet's disease, SNPs in the promoter region of the suppressive cytokine *IL10* have been confirmed in two GWAS, with evidence in stimulated monocytes that these variants cause reduced IL-10 production.[12] A different SNP downstream of *IL10* (rs3024505, which was not associated with Behçet's disease), has been found in association studies in SLE, Crohn's, and autoimmune diabetes. Genetic association with Behçet's disease in the *IL23R-IL12RB2* region showed greater overlap with the IL-23 receptor, consistent with findings in other diseases such as ankylosing spondylitis, psoriasis, and IBD. If the *IL23R* association is confirmed it would be of considerable importance, because it would implicate the Th17 axis in the pathogenesis of Behçet's disease. On the other hand, a recent study in SSc confirmed an intronic signal at the centre of *IL12RB2*, independent of *IL23R*. The IL-12 pathway may be important in scleroderma, since it promotes proinflammatory Th1 responses and signals through *STAT4*, which is another SSc susceptibility gene.

Genetics of autoimmune diseases in mouse models

Although mouse models have been very useful for studying specific immunological pathways in rheumatic diseases, a surprisingly large number of genetic manipulations led to a lupus-like illness in mice. However, these results must be interpreted with caution. Until very recently the techniques used for gene targeting ('knockout mice') always led to incorporation of sections of genome from two different mouse strains: 129 and C57BL/6. Interaction between various loci of 129 and C57BL/6 genomes commonly leads to lupus autoantibodies and in some cases organ involvement including nephritis.[26] As a demonstration of this issue, until recently it was thought that deficiency of *Fcgr2b* in mice led to lupus-like autoimmunity. However, *Fcgr2b*-deficient mice generated on a pure C57BL/6 genetic background failed to develop lupus.[32]

Researchers have identified genes responsible for certain lupus-predisposing genetic loci in inbred strains commonly used as mouse models of SLE. The key locus in BXSB mice, *Yaa*, is a duplication of TLR7 caused by Y chromosome translocation, since TLR7 is normally only present on the mouse X chromosome.[33] In MRL/*lpr* mice, the key locus *lpr* is a non-functional mutation of the apoptosis signalling receptor Fas. Notably, the human equivalent is Canale–Smith syndrome, a lymphoproliferative disorder,[34] and *lpr* mice on a C57BL/6 background only show mild autoimmunity, confirming the necessity of the MRL background in *lpr*-induced fatal lupus nephritis and organ damage. In (NZB×NZW)F1 mice, several loci have been identified including *Sle1* (subdivided a–d) on chromosome 1, analogous to a region of multiple SLE susceptibility

loci on human chromosome 1.[35] The *Sle1b* locus corresponds to polymorphisms in *Slamf6*, encoding the SLAM receptor Ly108, which regulates lymphocyte interactions and B-cell tolerance.

Mouse models of SSc have highlighted the importance of several pathogenic genes in causing systemic fibrosis.[36] In Tight Skin-1 (TSK-1) mice there is a duplication of the fibrillin-1 gene (*Fbn1*), which leads to skin fibrosis and evidence of autoimmunity. Excessive activation of TGF-β pathways in fibroblasts using a transgenic mouse with conditional expression of TGF-β receptor type I (TGFβRI) also mimicked SSc.

Environmental factors associated with connective tissue disease

Even if the complexity of genetic factors and how they interact could be fully understood, the evidence from twin studies suggests that other factors are needed to explain the predisposition to connective tissue diseases. The key groups of environmental factors for which there is at least some supportive evidence includes infectious agents, particularly in SLE and vasculitis, airborne exposure, especially smoking and silica, as well as certain toxins which cause syndromes mimicking CTD (summarized in Table 42.4).

Table 42.4 Environmental factors with reasonable evidence of causal association with connective tissue diseases

Exposure	Disease
Infections	
EBV	Systemic lupus erythematosus
Staph. aureus	Wegener's granulomatosis
Hepatitis C	Cryoglobulinaemia
Hepatitis B	PAN
Environment	
Sunlight/UV	Cutaneous lupus
Low vitamin D	Systemic lupus erythematosus
Airborne	
Smoking	Systemic lupus erythematosus, but not systemic sclerosis
Silica dust	Rheumatoid arthritis, systemic sclerosis
Drugs	
Hydralazine, procainamide and many others	Drug-induced lupus
TNF inhibitors, interferon-α	Lupus autoantibodies, occasional autoimmune phenomena
Propylthiouracil	ANCA-type vasculitis
Gadolinium	Nephrogenic systemic fibrosis
Toxins	
Rapeseed oil denatured with aniline	Toxic oil syndrome
Contaminated L-tryptophan supplements	Eosinophilic myalgic syndrome
Vinyl chloride	Scleroderma-like syndrome

Infections and connective tissue disease

Several infections have been shown to be critical pathogenic induction agents, particularly for the vasculitides. Hepatitis C virus is the causative agent for mixed cryoglobulinaemia, and hepatitis B is associated with polyarteritis nodosa (discussed in more detail in the relevant clinical chapters). Nasal carriage of *Staphylococcus aureus* is associated with relapse in ANCA-associated vasculitis, and hence antibiotic prophylaxis with septrin has been shown to reduce relapse.

There is a strong story for involvement of Epstein–Barr virus (EBV) in SLE pathogenesis. EBV is a human herpesvirus which infects 90% of all adults and is linked to several cancers, particular B-cell lymphomas (Hodgkin's and Burkitt's) and nasopharyngeal carcinoma. A study of children and young adults with SLE found virtually all (99%) had seroconverted against EBV compared to only 70% of controls.[37] SLE patients exhibit a 15-fold increase in EBV viral load.[38] The humoral response to EBV in 90% of healthy EBV-infected adults involves the generation of antibodies against Epstein–Barr nuclear antigen 1 (EBNA-1), one of several key EBV proteins which mark its latent cycle. Several groups have shown that antibodies against lupus autoantigens Sm B′ and Sm D1 cross-react with EBNA-1.[39] The suggestion is that epitope spreading against EBNA-1 and perhaps other EBV proteins including EBNA-2 may be central to propagation of lupus autoantibody responses.

Exposure to sunlight and ultraviolet light

Studies have consistently shown that 60–70% of SLE patients have abnormally low levels of 25-hydroxyvitamin D. There is limited evidence that serum levels of 25-hydroxyvitamin D may have an inverse relationship to disease activity, and that low vitamin D is associated with ANA positivity, even in healthy individuals.[40] However, longitudinal studies have not been done, nor have studies to determine whether vitamin D supplementation will have any impact on disease activity. An increasing body of literature has focused on the effects of the biologically active form 1,25-dihydroxyvitamin D on innate and adaptive immune responses, and found that 1,25-dihydroxyvitamin D and vitamin D receptor agonists have potent anti-inflammatory effects on B and T cells, including induction of regulatory T cells. A recent GWAS in multiple sclerosis, a disease known to have a north–south geographical distribution, identified two key genes in vitamin D metabolism (*CYP27B1* and *CYP24A1*), which encode 25-hydroxyvitamin D_3-1-alpha hydroxylase and 1,25-dihydroxyvitamin D 24-hydroxylase respectively. A study searching for SNPs with functional effects on serum vitamin D levels identified several which also showed an overlap with risk of type 1 diabetes.

Although photosensitive skin rashes are a widely recognized clinical feature of SLE, as evidenced by their inclusion in the diagnostic criteria for SLE, the mechanism is unclear. It is universally agreed that lupus skin manifestations can be induced and augmented by UV-B (280–320 nm), but there is less agreement over UV-A (320–400 nm). Some studies suggest that UV-A can also induce pathogenic skin lesions at slightly lower rates to UV-B.[41] One small controlled study suggested that low levels of longer wavelength UV-A1 (340–400 nm) can actually improve systemic disease activity in SLE. Anti-Ro and anti-La antibodies are associated with cutaneous lupus manifestations. Although some studies

found that anti-Ro or anti-La positive patients were more likely to show pathological photoprovocation reactions, this is not a consistent finding.[41]

Airborne environmental factors

Of occupational environmental factors, exposure to silica, especially due to mining, has consistently strong evidence for a link to development of multiple different connective tissue diseases. A meta-analysis of epidemiological surveys confined to SSc estimated the relative risk (RR) due to silica exposure in men to be 3.02 (95% CI 1.24–7.35).[42] This is largely derived from a German cohort study of 50 000 male uranium miners, which found a RR of 7.41 for development of SSc. Population studies which failed to find an association were usually based on occupation derived from death certificates, and may have miscategorized individuals with low or moderate silica exposure. A recent study looking at almost 800 confirmed cases of silicosis found a high proportion of patients with connective tissue disorders, especially RA and ANCA-associated vasculitis. However, a large Swedish case-control study with over 2200 Wegener's granulomatosis patients and 22 000 controls found no evidence of increased risk with any occupation.[43]

While there is good evidence for a link between cigarette smoking and increased risk of RA, this evidence has been harder to find for other connective tissue disorders. A large meta-analysis found that smoking modestly increased the risk of SLE, with an odds ratio of 1.5 (95% CI 1.09–2.08).[44] Smoking is specifically linked to increased lupus skin manifestations and subsequent scarring. Within SLE patients, presence of anti-dsDNA antibodies is more common in smokers and smoking may increase disease activity, revealing a parallel between the association of smoking and development of anti-CCP antibodies in the pathogenesis of RA. Unlike RA, smoking is not associated with increased risk of development of SSc.[45] Smoking substantially increases the risk of giant cell arteritis (sixfold) with a 17-fold increased risk with heavy smoking.[46]

Drugs

Drugs are a well-recognized cause of some connective tissue diseases, especially drug-induced lupus (DIL) and propylthiouracil in ANCA-associated vasculitis. Many drugs have been implicated in DIL (reviewed in ref. 47), and their chemical structures typically contain aromatic amines, hydrazines, or a phenol ring with or without sulfhydryl groups. The two commonest inducing agents are hydralazine and procainamide. The clinical features of DIL are covered in more detail in Chapter 126. Antibodies against DNA-binding histones are typically seen in DIL, but can also be seen in non-drug-related SLE. Drug–DNA interactions may be a pathogenic factor, since both procainamide and hydralazine are able to bind polynucleotide chains. However, hydralazine has also been shown to interact with DNA–histone complexes. In contrast to idiopathic lupus, HLA-DR4 (*DRB1*04*) has been associated with hydralazine-induced lupus, but it is difficult to draw any firm conclusions because of the small numbers of patients studied.

TNF inhibitors are well recognized to cause an increase in the development of ANA (range 23–57%) and to a lesser extent anti-dsDNA antibodies(9–33%).[47] However, induction of lupus-like features attributed to TNF blockade is rare, and the majority of patients with new lupus autoantibodies show no clinical signs. Only a few definite cases of new onset SLE have been reported. Similarly other biological agents, particularly IFN-α, are associated with autoimmune phenomena and autoantibody development, but only rarely cause full SLE.

Toxins

Although many studies have looked at chemical exposure and risk of various connective tissue disorders, the vast majority of these cases are not systematically linked to exposure to any particular group of chemicals or toxins. However, several syndromes with similarities to connective tissue disorders, particularly scleroderma, can be attributed to exposure to certain chemicals. Toxic oil syndrome occurred in Spain in 1981, and affected nearly 20 000 individuals, causing over 300 deaths. It was characterized by the development of acute pneumonitis, followed by a chronic illness affecting the skin, peripheral nerves, and muscles, with scleroderma-like skin thickening and neuromyopathy. The syndrome was attributed to ingestion of contaminated rapeseed oil, denatured by aniline. Individuals developed eosinophilia, elevated IgE, and in some cases autoantibodies. A few years later, peaking in 1989, at least 1500 individuals were affected by a second disease with similar features, named eosinophilia–myalgia syndrome (EMS).[48] Although the chemical exposure was traced in nearly all cases to dietary supplements containing L-tryptophan, an essential amino acid, it remains uncertain whether the true culprit was excessive doses of L-tryptophan itself, or other contaminants or chemical by-products. Vinyl chloride, a gas used to manufacture plastics, also caused another scleroderma-like illness in over 50 factory workers. Clinical features included pulmonary fibrosis, acro-osteolysis, and cryoglobulin formation. A previous controversy suggesting a link between silicone gel used in breast implants and scleroderma has since been disproven by several large studies and meta-analysis, which have found no association between silicone breast implants and risk of connective tissue disorders.[49]

Conclusion

GWAS have identified a large number of novel genes in SLE, SSc and Behçet's disease, and further studies are in progress in ANCA-associated vasculitis and inflammatory myopathies. These rewritten genetic susceptibility maps highlight the major overlap in genes predisposing to autoimmune diseases, but are also beginning to explain differences in genetic susceptibility between specific connective tissue diseases. Key environmental triggers to CTD include infections particularly viruses (EBV, HBV, and HCV), and airborne toxins, especially cigarette smoke and silica. Increasing evidence points to low vitamin D, which has genetic as well as environmental causes, as a risk factor for the development of autoimmune diseases.

CHAPTER 43

Genetics of juvenile rheumatic diseases

Anne Hinks and Wendy Thomson

Introduction

Juvenile rheumatic diseases (JRD) include juvenile dermatomyositis (JDM) and juvenile systemic erythematosus (JSLE) but the most common disease is juvenile idiopathic arthritis (JIA). The JRDs are all considered to be complex genetic diseases and as such are caused by a combination of multiple genetic and environmental risk factors. JIA is the only disease where the genetic component to susceptibility has been substantially investigated to date and is the main focus of this chapter. The chapter aims to discuss the evidence to support a genetic component of these diseases, to review the strategies used to discover genetic risk factors, to detail our current understanding of the genes involved in JRD susceptibility, particularly for JIA, and to discuss the future direction for research into the genetics of JRD. It is hoped that the identification of genetic risk factors for JRD will aid not only the understanding of disease pathogenesis but also the classification of these often heterogeneous diseases. It may help to predict outcome of disease and response to treatment and the discovery of new disease pathways may ultimately lead to potential novel therapeutic targets.

Juvenile dermatomyositis

Juvenile dermatomyositis (JDM) is a systemic autoimmune disorder, similar to adult dermatomyositis, which occurs in children. The symptoms include proximal muscle weakness, myalgias, fever, and rash. There have been no formal family or twin studies in JDM so the extent of the genetic basis for this disease is unknown. It is a serologically and clinically heterogeneous disease, and coupled with the fact that it is a rare disease this means that collection of large numbers of disease cases for genetic studies is a challenge; however, there is building evidence for association of the *HLA* region and *PTPN22* gene with JDM.[1]

Juvenile-onset systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is a chronic systemic autoimmune disease affecting skin, joints, kidneys, and other organs. 15–20% of patients present in childhood or adolescence and these JSLE patients often have a more severe disease. Multiple genetic susceptibility risk factors have been identified to date with SLE (see Chapter 42).

Juvenile idiopathic arthritis

JIA, according to the International League of Associations for Rheumatology (ILAR) criteria, is defined as all arthritic conditions which have unknown aetiology with onset before the age of 16 years and which persist for at least 6 weeks.[2] It is classified into seven more clinically homogeneous subtypes, with an additional subgroup for those cases that do not fall into one of the defined subtypes.[2]

JIA is the only disease where the genetic component to susceptibility has been substantially investigated to date and thus will be the main focus of this chapter.

Genetic component in juvenile idiopathic arthritis

Evidence for a genetic component for JIA has come from two main sources, twin and family studies. The monozygotic twin concordance rate is 25–40%.[3,4] The sibling recurrence risk, or λ_s, is a measure of the genetic component of a disease. The calculation of λ_s for JIA has been hampered by the difficulty in collecting twins or multiplex families with JIA because of its low prevalence; it was initially calculated to be between 15 and 30,[5,6] but the largest study to date estimated the λ_s as 11.6.[7] This is similar to that found for type 1 diabetes but higher than that for rheumatoid arthritis (RA).

Genetic risk factors in juvenile idiopathic arthritis

HLA associations

Much of the early research on the genetics of JIA focused on the HLA region, with many well-documented associations with multiple HLA alleles reported. It is often challenging to compare the published findings for HLA associations with JIA because many of the initial studies were small, and used different JIA classification criteria and different resolutions of HLA typing. But it is clear that the HLA associations with JIA are different from those for adult RA, with the exception of RF-positive JIA, which is also associated with the shared epitope, and the associations appear to be different

for each of the ILAR subtypes, though there are some overlapping associations.[8]

In JIA, the HLA region is estimated to explain approximately 17% of the λ_s, suggesting that many more genetic risk factors for JIA outside the MHC remain to be identified.[9]

Non-HLA associations

Two main approaches have been used in the search for non-HLA genetic susceptibility risk factors for complex genetic diseases such as JIA, linkage and association studies (see Chapter 37). Given the low prevalence of JIA it is difficult to collect the large numbers of multicase families needed for linkage studies, so these have been largely superseded by association studies.

Candidate gene association studies

Candidate gene association studies have been the main strategy used in the search for risk factors for JIA to date. The genes selected include those that are believed to be potentially important in disease pathogenesis, genes that are known to be associated with other clinically similar diseases, or genes in which rare mutations lead to monogenic forms of disease. The biggest issue in the study of the genetics of JIA is power. The observations emerging from association studies across different complex autoimmune diseases suggest that, apart from HLA, most complex genetic risk factors will only confer a small effect size (odds ratios for developing the disease of between 1.1 and 1.3). In order to detect these modest effect sizes, large case–control sample sizes are required and replication of findings is vital. As JIA is a relatively rare disease it has been slower to collect these large sample sizes, but a number of large collections have now been assembled. It would be fair to say that in JIA, as in other complex diseases, initial studies often used inadequate sample sizes with no replication and therefore any association seen should be viewed with caution as it may represent a false-positive result. Here only the loci with robust validated evidence of association in multiple independent cohorts are presented (Table 43.1).

Exploiting the now well-established overlap of some loci across different autoimmune diseases has proved a highly successful strategy in the search for JIA susceptibility loci. Investigation of loci that confer susceptibility to other autoimmune diseases such as RA and type 1 diabetes has identified multiple genes and regions associated with susceptibility to JIA.

PTPN22

A missense single nucleotide polymorphism (SNP) (rs2476601) within the protein tyrosine phosphatase N22 (*PTPN22*) gene is a well-established autoimmune susceptibility locus with association to diseases such as type 1 diabetes, RA, SLE and autoimmune thyroid disease (AITD).[10] It shows a well-validated association with JIA. It was initially identified in a United Kingdom cohort of all JIA cases,[11] where the association appeared to hold across all JIA ILAR subtypes apart from systemic-onset JIA. The association has since been validated in Norwegian,[12] Finnish[13] (although only in the polyarticular subtype), and United States cohorts[14] The gene confers a risk of developing JIA second only to that of the MHC, with an odds ratio of around 1.5. *PTPN22* encodes the protein Lyp, whose primary role is in negative regulation of T-cell activation, making this a very good candidate gene for general autoimmune response.

STAT4

An intronic SNP (rs7574865) in the signal transducer and activator of transcription 4 (*STAT4*) gene has now been associated with JIA in three independent cohorts.[14–16] *STAT4* has also been associated with RA and SLE.[17] *STAT4* is involved in interleukin (IL)-12 signalling and is essential for the differentiation of T helper cells.[17]

IL2RA

Like *PTPN22*, the interleukin 2 receptor alpha (*IL2RA*) gene is also emerging as a general autoimmune gene with association to type 1 diabetes, RA, SLE, multiple sclerosis (MS) and AITD.[18–20] There is evidence for association of a SNP in intron 1 of the gene with JIA in a United Kingdom and United States cohort,[21] although a second United States cohort found no association.[16] This region is interesting, however, as it appears that there are multiple different SNPs associated across the different autoimmune diseases.

IL2

The emerging genetic associations with JIA are now suggesting that the IL-2 pathway plays a central role in JIA disease pathogenesis, with validated association of a SNP in an intergenic region between the *IL21* and *IL2* genes on chromosome 4.[14,22,23] The same SNP (rs6822844) has been associated with RA, type 1 diabetes, and coeliac disease.[24–26]

TNFAIP3

Two independent SNPs close to the tumour necrosis factor alpha (TNFα) induced protein 3 (*TNFAIP3*) gene, one conferring risk for disease and the other protective which has been associated with RA and SLE also shows evidence for association with JIA in two independent cohorts.[15,16] *TNFAIP3* encodes the protein A20, which is a potent anti-inflammatory molecule.[27]

CCR5

A 32-base-pair insertion/deletion in the CC chemokine receptor 5 (*CCR5*) gene (CCR5Δ32) has been associated with protection from developing RA, type 1 diabetes, and coeliac disease, and has been investigated for association with JIA with some conflicting results—two showing association.[28,29] and the other with no association.[30] However, a meta-analysis combining the results from all three studies strengthened the association with JIA.[29] *CCR5* has been shown to be important in the recruitment of T helper cells to the synovium.

c12orf30/SH2B3/ATXN2

Three studies have found association of a region on chromosome 12 with JIA. The first study found association of a SNP in the gene *c12orf30*,[16] and this association has also been found in a more recent study in United States and German cohorts[14] In a United Kingdom study a SNP in the *ATXN2* gene which lies adjacent to *c12orf30* shows association with JIA.[31] Interestingly, the region shows extended linkage disequilibrium which also extends through the *SH2B3* gene, which has been associated with both RA and coeliac disease.[32] *SH2B3* encodes an adaptor protein involved in T-cell activation. There is also evidence that the SNP is correlated with expression of SH2B3.[33]

PTPN2

The *PTPN2* gene also shows multiple autoimmune disease associations (RA, type 1 diabetes, coeliac disease, Crohn's disease). SNPs

Table 43.1 Juvenile idiopathic arthritis: non-HLA genetic susceptibility loci validated in more than one independent cohort

within the gene have recently been found to be associated with JIA in a United States cohort and replicated in an independent cohort of United States and German cases.[14] *PTPN2* encodes a protein tyrosine phosphatase, similar to PTPN22, which also plays a role in activation and regulation of T and B cells.

COG6 and ANGPT1

A recent study in a United States cohort found two novel associations with JIA in the *COG6* and *ANGPT1* genes; these were validated in an independent cohort of United States and German cases and controls.[14]

Other potential loci

There are a number of loci which show association with JIA in just one study which require validation in independent cohorts or with meta-analysis. These include associations in the C-type lectin domain family 16, member A (*CLEC16A*) gene,[34] cytotoxic T lymphocyte antigen 4 (*CTLA4)*, AF4/FMR2 family member 3 (*AFF3*), protein kinase C, theta (*PRKCQ*), and the lim domain containing preferred translocation partner in lipoma (*LPP*) genes.

The candidate gene approach has been successful in the search for JIA genetic susceptibility risk factors, but is obviously limited by prior knowledge of a disease.

Genome-wide association studies in juvenile idiopathic arthritis

Genetic studies of complex autoimmune diseases have been transformed by the development of the genome-wide association study (GWAS) in the mid 1990s following a number of advances, the identification of millions of SNPs across the genome, and the technical ability to genotype these SNPs rapidly and cheaply. This approach has proved highly successful in identifying novel risk factors for many complex diseases. It would be fair to say that the difficulty in collecting large sample sizes for JIA has hindered progress in the search for genetic risk factors for JIA using GWAS approaches, but these are now being published. The first two were performed on very modest sample sizes. The first identified association with the *TRAF1/C5* locus on chromosome 9[35]; different SNPS in this region have also been associated with JIA in independent candidate gene studies.[15,36] The second identified association of the *VTCN1* (B7-homolog4 (*B7-H4*) gene with JIA, which was validated in an independent dataset.[37] More recently a larger study has been reported investigating United States and European JIA cases and controls. It identified two novel JIA susceptibility loci, *c3orf1*, IL-15 (*IL15*), and the jumanji domain containing 1C (*JMJD1C*) region,[38] which show replication in United Kingdom and German cohorts. Further JIA GWAS are in progress; combined meta-analyses of the studies to date will validate previous findings, and the increased power should enable the discovery of additional novel loci.

Fine mapping and identification of causal variants

There is now a growing list of SNPs associated with JIA. In most cases these SNPs will not be the actual disease-causing variant but will be correlated with nearby variants that cause a functional change to the gene and thus cause disease. The next stage of analysis is challenging: in some cases there may be obvious candidate genes in the region and candidate SNPs such as exonic SNPs or SNPs which affect the expression of the gene. But in most cases a large study investigating all possible variation in the region by resequencing, followed by fine mapping to identify the most likely causal variant, is required. This will then be followed by appropriate functional studies to show how the variant alters the gene function (e.g. protein expression level or differences in cellular function).

For JIA the fine mapping stage is being facilitated by involvement in the Immunochip consortium which was initiated by the Wellcome Trust Case-Control consortium (WTCCC) of leading investigators of a number of different autoimmune diseases.[39] The Immunochip is an Illumina Infinium custom genotyping chip designed for fine mapping of established genes associated with autoimmune diseases, many of which also confer susceptibility to JIA. It enables cost-effective fine mapping and the potential for identification of novel JIA loci. Large cohorts of JIA cases from the United Kingdom, the United States, and Germany have been genotyped and the consortium are sharing control data, thereby increasing power for the individual studies.

Subtype-specific associations

Power issues in JIA are compounded by the fact that JIA is a clinically heterogeneous disease and can be classified into more homogeneous subtypes by the ILAR classification criteria.[2] Thus the search for genetic risk factors for JIA to date has been across all JIA subtypes or just the most common subtypes, oligoarthritis and RF-negative polyarthritis. But it is likely that there will be subtype-specific effects, as there may be distinct pathogenic pathways for these clinically diverse subtypes. Any stratified genetic analysis by ILAR subtype leads to small sample sizes and the subsequent loss in power that this entails, as well as multiple testing issues.

A number of potential subtype-specific associations have been identified but it is clear that large collaborative efforts are required to confirm or refute these findings.

The systemic JIA (sJIA) subtype is now more often thought of as an autoinflammatory disease rather than an autoimmune disease like the other JIA subtypes.[40] There is some emerging data that the subtype also differs genetically: for example, there is no evidence that sJIA is associated with *PTPN22*[41] and the HLA associations identified to date are weak. There is evidence for validated association of SNPs in the IL-1 ligand and receptor cluster with sJIA.[42]

The enthesitis-related arthritis (ERA) subtype of JIA is characterized by arthritis and enthesitis which may widen to affect the sacroiliac and spinal joints. The children may develop symptoms similar to ankylosing spondylitis (AS) and it mainly affects male, *HLA B27* positive, children. A non-synonymous SNP in the endoplasmic reticulum aminopeptidase 1 (*ERAP1*) gene is a well-established susceptibility gene for AS and a recent study found that this SNP was also associated with the ERA subtype of JIA.[43] Likewise the *IL23R* gene is a confirmed psoriasis susceptibility gene and a SNP in this gene shows association with the juvenile-onset psoriatic arthritis subtype.[43] Both these findings require validation in independent datasets for confirmation, but suggest distinct pathogenic pathways for these subtypes.

It is hoped that a greater understanding of the genetic basis of JIA as a whole may help clinically in defining the different subtypes of JIA and aid in the classification of this heterogeneous disease.

Prediction of disease risk and outcome

One of the original goals in genetic studies was that the identification of genetic risk factors would enable the prediction of individual disease risk for patients. But the evidence emerging from these genetic studies of complex diseases is that there will be multiple genetic risk factors (possibly hundreds), each conferring a very small effect, and we are yet to understand how these may interact with each other.

It is proposed that the knowledge of genetic susceptibility factors may be more useful in the prediction of disease outcome in children with JIA. The identification of children with a poorer prognosis would enable potentially more targeted or aggressive treatment which is especially important in children to prevent future joint damage and disability. These investigations rely on large long-term

prospective outcome studies such as the Childhood Arthritis Prospective Study (CAPS)[44] and Childhood Arthritis Response to Medication study.[45,46]

Conclusions

The last few years have seen great progress in the understanding of the genetic basis of JIA with new loci identified and confirmed in independent cohorts. There are now 12 JIA susceptibility loci with evidence for association in more than one study, but further advances will emerge in the next few years following large scale GWAS, meta-analyses, and fine mapping strategies. Many of the loci identified to date confer susceptibility to multiple autoimmune diseases and play a role in the immune response. It is hoped that this knowledge will lead not only to a better understanding of disease pathogenesis for JIA and its subtypes but also aid in the classification of this heterogeneous disease. It may identify new pathways for potential therapeutic targets and help in the prediction of disease outcome.

and Frances M. K. Williams

Introduction

Charcot is credited with first recognizing the hereditary nature of osteoarthritis (OA) of the hands in his description of this condition in 1881.[1] The 1940s saw the first formal study of familial clustering of the disease when Stecher showed a two- to threefold increased risk of the disease among the mothers and sisters of cases with Heberden's nodes.[2] Stecher's work was confirmed and extended by Kellgren et al, in epidemiological studies conducted in the United Kingdom in the 1950s and 1960s,[3] which showed that 'generalized OA' (co-occurrence of hand and knee OA) conferred a twofold risk of disease to first-degree relatives of affected cases compared with population controls.

Modern era twin and family studies

Limitations of these early family studies include their methods for case selection, the lack of standard methods for case definition (including a lack of distinction between clinical and radiographic disease), and the lack of age matching among relatives, all of which might potentially upwardly bias the assessment of genetic influence. However, with the advances in knowledge of the biology and clinical characteristics of OA, greater standardization of radiological and clinical definitions, and the emergence and maturation of large, genetically informative cohorts of twins and families, a more comprehensive picture of the genetic influence on OA has emerged.

In 1996, the St Thomas' UK Adult Twin Registry reported evidence that radiographic OA at the hand and knee has a substantial heritable component.[4] This was followed by two studies published in the 1998 (the Baltimore Longitudinal Study of Aging[5] and the Framingham Offspring Study[6]) that showed significant familial clustering for hand and knee OA. Both family studies used unselected population samples; a particular strength of the Framingham Offspring Study design was that all the subjects were assessed at adult ages. A genetic influence on hip OA was suggested in two studies[7,8] that showed a higher than expected prevalence of hip OA among relatives of probands with total hip replacement. These observations were confirmed using data from Nottingham.[9] Through to 2010, further studies conducted in the TwinsUK Registry confirmed a genetic contribution to radiological disease at the hip.[10]

Twin studies may be used to derive quantitative estimates of heritability, a measure of the proportion of variation of a trait attributable to population-level genetic variation. For hand, hip, and knee OA reported heritability estimates in the range 40–75% are evidence that individual genes have a causal role in the disease. Family studies also offer further insight into the mode of action of genes. Modelling segregation patterns based on the distribution of hand and knee OA in the Framingham Offspring Study[6] has provided evidence of a polygenic mode of inheritance, in which the disease is accounted for by multiple genetic variants each having small effect on risk. These studies have provided the justification for the more detailed search for individual genes that has escalated in recent years through major advances in genetic technology.

Insights from inherited osteoarthritis

While segregation studies indicate that classical mendelian inheritance does not explain the population occurrence of the disease, insight into the mechanisms by which individual genes might have a direct influence on the occurrence and expression of OA emerges from studies of inherited diseases in which OA is a feature (Table 44.1).[11] These inherited diseases illustrate that a range of genetically determined features have a bearing on the OA phenotype. They also highlight the depth of penetrance of gene action by showing that single gene defects can have ramifications through the disease phenotype. In addition, they provide a framework for the systematic search for the gene variants responsible for the occurrence of OA in the general population.

Linkage, candidate gene, and genome-wide association studies

Advances in understanding the role of individual genes in OA need to be interpreted against a backdrop of rapid progress in genotyping technology and analytical techniques applied to increasingly extensive and detailed clinical collections of people with OA; and population samples of both symptomatic and radiographic disease. With this continuing exponential rise in genetic information, any account of the gene variants implicated must be qualified by an appreciation of the rate at which new pathways are continuing to emerge. Online tools, including for example the Human Gene

Epidemiology Navigator,[12] provide a continuously updated account of this rapidly evolving picture.

For more than a decade researchers have been engaged in comprehensively screening the genome to detect gene variants implicated in OA. The first approaches involved studies designed to detect genetic linkage using methods that examine whether chromosomal regions are coinherited among related individuals with the disease. Several regions have been implicated in OA through linkage. This information was brought together most recently in a meta-analysis conducted by Lee et al.[13] which combined the results of three whole-genome linkage scans[14–16] using the Genome Scan Meta-Analysis (GMSA) method.[17] Five regions provided combined evidence of linkage with a probability <0.05: 7q34–7q36.3, 11p12–11p13.4, 6p21.1–6q15, 2q31.3–2q34, 15q21.3–15q26.1. These findings have generated considerable interest, and have concentrated attention on specific genes harboured within linked regions. including the interleukin (IL)-1 gene cluster, *FRZB*, and matrillin-3 located on chromosome 2, and the IL-4 receptor gene on chromosome 16.[18]

Candidate gene studies that focus on identifying the risk of disease associated with genetic variants among individuals in the population provide an additional approach to linkage analysis. Typically these studies target genes for which there is biological evidence to support a potential role in disease. They are therefore limited by knowledge of disease pathways in the tissues involved in OA, for which there remains considerable uncertainty. It is difficult to know how much importance to attach to candidate gene findings. However, for some time there has been the capability to conduct genome-wide association studies (GWAS), and screen for genetic associations agnostically. Technological advances continue to extend screening to a greater depth, allowing the detection of rare variants.[19]

The vast potential of genetic association studies to screen for large numbers of associations brings with it a substantial risk of false discovery. Interpretation needs attention to both the statistical veracity of reported associations and their reproducibility in different settings and in different population groups. With these caveats, a number of genes have emerged that merit more detailed attention.[20] For a number of the strongest and most consistent associations, functional genetic studies have begun to provide further evidence of their role in disease pathogenesis.

Collagen-related genes

Collagen genes have been considered as candidates of interest given their role in inherited diseases in which OA is a feature. Numerous studies have reported associations with genes encoding collagen I, II, IV,, and XI variously at the hip, knee, and spine.[21] However, there has been remarkable inconsistency between studies and a failure to replicate. In GWAS, the collagen type VI alpha 4 pseudogene 1 gene (*COL6A4P*; previously named dual von Willebrand factor A (*DVWA*)) emerged as the strongest association in a 2008 study conducted among Asian populations.[22] Most recently, *COL11A1* was reported as one of the strongest signals to emerge in association with hip OA in the United Kingdom arcOGEN study.[23] This gene codes for the alpha-1 polypeptide chain of type XI collagen, penetrant mutations of which are responsible for Stickler's syndrome (Table 44.1).

Growth and differentiation factor 5 gene (*GDF5*)

Associations with genes encoding GDF5 are some of the most consistently reported in OA.[20] GDF5 is an extracellular signalling molecule (member of the transforming growth factor beta (TGF-β) superfamily) and is intimately involved in bone formation and in

the maintenance and repair of joint tissue. Functional studies of OA-associated single nucleotide polymorphisms (SNPs) in *GDF5* alleles have revealed allele-dependent differences in gene transcription—an effect that is seen in all joint tissue and not confined to cartilage alone.[24] This gives strong support for an aetiological role of *GDF5* variants in OA.

Asporin gene (*ASPN*)

Asporins are components of extracellular matrix, bind TGF-β, and are negative regulators of chondrogenesis. Overexpression of *ASPN*, the gene encoding asporin, leads to a decrease in TGF-β1 mediated chondrogenesis. Associations between *ASPN* with knee OA have been reported in Japanese, Korean, and Chinese populations,[25] although they have been either weak or absent in European populations.[26]

SMAD family member 3 (*SMAD3*)

The SMAD proteins are downstream mediators of TGF-β signals. SMAD3 acts to maintain articular cartilage in the quiescent state by repressing chondrocyte hypertrophic differentiation and regulating matrix molecule synthesis. The gene has been associated with OA in independent European hip and knee cohorts.[27]

Acidic leucine-rich nuclear phosphoroprotein 32 family member A gene (*ANP32A*)

Chondrocyte apoptosis is evident in OA when compared with age-matched controls.[28] *ANP32A* encodes a tumour suppressor molecule that has a regulatory role in apoptosis and interferes with Wnt signalling. It has been associated with hip OA in white women.[29]

Type II iodothyronine deiodinase gene (*DOI2*)

The gene encoding type II iodothyronine deiodinase (*DOI2*) is responsible for the bioavailability of thyroid hormone in a number of tissues including growth plate, and has a role in chondrocyte proliferation and differentiation. This was one of the few genes to be identified in both GWAS and linkage studies.[20] The association with OA may be mediated though an influence on hip geometry.[30]

Interleukin genes

Associations with interleukins are of interest given the contribution of inflammation to the pathogenesis of OA. Variants in *IL1*, *IL6*, and *IL10* have been reported to be associated with OA, with some variants in *IL1* reported to be associated with OA severity.[20]

Frizzled related protein gene (*FRZB*)

Frizzled related protein is involved in bone formation and in regulation of the Wnt receptor signalling pathway that has a central role in skeletal development and is involved in the maintenance of the structure and function of bone and cartilage. Variants of *FRZB* have been reported in a number of studies to be associated with hip OA and knee OA.[31,32]

Oestrogen receptor gene (*ESR1*)

The oestrogen receptor is an important mediator of signal transduction and is expressed in human chondrocytes. Associations with OA have been reported in some white and Asian populations, although the differences in variants examined and the overall inconsistency of these associations make the data hard to interpret.[20]

Vitamin D receptor gene (*VDR*)

The role of vitamin D in OA is of interest because of its established role of bone metabolism and inflammation. *VDR* has been of the

Table 44.1 Inherited diseases in which osteoarthritis is a feature

Condition	Features	Mode of inheritance	Gene/protein implicated
Spondyloepithelial dysplasia	Heterogeneous group of disorders characterized by abnormal development of axial skeleton; dwarfism. Generalized OA in early teens. Disc herniation been reported in spondyloepithelial dysplasia tarda	AD, AR, and XL	COL2A1
Familial calcium pyrophosphate disease	Chondrocalcinosis of knees symphysis pubis and wrist	AD and AR	Linkages in humans reported to chromosome 5p and 8q in one family; *ank* gene implicated in mice
Familial hydroxyapatite deposition disease	Teninitis, bursitis, and articular OA commonly involving the shoulders wrists and hips	AD	
Stickler's syndrome	Myopia, hearing loss, epiphyseal dysplasia. Mandibular dysplasia. Severe OA develops in the third and fourth decades	AD	COL2A1, COL11A2, COL11A1
Kniest dysplasia	Shortening of trunk and limbs, flattening of the face. Articular cartilage soft with low resilience. Severe premature OA of the hips and knees	AD	COL2A1
Multiple epiphyseal dysplasia	Heterogeneous group of disorders characterized by alteration in epiphyseal growth, irregularity, and fragmentation of epiphyses of long bones. Premature OA in weight bearing and non-weightbearing joints in childhood or early adulthood	AD and AR	COMP, MATN3, COL9A1,COL9A2. COL9A3, DTDST
Metaphyseal chondrodysplasia	Group of disorders characterized by metaphyseal dysplasia. Short stature, short limbs. Bowed legs. Premature OA of the hips and knees	AD	COL10A1. PTH/PTHrP
Achondroplasia	Short limb dwarfism. OA and spinal stenosis in adulthood	AD	fibroblast growth factor
Blount's disease	Disturbance in growth of medial aspect of the proximal tibial epiphysis. Premature OA of the knees	AD	
Alkaptonuria	Inborn metabolic defect leading to deposition of homogentisic acid. Results in premature OA involving the shoulders and the lateral compartments of the knees. High frequency of intervertebral disc disease	AR	HGD
Familial lumbar stenosis	Case report of familial lumbar stenosis with disc herniation	AD	
Kyphoscoliosis	3-dimensional deformity of spinal growth ; disc lesions common	AD and XL	Genome-wide microsatellite screen identified areas suggestive of linkage on 9q31.2-q34.2, and 17q25.3
Camptodactyly–arthropathy–coxa vara–pericarditis syndrome	Rare familial disorder characterized by flexion contractures of the fingers, coxa vara deformity, and a non-inflammatory arthropathy with synovial hyperplasia, features of and non-inflammatory pericardial effusion	AR	Defects secreted proteoglycan (superficial zone protein)

AD, autosomal dominant; AR, autosomal recessive; XL, X-linked.

most extensively studied candidate genes in OA, with associations demonstrated at the knee and spine.[21] However, reports of association have been inconsistent and *VDR* has notably failed to emerge strongly in GWAS studies as associated with OA.

Disease heterogeneity

While OA is characterized by common pathological features and disease mechanisms, it also shows considerable clinical heterogeneity. Epidemiologically there is variation in the contribution of risk factors for disease, for example in males and females, at different ages, and for different joints. It would be naive to assume that the genetic influences in OA are constant across all affected individuals and all clinical disease features.

Twin studies indicate that the strength of the genetic influences differs among individual disease features even within the same body site. For example at the hip, while joint space narrowing is strongly heritable, sclerotic changes in bone associated with OA and osteophytes show significantly less genetic influence.[10] Genetic influences also differ across body sites. In an analysis of monozygotic and dizygotic twin participants in the TwinsUK Registry assessed radiographically for OA at the hand (DIP, PIP, and CMC joints), knee, and hip joints, genetic influences were strongly correlated among joints in the hand; however, there was little evidence of common genetic pathways to account for the co-occurrence of OA at the hand, knee, and hip.[33] This work showed no evidence that common or shared genetic factors determine the occurrence of disease across all these skeletal sites.

The findings suggest that there are important aetiological differences in the genetic contribution to disease at different skeletal sites. This observation helps explain some of the inconsistency in results of linkage and association studies that has emerged.

The extended OA phenotype including musculoskeletal pain

Genetic influences on OA extend beyond measures of radiographic change. Joint shape, itself a potential predictor of disease, is strongly genetically determined. For example, acetabular dimensions including acetabular depth and centre edge angle have been shown to have a heritability of 60%.[34] COMP, a biomarker of cartilage degeneration, is also genetically determined.[35] C-reactive protein (CRP) levels are also recognized to be influenced genetically.[36] Thus the genetic influence on OA acts on collagen structure and cartilage metabolism, and on the pro-inflammatory cytokine cascades that influence the inflammatory component of the disease.

There is an increasing awareness of a genetic influence on pain, including joint pain in OA. Studies conducted among twins have shown that reported pain has a heritability between 28–39% at a range of peripheral sites including the knee, thigh, hand, and foot.[37] In the same dataset, pain reporting at different sites was modestly but uniformly correlated, with a single factor accounting for 95% of the overall variance in pain reporting. This common pain reporting factor itself has a heritability of 46%. The observations in twins support the notion that a single genetic factor underlies a general propensity for individuals to report joint pain. This is in stark contrast with radiographic OA which is determined by genetic factors specific to each anatomical site and suggests that the genetic influence on radiographic OA and the pain related to OA are quite distinct. The genetic architecture of OA thus mirrors the clinical observation that pain and the extent of radiographic disease are poorly correlated.

Genes implanted in pain in osteoarthritis

As with the study of radiographic OA, the capacity to identify individual genes that might be implicated in pain in OA continues to expand rapidly.[38] A number of genes have emerged that are of particular relevance.

Catechol-O-methytransferase gene (COMT)

Catechol-O-methyltransferase is involved in the regulation of catecholamine and encephalin levels. Polymorphic variation in the COMT gene has been associated with clinical pain processing. Functional variants of COMT have been associated with hip pain in OA.[39]

Sodium channel protein type 9 gene (SCN9A)

This gene encodes a voltage-gated sodium channel which plays a significant role in nociception signalling. When present in OA it is associated with higher pain scores than in controls.[40]

Sparteine/debrisoquine oxidase gene (CYP2D6)

Sparteine/debrisoquine oxidase is one of the hepatic cytochrome p450 enzymes and is involved in the activation of codeine by O-demethylation to morphine. Poor metabolizer status occurs in 10% of white people and 2% of Asians and African Americans. In both clinical and experimental pain, poor metabolizers show reduced analgesic efficacy to codeine.[41] Basal pain thresholds are also influenced by CYP2D6 status.[42]

Paired amino acid converting enzyme 4 gene (PACE4)

A single nucleotide polymorphism in the gene that encodes PACE4 has been shown to protect against pain in subjects with knee OA.[43]

Mice carrying a null mutant of this gene are resistant to acute pain. PACE4 is expressed in peripheral and central nervous system tissues involved in nociception, including dorsal root ganglia, amygdalae, and spinal cord.

Transient receptor potential cation channel subfamily V member 1 gene (TRPV1)

TRPV1 encodes the capsaicin receptor and is responsible for mediating the sensation to scalding heat. A study of seven cohorts from the United Kingdom, the United States, and Australia showed an association between low thermal pain sensitivity TRPV1 genotype and a lower risk of symptomatic knee OA.[44] TRPV1 is an excellent target for pharmacological intervention: capsaicinoids are used widely in the treatment of pain and there are several new molecules acting on this receptor under investigation at present.[45]

Epigenetic influences on osteoarthritis

Epigenetic effects are the heritable changes in gene expression that occur without changes in primary DNA sequence. They include DNA methylation, histone modification, and non-coding RNAs. These effects can arise from environmental influences and act either at the level of gene transcription or post-transcriptionally. There is accumulating evidence of epigenetic processes operating in OA.[46] Altered methylation patterns have been associated with the promoter of genes encoding metalloproteinase including MMP13 and ADAMTS4; histone methylation has been associated with increased COX-2 and iNOS transcription; non-coding microRNAs are differentially expressed in normal and OA cartilage and may induce the expression of matrix-degrading enzymes.

Epigenetic effects may have an impact on the penetrance of disease susceptibility genes. For example, the imbalance in allele expression of GDF5 has been shown to be influenced significantly by DNA methylation.[47] These findings serve to emphasize that studies of allelic association alone are unlikely fully to explain the heritability of OA, and that knowledge of the epigenetic status of genetically associated disease genes will be a vital part of understanding their contribution to disease.

Conclusion

A genetic influence of OA is firmly established and rapid technological advances in molecular genetics are providing a more detailed picture of the role of individual gene variants in determining the diverse phenotypic manifestations of the condition. While the genetic contribution to OA is manifestly complex, knowledge of the genetic influence on all aspects of the OA phenotype provides insight into disease mechanisms and potential therapeutic targets. The increasing understanding of OA genetics also raises the realistic possibility of developing tools for detecting susceptible groups, and for targeting individualized treatments.

CHAPTER 45

Genetics of chronic musculoskeletal pain

Kate L. Holliday, Wendy Thomson, and John McBeth

Introduction

Regional and widespread musculoskeletal pain disorders are common in the general population, with 33% reporting low back pain (LBP) and 11% chronic widespread pain (CWP), the defining feature of fibromyalgia (FM), in any one month.[1] For most pain disorders prevalence increases almost linearly with age, plateauing around the sixth decade, and women are more likely to report symptoms at all ages.[2]

Aetiology is poorly understood and current treatments lack efficacy. Twin studies suggest a genetic basis; however, research has been hampered by small sample sizes and phenotypic complexity,[3] since gastrointestinal disorders, fatigue, sleep disturbance, cognitive dysfunction, and psychological distress, among others, are common comorbidities. Elucidating the genetic susceptibility could identify the biological mechanisms involved, phenotypic subgroups, and novel therapeutic targets for use in personalized medicine. Additionally, other rheumatic diseases may benefit from this research as it could, for example, help to explain the common discordance in structural damage and pain severity observed in osteoarthritis (OA) or why FM is prevalent in rheumatoid arthritis (RA) patients. This chapter presents a state-of-the-art summary of current research in the field of pain genetics and highlights some of the methodological challenges in this field.

Heritability

Family studies have suggested a genetic component to FM; relatives of FM patients were eight times more likely to have FM than relatives of RA patients.[4] The extent of variance explained by additive genetic effects compared to shared environment was estimated in a study of Finnish twins with possible FM (based on a number of symptoms including tenderness, stiffness, and neck pain) to be approximately 50%.[5] A similar estimate of heritability (h^2) was reported for CWP in a study of Swedish twins (Table 45.1).[6]

The majority of twin studies have been conducted on LBP and neck pain, and h^2 estimates vary widely.[7–18] In a cohort of United Kingdom twins a common factor explained 95% of the variance in pain reporting at seven bodily sites for which h^2 = 46% (95% confidence interval 0.40, 0.52), suggesting that the genetic component to pain reporting did not differ by pain site. It may, however, differ by the extent and severity of pain reported. Higher h^2 has been reported for multisite than single-site pain,[15,17] and severe disabling and/or radiating pain results in higher h^2 estimates compared to ever reporting LBP or neck pain.[10]

Age also appears to influence h^2, with low estimates reported for widespread and LBP in 11 year old Finnish twins.[19,20] Similarly, a study of Danish twins found that h^2 was low in under 16s; however, h^2 increased dramatically in 16–18 year olds and then decreased to age 40.[8] Other studies have also suggested a decline in h^2 with age. Among subjects aged over 70 years in a Danish cohort there was no evidence of h^2 for LBP in females but h^2 = 27% in men, while h^2 was negligible for neck pain for both sexes.[11] Despite the increased prevalence of chronic musculoskeletal pain in females, h^2 estimates have not significantly differed between genders in most studies.[6,15,21]

These twin studies have mainly relied on self-reported pain and in some cases a simple question such as 'Have you ever had back pain?' has been used to classify subjects. This may be problematic, particularly in elderly populations where pain may be explained by structural damage or disease. Despite a strong correlation between lumbar disc degeneration (LDD) and LBP, only a limited amount of h^2 for LBP was explained by LDD[13,18] in twin studies that have undertaken clinical assessments and used MRI to assess pathology.

What genes are likely to be involved?

Heritability studies point to genes that may be involved in chronic pain susceptibility. A common heritable component to chronic pain, anxiety, depression, and psychological distress has been reported,[7,10,22] suggesting that susceptibility genes for mood disorders may also be involved in chronic pain susceptibility. A common heritable component to CWP and other functional pain syndromes independent of mood disorders has also been reported,[22] suggesting that genes influencing pain processing and perception may be

involved. The susceptibility genes may differ in accordance with subphenotypes. Some individuals report pain but not psychological disturbance while others have severe psychological distress. Chronic pain is a heterogeneous phenotype and its genetic makeup is likely to reflect this.

Mendelian-inherited pain disorders have identified a number of genes which are important in pain perception, particularly in ion channels. *SCN9A* encodes the alpha subunit of the voltage-gated sodium channel Na$_v$1.7. Multiple mutations in *SCN9A* resulting in either a severe pain disorder or congenital insensitivity to pain

Table 45.2 Genetic association studies of chronic musculoskeletal pain

Gene	Polymorphism(s)	Phenotype(s)	Findings	Reference
ADRB2	rs1042713 (R16G), rs1042714 (Q27E)	FM	Haplotype of rs1042713 (R allele) and rs1042714 (Q allele) associated with increased risk of FM	Vargas-Alarcon et al., 2009 (35)
	Multiple SNPs including rs1042713 (R16G)	Chronic pain, CWP	R allele of rs1042713 associated with reduced risk of CWP	Hocking et al., 2010 (31)
COMT	rs4680 (V158M)	Symptomatic hip OA	M allele of rs4680 associated with increased risk of hip pain in women	van Meurs et al., 2009 (33)
	Multiple SNPs including rs4680 (V158M)	Chronic pain, CWP	No association	Hocking et al., 2010 (31)
	rs4633, rs4680 (V158M), rs6269, rs4818	CWP	No association	Nicholl et al., 2010 (32)
GCH1	rs10483639, rs3783641, rs8007267	CWP	No association.	Holliday et al., 2009 (37)
HTR2A	Tag SNPs including rs6313 (T102C)	CWP and number of pain sites reported	Evidence of association between SNPs and CWP and the number of pain sites reported	Nicholl et al., 2010 (40)
OPRM1	rs1799971 (N40D), rs563649	CWP	No association	Holliday et al., 2009 (37)
SCN9A	rs6746030 (R1150W)	WOMAC pain score	W allele associated with increased pain scores	Reimann et al., 2010 (23)
	rs6746030 (R1150W)	WOMAC pain score, widespread pain	W allele not associated with WOMAC pain score but associated with increased risk of widespread pain	Valdes et al., 2010 (47)
SLC6A4	44bp indel (5HTTLPR)	FM	No association	Potvin et al., 2010 (42)
TRPV1	rs8065080 (I585V)	Symptomatic knee OA	II genotype associated with reduced risk of symptomatic knee OA	Valdes et al., 2011 (27)

CWP, chronic widespread pain; FM, fibromyalgia; OA, osteoarthritis; WOMAC, Western Ontario and McMaster Universities Arthritis Index.

have been reported in families.[23] Susceptibility loci for common complex diseases commonly occur in genes causing phenotypically similar mendelian disorders, therefore, as well as adding to the understanding of the biological mechanisms underlying pain perception, these studies highlight candidate genes for chronic pain susceptibility.

Candidate gene studies

Candidate gene genetic association studies of chronic musculoskeletal pain phenotypes have been undertaken to identify susceptibility genes. The main findings of these studies are summarized below and in Table 45.2.

Voltage-gated sodium channel, Na$_v$1.7 alpha subunit (SCN9A)

Reimann et al. identified a non-synonymous SNP, R1150W (rs6746030), in SCN9A associated with pain perception in OA and replicated this finding in other cohorts with different types of clinical pain.[23] The variant W allele, which was associated with increased pain scores, increases excitability of nociceptive neurons in the dorsal root ganglion.[24] Valdes et al. subsequently disputed the finding of Reimann et al. as they observed no association with pain scores in OA but they did observe an association with widespread pain in population-based cohorts.[25]

Transient receptor potential vanilloid receptor 1 (TRPV1)

TRPV1 is an ion channel gene which encodes a thermosensitive channel expressed in primary afferent neurons. Valdes et al.[27] observed that the II genotype of the non-synonymous SNP I585V

(rs8065080) in TRPV1, which has been associated with reduced cold pain sensitivity,[26] was associated with reduced risk of knee OA in 4368 cases compared to 3852 controls from seven United Kingdom cohorts. The effect was much larger when comparing symptomatic to asymptomatic knee OA cases or controls, implicating the SNP in peripheral pain sensitivity in OA.[27]

Catechol-O-methyltransferase (COMT)

COMT is an enzyme which degrades catecholamines, such as dopamine and adrenaline (epinephrine). COMT is the most widely studied pain susceptibility gene, largely due to a non-synonymous SNP (V158M) affecting enzymatic activity,[28] and a study found the M allele to be associated with increased pain sensitivity as a result of reduced μ-opioid activity in the brain in response to a painful stimulus.[29] V158M is located in a haplotype shown to distinguish pain sensitivity levels in healthy females and to be associated with incident temporomandibular joint disorder (TMD).[30] V158M has also been investigated in multiple small scale candidate gene studies of FM but with equivocal findings.[3]

More recently, COMT has been investigated in larger population-based cohorts. No association was observed between V158M or 10 other SNPs in COMT and CWP in a United Kingdom birth cohort.[31] Nor was an association observed between the pain sensitivity haplotype and CWP in United Kingdom and European cohorts.[32] In contrast, in a Dutch population-based cohort, the M allele of V158M was associated with an increased risk of hip pain in women with radiographic hip osteoarthritis.[33]

β₂ adrenergic receptor (*ADRB2*)

The catecholamines target the adrenergic receptors, one of which has been implicated as a chronic pain gene. An *ADRB2* haplotype including the variant alleles of two common non-synonymous SNPs (rs1042713 and rs1042714) has been associated with incident TMD and reporting somatic symptoms in 202 United States females.[34] and increased risk of FM in 156 FM cases and 119 controls from Mexico and Spain.[35] In contrast in a United Kingdom birth cohort, the minor A allele of rs1042713 was associated with a reduced risk of having CWP (n = 846) compared to a pain-free control group (n = 3310).[31]

μ-opioid receptor (*OPRM1*)

OPRM1 encodes the μ-opioid receptor which binds exogenous and endogenous opiates. A non-synonymous polymorphism, N40D (rs1799971) known to influence receptor binding affinity has received a lot of attention. The largest study to date to examine N40D was a comprehensive study of the variation across *OPRM1* with pain sensitivity. Although N40D did not associate, an additional potentially functional SNP (rs563649) was associated with increased pain sensitivity.[36] However, rs563549 and N40D did not associate with CWP in two population-based cohorts.[37]

GTP cyclohydrolase (*GCH1*)

GCH1, which encodes GTP cyclohydrolase, an enzyme involved in the production of BH4, which is essential in synthesis of neurotransmitters, has also been implicated in influencing pain sensitivity. A low pain sensitivity haplotype in *GCH1,* also shown to protect against persistent pain, has been reported and is associated with reduced expression of *GCH1*,[38] but findings in subsequent studies of pain sensitivity have been conflicting. The low pain sensitivity haplotype was found to be more common in individuals with persistent CWP (19%) compared to pain-free individuals (15%) in a UK population-based cohort, but the difference was not statistically significant.[37]

Serotonergic system

Because of the strong link between psychological distress and incident chronic pain, pathways that may mediate this relationship have also been investigated in candidate gene studies. One such pathway is the serotonergic system, abnormalities in which have been reported in FM.[39]

A synonymous SNP, S34S (rs6313, also known as T102C) in a serotonin (5HT) receptor gene (*HTR2A*) has been investigated in a number of small studies of clinic-based FM patients and healthy controls, with equivocal findings.[3] A recent study comprehensively assessed the role of SNPs across *HTR2A* in CWP cases compared to pain-free controls and with a quantitative measure of pain reporting (measured by the number of painful sites reported). A region of moderate to high linkage disequilibrium around rs6313 showed association with both phenotypes in two population-based cohorts, implicating this region as a pain susceptibility locus. Comorbid mood disorder is common in subjects with pain disorders and serotonin also has a role in depression, therefore the findings were adjusted for depressive symptoms. This attenuated the effects but associations persisted, suggesting that this region may have pleiotrophic effects on pain and mood disorders as proposed by twin studies.[40]

A 44 bp insertion or deletion (indel) in the promoter of a 5HT transporter gene, *SLC6A4,* known as 5HTTLPR, has been widely studied with psychological and psychiatric disorders due to its effect on expression.[41] Studies investigating the role of the indel in chronic musculoskeletal pain have been limited to small groups of clinic-based FM patients and healthy controls, which have yielded equivocal findings.[3,42]

The candidate gene studies of chronic musculoskeletal pain phenotypes conducted to date have yielded conflicting findings. There are a number of factors which may have contributed to this. Differing phenotypes assessed in different ways have been studied for the same genes/SNPs. For example, FM clinic patients may not be directly comparable to community subjects with CWP. However, the predominant limitation in these studies is sample size, particularly in clinic-based studies. Larger population-based studies are emerging but are most likely still underpowered to detect the anticipated modest genetic effects. Compared to other complex traits pain research is in its relative infancy, and therefore the known study design challenges of genetic association studies have largely not been addressed.[3]

Genome-wide association studies

Despite an extensive list of potential candidates only a small number of genes have been investigated and a limited number of polymorphisms within those genes studied. Genome-wide association studies (GWAS) can address both these limitations but have not yet been utilized. GWAS studies of migraine have been conducted and have demonstrated that susceptibility loci can be identified and validated with large sample sizes and well-defined phenotypes.[43,44]

Challenges

Pain is a subjective experience that is largely dependent on self-report. The genes underlying the psychological factors that influence how people report pain may prove as important as the genes involved in pain processing pathways. Pain is also episodic and will resolve in some individuals and persist in others, and assessing pain at a single time-point may not be informative. Genetic factors may have a key role in determining whether pain is transient or persistent and longitudinal studies could be used to address this question.

Pain is heterogeneous, and defining the phenotype for use in genetic studies is challenging. for example, in studies of fm the acr 1990[45] criteria are commonly used; however, these criteria only incorporate widespread pain (pain above and below the waist on both sides of the body and in the axial skeleton) and tenderness (11 or more of 18 tender-points), ignoring other common features such as fatigue, somatization, sleep disturbance, and cognitive dysfunction. New criteria for FM have recently been proposed that incorporate these characteristics[46]; however, subjects identified using these new criteria are also likely to be a heterogeneous group.

Likewise, identifying suitable controls is challenging. Some studies have used pain-free groups as controls; however, they are not representative of the general population as experiencing some pain is normal. Using large population-based cohorts as controls is now common place in GWAS, but owing to the relatively high prevalence of chronic pain disorders this approach will reduce power to detect modest genetic effects.

Future prospects

In order for genetic studies of chronic musculoskeletal pain to be fruitful, large well-phenotyped cohorts are required. More

sophisticated approaches could be utilized to elucidate the genetic component. One such approach may be to use intermediate phenotypes, which are quantifiable phenotypes related to the outcome that have a simpler genetic basis. Alternatively, subgroups with different phenotypic characteristics could be identified, reducing heterogeneity and increasing the ability to detect subtle effects. Dissecting cohorts in this way means that much larger sample sizes will be required.

Genetic architecture varies by phenotype and the contribution of common genetic variation to chronic pain susceptibility may be limited. Other types of variation such as rare variants, structural variation (e.g. copy number variation or epigenetic modification) as well as gene–gene (epistasis) and gene–environment interactions may contribute to the heritability of chronic musculoskeletal pain and should be considered in future research.

Conclusion

Twin studies strongly suggest musculoskeletal pain is heritable. Genes involved in psychological distress and pain processing pathways may be important. Genes that influence pain perception have been identified in families. Attempts to elucidate the genes involved, however, have been limited with underpowered studies yielding equivocal findings. Current methodologies such as GWAS and next-generation sequencing have yet to be utilized, most likely due to limited availability of suitable cohorts. To move this research forward, phenotypes need to be refined and sample sizes increased.

CHAPTER 46

Normal functional anatomy of joints

Mike Benjamin and Dennis McGonagle

Introduction and basic definitions

Joints occur where skeletal elements meet and they can be classified in different ways (Box 46.1). From a functional stance, joints can be distinguished according to the amount of movement allowed as diarthrodial (highly moveable), amphiarthrodial (slightly moveable), and synarthrodial (immoveable) joints. However, a functional classification is less common than an anatomical one. According to such a scheme, the major joints recognized are synovial, secondary cartilaginous and fibrous joints. Synovial joints are typical of the limbs and their defining feature is the presence of a synovial cavity containing fluid secreted by a synovial membrane. It is the lubricated cavity between the skeletal elements that promotes the free movement that characterizes these joints. The functional integration between synovium and cartilage is well recognized, with the cartilage deriving its nutrition and lubrication from the synovium via the fluid—a plasma ultrafiltrate. The synovial membrane also contains a population of resident macrophages that are likely to remove microdebris from the joint cavity and help to maintain the rheological properties of the fluid. This arrangement underlies normal cartilage homeostasis but is delicately poised, with any disruption of synovial or cartilage homeostasis rapidly culminating in joint inflammation that can exacerbate cycles of joint damage, irrespective of the trigger.

Fibrous and fibrocartilaginous joints lack synovium, and disease at the latter is especially associated with the seronegative spondyloarthopathies.[1] The cartilage of fibrocartilaginous joints is referred to as 'secondary cartilage' as it appears relatively late in development and *after* ossification has commenced in the contributing skeletal elements. Thus, a secondary cartilaginous joint (like a primary one—see next paragraph) is one where cartilage unites the bones. However, whereas in a primary joint the formation of cartilage precedes that of bone, in a secondary joint it is the other way around. Secondary cartilaginous joints may be called fibrocartilaginous joints, because the tissue uniting the bones is fibrocartilage, rather than hyaline cartilage. They are also called symphyses. Examples of such joints include the manubriosternal joints, the pubic symphysis, and the joints between adjacent vertebral bodies. From a functional standpoint, they can be regarded as amphiarthroses. Finally, fibrous joints are those where the skeletal elements are linked by pure fibrous tissue. Some fibrous joints completely preclude any

movement (i.e. are synarthroses, like the sutures between the bones of the cranium), but others allow slight movement (syndesmoses—such as the inferior tibiofibular joint). Whether movement is completely or partly prevented depends on the quantity of fibrous tissue that holds the bones together. There is more fibrous tissue in a syndesmosis and it spans a greater distance across the bones.

In all the older anatomy texts, the site at which a long bone epiphysis meets the shaft early in development is regarded as a joint. The

---

Box 46.1 The classification of joints

Functional

- Diarthrodial (highly moveable—e.g. synovial)
- Amphiarthrodial (slightly moveable—secondary cartilaginous)
- Synarthrodial (immoveable—e.g. sutures)

Structural (anatomical)

Fibrous

- Suture (e.g. between skull flat bones)
- Syndesmosis (e.g. inferior tibiofibular)

Cartilaginous

- Primary (e.g. a long-bone growth plate)
- Secondary (e.g. manubriosternal)

Synovial

- Plane (e.g. facet)
- Hinge (e.g. interphalangeal)
- Pivot (e.g. superior radioulnar)
- Condyloid (e.g knee)
- Ellipsoid (e.g. wrist)
- Ball and socket (e.g. glenohumeral or hip)
- Saddle (sellar) (e.g. 1st carpometacarpal)

site of union is marked by a plate of hyaline cartilage that is a temporarily persisting part of the cartilaginous anlagen that preceded any bone formation. Specifically, such a structure is referred to as a *primary cartilaginous joint*. However, in the view of Rogers,[2] such a 'joint' is better known by its alternative name of 'growth plate' or 'epiphysial plate' and should not be regarded as a joint at all, for it is simply a temporary feature of a single skeletal element. Wood Jones,[3] on the other hand, regards epiphyses as 'separate ossifications developed in joint cavities as specializations of articular cartilage'. He regarded them as quite distinct bones that unite with the limb bones at a fused junction called a *synchondrosis*. Nevertheless, whatever standpoint is adopted, the term 'joint' most typically refers to permanent features of the skeleton. With respect to the rheumatic diseases, the epiphyseal plate regions are rarely recognized as being the primary drivers, or indeed being involved in the pathogenesis of the rheumatic diseases, and as such support the concept that these regions are not joints from the pathophysiological functional standpoint. However, thus far, one possible exception has been recognized. In the Muckle–Wells syndrome, a hereditary autoinflammatory disease, epiphyseal hyperplasia in association with joint inflammation is well recognized.[4] This raises the question of whether epiphyseal plate cartilaginous tissue could indeed be of more widespread relevance for understanding joint inflammation, especially in paediatric inflammatory disease.

Synovial joints

General features

Although a synovial joint permits free movement between bones, the plane of movement (i.e. the joint cavity) is actually between two layers of cartilage that cover or line the ends of the bones and not directly between bone tissue (Figure 46.1). This is because cartilage is better suited to withstanding compression than bone. In most instances, the cartilage is hyaline cartilage, though occasionally it is fibrocartilage (e.g. in the temporomandibular joint).

The reason that cartilage can withstand compression is because it has a high water content and is avascular. Blood vessels are absent because they would collapse under pressure. This also explains why there is no perichondrium on the surface of articular cartilage. The high water content of cartilage relates largely to the presence of aggrecan. This is a large proteoglycan that attracts tissue fluid into the cartilage by capillarity. The collagen fibrils within the articular cartilage hold the aggrecan molecules in place, thus maintaining the capillary channels and ensuring that the tissue fluid is not readily squeezed out. Some inevitably is lost during the daytime, but it seeps back at night. The high tissue fluid content of articular cartilage not only enables the tissue to withstand compression, but contributes along with the synovial fluid (see next paragraph) to ensuring that chondrocytes can survive without blood vessels. Not only is articular cartilage avascular, it is also aneural. This contributes to the lateness with which osteoarthritis (OA) is often detected. There is an absence of pain until the cartilage is completely eroded and the underlying (highly innervated) bone is exposed.

The other striking feature of a synovial joint is the synovial cavity that contains a thin film of slightly viscous fluid, secreted by a synovial membrane. This membrane lines all non-articular surfaces of the joint (i.e. it is not found on the surface of the articular cartilage, because of the vascularity of the cartilage) and has two layers—a surface or intimal layer that is highly cellular and a vascular subintima that contains connective tissue. Its surface area can be significantly increased by folds (synovial villi)—a proliferation of which is a characteristic feature of synovitis. In some joints, the cavity extends through and
Fig. 46.1 Diagrammatic representation of the three types of joints included in a basic anatomical classification: (a) A synovial joint. The articulating bones (B) are (typically) covered with hyaline articular cartilage (AC) and separated by a joint cavity (JC) containing fluid secreted by a lining synovial membrane (S). This lines the non-articular parts of the joint, including the joint capsule (C). (b) A cartilaginous joint, exemplified by a secondary cartilaginous joint. The bones are covered with a thin layer of hyaline cartilage, but joined by fibrocartilage (FC). (c) A fibrous joint, exemplified by a suture. Here the bones are joined by dense fibrous connective tissue (F).

thus beyond the joint capsule to become continuous with associated bursae. This is the case with the subdeltoid bursa at the shoulder that serves to reduce friction between the joint and the deep surface of the deltoid muscle. However, there are other bursae close to joints that are not in direct communication with joint cavities.

The lubricating molecule that is secreted by the synovial membrane and reduces the frictional forces between the bones is lubrican. This, together with hyaluronan, is produced by fibroblasts (type B synoviocytes) within the intimal layer. The other common intimal cell type is the macrophage (type A synoviocyte)—cells that can phagocytose debris within the synovial cavity and which are also act as antigen-presenting cells. The water content of the synovial fluid represents an exudate from blood vessels in the subintima and its presence aids the access of nutrient and metabolites to and from the cartilage cells. The subintima is a connective tissue layer of variable character. It may be fibrous, loose connective (areolar), or adipose (fatty) tissue. Sometimes the fat in synovial joints is so striking that it merits a specific name, e.g. Hoffa's fat pad in the knee. It seems that adipose tissue is a particular feature of joints that bear significant pressure and absent in those that do not.[3] Thus, fat is not seen in large quantities in the shoulder, wrist, or hand. It is always present where a non-articular part of a bone lies within the joint capsule.[3] The tissue is likely to be implicated in joint pain, for it contains nociceptive nerve fibres[5] and it promotes the efficient spread of synovial fluid. The nerve fibres contain mediators including substance P that can induce an inflammatory response within the knee joint and trigger vasodilation and associated oedema.[5]

Clearly, with the presence of a complete cavity between the articulating bone, there must also be strong, fibrous bonds between the bones. The linkage is created by a fibrous capsule and associated ligaments (Figure 46.1). The capsule develops from the same population of mesenchymal cells as those that are present around the developing bones and give rise to the periosteum. Wood Jones[3] regards this sleeve of tissue as a specialized part of the deep fascia—called 'periosteum' around the bones and 'capsule' around the joints. The ligaments may be local thickenings of the capsule (e.g. the medial collateral ligament of the knee) or independent structures outside (e.g. the lateral collateral ligament of the knee) or inside (e.g. the cruciate ligaments) the joint cavity. Tendons can also reinforce or replace the joint capsule (see below), or can pass through the joint cavity. This is particularly so where their associated muscle has undergone phylogenetic shifting: i.e. with postural changes during evolution, there has been a migration of the origin or insertion of the tendon.[3] As a generalization, ligaments serve to guide and limit joint movements: i.e. because of the way in which they are arranged around the joint periphery, they allow some movements, but prohibit others. They resist stretch (i.e. have a high tensile strength) and thus have a high content of type I collagen and a sparse population of cells. The cells are usually fibroblasts, but if the ligament also needs to resist compression (e.g. in the annular ligament of the superior radioulnar joint), fibrocartilage cells may be evident. The relatively low numbers of cells and the paucity of blood vessels are significant factors accounting for the slow healing of ligaments following injury.

Tendons that fuse with or replace joint capsules include those of the rotator cuff and the extensor tendons that cross the interphalangeal joints. Here, the tendons not only replace the joint capsule dorsally, but also form an articular surface for the neighbouring bone. It is thus worth noting that when a finger is flexed, the head of its proximal phalanx articulates with the deep surface of the extensor tendon in addition to the base of the intermediate phalanx.[1] It is intriguing that the articular fibrocartilage of the tendon (referred to as a sesamoid fibrocartilage[1]) is the region clearly perforated in a boutonnière deformity of the finger and is where a signal change in MRI can be evident in dactylitis.[6]

Some synovial joints contain menisci. They are generally fibrocartilaginous discs but their function is sometimes unclear. It has been suggested that they serve as shock absorbers, that they increase joint congruity and make for a more efficient distribution of weight across a joint surface. That they aid load distribution is a widely accepted view of their function in the knee joint, and doubtless relates to the observation that there is a significant increase in the incidence of OA after meniscectomy.[7] Prominent though knee joint menisci are, they do not create two separate compartments within the joint as they can do elsewhere, e.g. in the sternoclavicular and temporomandibular joints (TMJ). Here it is suggested that they allow for different movements in the two compartments on either side of the disc. Thus, it is often proposed that the superior joint compartment in the TMJ facilitates gliding movements and the inferior compartment allows for hinge-like movements. However, as Wood Jones[3] points out, the disc in the sternoclavicular joint is very similar to that in the TMJ, but no one has ever suggested that it has a similar functional role. Wood Jones favours the idea that the disc is present in both joints because all moving bones are membrane bones and thus the bearing surfaces must develop from the mesoblasts of the primitive joint cavity.[3]

Different types of synovial joint

The subclasses of synovial joint include plane, hinge, pivot, condyloid, ellipsoid, ball and socket, and saddle (sellar) joints.[8]

Plane synovial joints

In a plane synovial joint, the articular surfaces are flat, as in the intercarpal joints, and such joints promote only a slight gliding movement between the bones. The movement allowed by the other joints is more obvious and can be uniaxial (hinge or pivot joints), biaxial (condyloid and ellipsoid joints), or multiaxial (ball and socket and saddle joints).

Hinge joints

Hinge joints are exemplified by the elbow, ankle, and interphalangeal joints. The movements are simple flexion and extension movements, restricted to one plane only.

Pivot joints

Pivot joints are represented by the atlanto-axial joint, where the head, supported by the atlas, pivots around the dens, within the confines of a restraining transverse ligament. The rotatory movements between atlas and axis allow the head to move from side to side. The only other pivot joint is the superior radioulnar joint, where the rounded head of the radius pivots around the ulna within the confines of the restraining annular ligament. As Sinclair[9] points out, the 'pivot' of each joint lies vertically when the body is in the anatomical position.

Condyloid joints

Condyloid joints are those in which the articular surfaces form distinct condyles—as in the knee, but also in the metacarpophalangeal joints.

Ellipsoid joints

In ellipsoid joints, one articular surface is again in the form of a socket, but the other forms an ovoid, rather than spherical, articular surface. The wrist joint is the classic example.

Ball and socket joints

Ball and socket joints include those of the hip and shoulder, but also the talocalcaneonavicular joint. They are multiaxial joints permitting a wide range of movement. One articular surface is spherical and fits into a cup-shaped socket. The socket is deeper in the hip joint to promote greater stability and shallower in the glenohumeral joint to promote a free range of movement. Such is the complexity of movements in a ball and socket joint that, for descriptive purposes, they are referred to as flexion, extension, abduction, adduction, medial rotation, and lateral rotation.

Saddle (sellar) joints

A saddle joint is only found in the thumb and is the joint between the trapezium and the first metacarpal bone. As the name suggests, the articular surfaces are reciprocally saddle shaped. It is important for the dexterity of the thumb.

Biomechanical/functional considerations

The position at which the contact area between the contributing bones of a synovial joint is maximal is the most stable position of the joint and is known as the close-packed position. It effectively converts the bones into a unified lever and is the most efficient weight-bearing and/or stress-reducing position.[9] Close packing usually occurs towards the end of the range of movement of a joint when the capsule and the ligament are tense.[2] Thus, at the knee joint, the close-packed position more or less corresponds to full extension. According to Sinclair,[9] close packing is rarely maintained for long because it is less conducive to efficient joint lubrication. He argues that even when standing upright, there are subtle movements of the lower limb joints that encourage the spread of synovial fluid within the joint. In contrast to the close-packed position, where ligaments are tense, there is also a 'position of rest' where the ligaments are slack and the surrounding muscles relaxed. Wood Jones[3] gives a good account of the position of rest of the hand.

Although joint stability is clearly an issue greatly influenced by the shape of the articulating bones and the restraining action of the capsule and ligaments, another key factor is surrounding muscles. This is clearly explained by Sinclair.[9] Briefly, the simplistic view of an antagonistic muscle relaxing while a prime mover contracts to enable the movement is misleading. What generally happens is that the antagonists continue to generate tension in order to prevent any dangerous overcontraction of the prime movers. Thus, the antagonists actually lengthen as they generate tension—a movement known as 'eccentric contraction'. Sinclair[9] refers to muscles acting in such a manner as 'extensile ligaments' and points out that they are common in highly mobile joints such as the glenohumeral joint. Here, the shallow glenoid cavity and the slack capsule promote dislocation, but the efficiency of the rotator cuff muscles reduces the risk.

When rapid movement occurs in a joint, there may be a tendency for the two sides of the joint to come apart. Muscles that cross the joint and run along the long axis of one of the bones play a key role in preventing this, e.g. brachioradialis. This is an example of a 'shunt muscle' because it shunts one bone into another.[10] It crosses the elbow joint, spanning between the inferior part of the humerus and the lower end of the radius. As the elbow is straightened by a rapid contraction of triceps, brachioradialis contracts to help maintain joint integrity. The fact that brachioradialis inserts at such a distance from the elbow adds to the efficiency with which it can act as a shunt muscle. Triceps, however, is acting as a 'spurt muscle' in this example, for it allows for a fast movement. Its insertion immediately beyond the joint on which it acts (to the olecranon) is conducive to a fast movement.

Movement at a synovial joint may be 'active' if it is actioned by skeletal muscles that cross the joint and act on it, or 'passive' if it is the consequence of an external force. (including gravity). The range of passive movement is nearly always greater than that of active movement.[9] This is easily exemplified by using one hand to bend the fingers of the other passively beyond the limits that can be achieved by contraction of the extensor muscles. Passive movements can also occur at joints that cannot be matched by the active movement of muscles—e.g. the slight rotation that can be achieved passively at the metacarpophalangeal joints, where there are no muscles that can promote active rotation.

Particularly in highly mobile synovial joints, there is often a complex network of blood vessels in the vicinity. These 'anastomoses' offer alternative routes for blood flow if some vessels are temporarily occluded because of joint position.

Fibrocartilaginous joints

In a fibrocartilaginous joint, the ends of the bones are covered with a thin layer of hyaline cartilage (which in the symphysial joints of the vertebral bodies is represented by the vertebral endplate) and joined by a plug of fibrocartilage. Although there is no synovial joint cavity, a cavity may develop in the middle of the tissue. Intriguingly, all fibrocartilaginous joints lie in the sagittal plane of the body. Their clinical significance relates strongly to their involvement in the seronegative spondyloarthropathies and we have conceptualized this in relationship to simultaneous tension and compression forces contributing to the triggering of an osteitis at sites of bony microdamage.[11]

Fibrous joints

Fibrous joints are those where the bones are united by pure dense fibrous connective tissue (i.e. with no cartilaginous phenotype). They include the sutures of the skull and the syndesmotic inferior tibiofibular joint. Only a small amount of movement is possible, but is nevertheless important. Thus, it allows the mortise created by the malleoli of the ankle to widen slightly during dorsiflexion—which is necessary because of the shape of the trochlear surface of the talus. It is also important that skull sutures can allow some movement, so that the infant's head can be moulded during childbirth.[12]

Structures related to joints—bursae

Bursae are thin sacs lined partly or completely by synovial membrane and containing a film of synovial fluid that facilitates movement between adjacent structures. They are common near synovial joints because the movement promoted between the bones means that other tissues may also have to move relative to each other during joint movement. For example, when the knee is flexed, the skin

over the patella must move freely over the bone, or it will be torn; hence the need for a 'prepatellar bursa'. A further example is given by the deep infrapatellar bursa which occupies the angle between the patellar tendon and the tibia at the insertion site of the tendon. This allows the insertional angle of the patellar tendon to change during flexion and extension of the knee and is a specific example of a general class of bursae known as 'subtendinous bursae' that characterize insertion sites that lie close to synovial joints.[13]

Recent advances in understanding functional anatomy and predicting disease

Historically, the link between cartilage and synovium has focused on the relationship between articular surfaces and synovium in synovial joints such as the knee, hips, and small joints. The functional anatomy of this interlink is described above. However, we have recently drawn attention to the intimate link between synovium and the cartilage of numerous enthesis organs, including that of the Achilles tendon.[14] We have termed such functional units 'synovio-entheseal complexes' and have highlighted their importance for understanding mechanisms of synovitis in spondyloarthritis (SpA) and OA.[14] e complexes are also conspicuous at sites within the mid-substance of joint capsules (e.g. in the proximal interphalangeal joints) and also where tendons wrap around bony prominences. Thus, the functional integration of synovium and cartilage is much wider than previously appreciated and this may have far reaching consequences for understanding perturbed tissue homeostasis and joint inflammation in different settings.

Conclusion

In the last decade it has emerged that the functional anatomy of joints is highly relevant for a better understanding of why it is that different rheumatic disorders localize to different sites. With the availability of modern imaging, site-specific derangements of these tissues and structures can now be appreciated. This is important for diagnosis and for the development of a better understanding of joint disease.

Measuring movement and gait

Lindsey Hooper, Mark Taylor, and Christopher Edwards

Introduction

Measuring movement and gait is an important part of assessing the effect of rheumatological disorders on a patient's ability to perform tasks of daily living. In order to do this, clinicians need to understand how the biomechanical properties of joints are influenced by anatomy, physiology, and pathology. This can be a complex challenge that requires the sharing of ideas between the disciplines of mechanical engineering and medicine.

New technology has made the collection and analysis of biomechanical information much easier and a realistic possibility in many clinics (Figure 47.1). Clinicians of the future may well find themselves engaging with technology-assisted gait assessment, which synthesizes three-dimensional (3D) motion capture and joint imaging. With this in mind we aim to introduce the rheumatologist to the basic principles of measuring movement and gait, in both healthy and pathological joints and tissues. The clinical application of mechanical theory is discussed and the knee is considered as an example throughout.

Key definitions and phases of gait

There are three main planes of motion that describe movement. The sagittal plane passes through the body, front to back, dividing it into left and right halves. Movement in this plane is described as flexion or extension. The frontal (or coronal) plane passes through the body left to right, dividing it into front and back halves. Movement in this plane is described as adduction or abduction. The transverse plane passes through the middle of the body dividing it into upper and lower halves. Movement in this plane is described as internal or external rotation.

Gait, the motion of bipedal walking, is a coordinated repeated sequence of movements that occur simultaneously in a number of joints of the lower limb, in multiple planes. This repeated pattern of movement is termed the gait cycle and can be divided into two further phases; the stance phase, when the foot is in contact with the ground (40–60% of cycle), and the swing phase, when the foot is above the ground. A further period during the gait cycle is that of double support, where both feet are in contact with the ground. The period of double support, occurring at the beginning and end of each stance phase, is particular to a walking gait and is absent during running. The duration of double support depends upon the gait velocity. At a normal velocity (3–4 mph or 5–6 km/h), there will be two double support phases, each lasting 10–12% of the cycle.[1]

The stance phase is divided into four episodes: heel strike, foot flat, heel off, and toe off. Clinical observation of these key events can be used to help identify and evaluate problems in the sequencing, timing or coordination of gait. Abnormalities occurring within the stance phase are considered to be particularly pertinent because of the undue stress exerted upon the joints or soft tissues when loaded.

Evaluating gait

Kinematic analysis

The evaluation of movement, without regard to the forces that cause it, is termed kinematics. Thus, the kinematic evaluation of gait is concerned with observing and describing:

1. In which joints is movement occurring?

2. In what plane of motion is movement occurring?

3. How much movement is occurring?

4. Is the movement occurring in the correct sequence?

A structured observation of these elements provides a basis for systematic analysis. Clinically, assessment of gait can be enhanced with joint-by-joint evaluation of movement against normal ranges of motion (Table 47.1). However, it is rare for a single joint to only move in the primary range of motion, i.e. the desired direction. In fact, a number of accessory movements can occur in perpendicular planes and their clinical effect should be evaluated.

Observation of multiple joints in sequence is the first step in measuring movements associated with gait. Comparing observed

Fig. 47.1 The historical and future application of mechanical analysis within rheumatology.

motion with normal ranges allows the clinician to begin to identify problematic areas. However, it would be unwise to consider only a single joint in isolation. Movement of a single joint may have a consequential effect on neighbouring proximal and distal joints. Therefore, a joint that appears to be functioning abnormally may be doing so in compensation for a damaged neighbouring joint and have no disease itself.

> ### Clinical application: accessory movement at the knee joint
>
> The primary motions of the knee, specific to the tibiofemoral joint, are flexion and extension, along with smaller degrees of anterior–posterior translation and internal–external rotation. Accessory knee motions consist of medial–lateral translation and valgus–varus tilting, although these are considered to be minor in a healthy joint. Nonetheless, this combination of motions leads to a complex movement of rotational gliding and rolling of the bony structures. Such complex movements result in changing orientations of the femur or tibia, which has an effect on the neighbouring proximal hip and distal ankle joint function. The converse is also true, with the knee being affected by movements occurring in the hip or ankle.
>
> For example, excessive pronation at the subtalar joint may result in increased internal rotation of the tibia due to the tightly bound connective tissue ankle mortise. During internal rotation of the tibia, the lateral femoral condyle moves backwards over the lateral tibial condyle while the medial femoral condyle moves forwards over the medial tibial condyle. During external rotation the reverse mechanism takes place. Therefore the bony orientation of each articulation, and the relative degree of motion, will affect the pattern of movement. In this case, the knee may appear excessively inward facing (squinting patella) or have a genu valgum appearance. During gait, increased episodes of medial loading during the stance phase may be evident and become clinically symptomatic. Correction of the foot position, via inhibition of excessive pronation, will reduce the linked-segment rotational effect and help reorient the knee into a more neutral alignment. Conversely, management of the knee in isolation may relieve symptoms in the short term, but would not address the underlying problem.[2]

Evaluating kinematics using technology

The use of technology in gait analysis aims to quantify the movements associated with human walking. This can provide more robust data than that generated by clinical observation alone. The technology used has progressed dramatically since the photogrammetry systems used prior to 1990, because of major advances in computing hardware (camera/sensor and computing devices), and software (engineering algorithms).[3] Previous systems were also labour intensive and therefore mainly restricted to research activity. However, it is increasingly possible to collect, filter, and process digital movement sequences ready for analysis within the period of a clinical appointment. Thus, the use of assistive motion analysis technologies, for the purposes of biomechanical assessment, within the clinical setting, is an increasingly realistic option.

Motion analysis captures information about the relative movement of adjacent structures (indicated by markers positioned on the patient), muscular activity (ascertained via electromyography), and forces exchanged with the environment (typically indicated with a force plate). Multiplanar movements and resultant loads transmitted across body segments are then calculated. The positioning of markers and analysis processes used for gait analysis have been standardized by the use of internationally agreed recommendations.[4] The movement of the markers is recorded by infrared or electromyomagnetic camera systems, which track the orientation of the markers around a known capture area. The use of multiple cameras means that the information from the markers can then be reconstructed using mathematical algorithms to replicate 3D models of the patient. The acquired force information can be added to the model to generate estimations of the dynamic joint forces and moments during the observed movement. Similarly, the acquired elecromyographic (EMG) data can be added to the model to generate estimations of individual muscle function throughout the gait cycle.

Kinetic analysis

The kinematic evaluation of gait can provide a good basis for the evaluation of human walking. However, kinematics does not take into account the forces that cause joint movement, or occur as a consequence of it. Thus, the evaluation of movement, with regard to the forces that cause it, termed kinetics, is important in motion analysis. Kinetics is concerned with both the magnitude and direction of a number of forces which may be applied and generated simultaneously across a joint or the mass of a segment (e.g. the thigh).

External forces are applied to the body as a result of gravity acting upon the body's mass and its interaction with external surfaces. Internal forces are generated by the muscles in order to produce the movement of a body segment (lever) about a joint (pivot) and

Table 47.1 Lower limb joint ranges of motion during gait

Joint	Active movement	Accessory movement	Typical range of motion	Phase of the gait cycle at which movement occurs
Hip	Flexion (anteversion)	Medial glide	120–140°	Stance phase (initial contact—midstance) and swing phase (toe off—midswing)
	Extension (retroversion)	Lateral glide	20–30°	Stance phase (midstance—toe off) and swing phase (midswing—heel strike)
	Internal rotation	–	40°	Midstance—toe off
	External rotation	–	30° (hip extended) 50° (hip flexed)	Loading response after heel strike
	Abduction	–	50° (hip extended) 80° (hip flexed)	Swing phase
	Adduction	–	30° (hip extended) 20° (hip flexed)	Loading response after heel strike
Knee (tibiofemoral)	Flexion	Anterior/ posterior translation, Internal/ external rotation	120–150°	Stance phase (initial contact—midstance) and swing phase (toe off—midswing)
	Extension	Anterior/posterior translation, Internal/ external rotation	5–10°	Stance phase (midstance—toe off) and swing phase (midswing—heel strike)
	Internal rotation	–	10°	Stance phase (initial loading response)
	External rotation	–	30–40°	Midstance and swing phase
Knee (patellofemoral)	Proximal translation	Lateral glide	-	As knee flexion
Ankle	Plantarflexion	–	30°	Loading response, end of stance phase and at terminal swing
	Dorsiflexion	–	0–10°	Midstance and toe off
Subtalar	Pronation	–	5°	Stance phase (heel strike—midstance)
	Supination	–	20°	Stance phase (midstance—toe off)

additional forces are generated by the passive constraints of ligaments and other soft tissues. Thus, in a similar manner to the observation of kinematics discussed in the previous section, it is possible to determine the magnitude and direction of forces acting upon a single joint as a consequence of multiple imputations of complex movements and forces.

Determining joint forces and moments

The net forces and moments, (the sum of segment mass, speed and direction of motion, and force direction and magnitude), acting across a joint can be calculated based upon a simplified anatomical model, termed a link–segment model (Figure 47.2a). The moment calculation is completed using a technique known as inverse dynamics. In order to complete this analysis, three sets of information are required:

- kinematic data (the relative positions of segments and their accelerations)
- kinetic data (external forces acting upon segments)
- anthropometric data (the dimensions and masses of segments).

The link–segment model only accounts for bony anatomy and ignores the action of muscles. Therefore, only the net force

and moment acting across a joint is derived. During a particular activity there may be cocontraction of antagonistic muscle pairs. However, using inverse dynamics, only the net moment is calculated. For example, either a net flexion or extension moment, representative of the overall anatomical movement, is derived (Figure 47.2b). Additionally, as with any mathematical model, there are a number of assumptions that impact the predicted output. The following constraints should therefore be considered:

- The joints are idealized; for example, the knee is commonly modelled as a simple hinge.
- The anthropometric data is usually scaled from standard tables and may not truly represent the patient's anatomy.
- The kinematic data may not truly represent the underlying motion of the bony segments, due to motion artefact of the markers placed on the superior skin surface.

While the determination of predicted forces and moments can be highly indicative, the absolute values should be treated with caution. None the less, this assessment method is often reported in clinical gait studies and has been successfully used to identify normal and pathological movement characteristics.

(a) Data collection

1. Kinematic data from motion capture
2. Kinetic data from force plates
3. Anthopometric data from clinical measures

(b) Link segment modelling

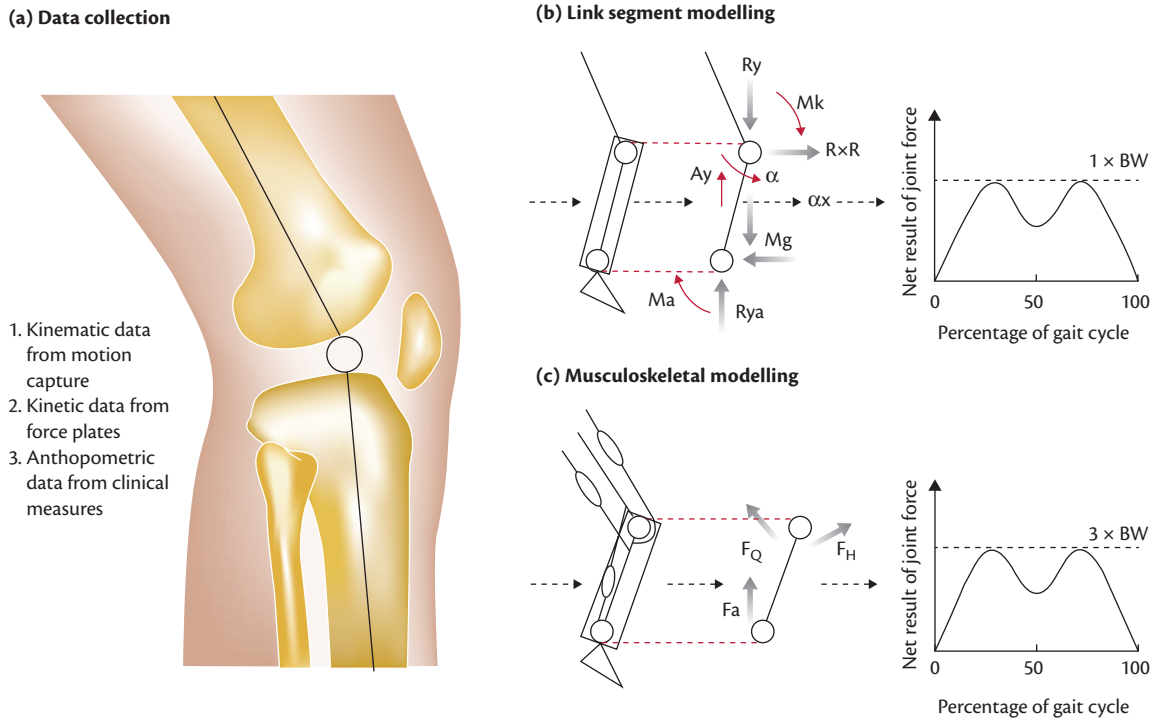
(c) Musculoskeletal modelling


Figure 47.2 Determination of knee joint forces and moments.

Clinical application: calculation of internal forces in a knee joint

The knee joint contact forces can be estimated using reconstructed data algorithms (discussed in the section 'Evaluating kinematics using technology').

The link–segment model can be enhanced to include representations of muscles and ligaments. The enhanced models allow the calculation of intersegmental muscle and contact (bone-on-bone) forces. However, because of the number of muscles in the lower limb, the number of unknown parameters usually exceeds the number of equilibrium equations possible, leading to an indeterminate calculation. Therefore mathematical optimization techniques are used.[5] A number of other assumptions, including the line of action, geometry, and cross-sectional area of each muscle, are also assumed to complete the model. During level gait or stair climbing it is estimated that the knee experiences average forces of between 3.1 and 5.4 times body weight. In addition, accessory shear forces of between 0.6 and 1.3 times body weight can occur (Figure 47.2).[5] However, data from in-vivo measurements of joint forces, using telemetric implants, suggests the models overestimate internal forces, particularly at high flexion angles, and more realistic values are between 2.5 and 4 times body weight.[6] Thus, moving from theory to clinical practice remains somewhat constrained. However, modelling techniques are rapidly evolving, particularly with regard to joint replacement surgery or modelling pathology.[8] For patients undergoing total knee replacement surgery, observation of the internal loads generated pre- and postoperatively, to both the surgical and neighbouring joints, may inform the likely long-term outcome. For example, the function of the limb during gait or the stresses exerted on an artificial implant can be calculated. Particular kinetic changes, e.g. elevated adduction moments in the contralateral knee, can be calculated postoperatively and their effect on the gait cycle determined.[7]

The importance of biomechanics in rheumatological disease

The application of biomechanics to rheumatology requires clinicians to consider (1) biomechanical principles, (2) the anatomy, physiology, and morphology of the patient, and (3) the pathological processes of rheumatological disease. All three components are inherently linked and need to be considered when assessing movement within a patient. In many rheumatological conditions both the internal architecture of the joint (e.g. articular surface congruency, malalignment deformity, synovial fluid viscosity), and the integrity of conjunctive soft tissues, (e.g. ligament laxity, calcification of connective tissues, myopathy), is impacted. Thus, a joint that has deteriorated as a consequence of disease may function in an abnormal manner. Conversely, a joint functioning in an abnormal manner may affect the loading response or mechanical wear of joint tissue and exacerbate a rheumatological condition. Therefore when considering the relationship between rheumatological disease and biomechanical function two questions should be considered:

◆ To what extent is disease activity or progression impacting the biomechanics of gait?

◆ To what extent is the biomechanics of gait impacting disease activity or progression?

These questions should be evaluated in conjunction with the biomechanical analysis approaches discussed earlier (see 'Kinematic analysis'). Clinicians may find a logical structural approach to biomechanical assessment within rheumatology useful, as exemplified in Table 47.2.

Clinical example: The relationship between pathology and biomechanics in the knee joint

The knee is an inherently unstable joint, particularly following injury or trauma, and achieves its stability during dynamic motion mainly through the action of soft tissue structures such as ligaments and tendons. An unstable knee joint produces abnormally high stresses on the articular cartilage, menisci, or other ligaments attempting to restrain hypermobility, and early osteoarthritis (OA) may develop in approximately 15–20% of patients.[9] The processes of OA development are not fully understood, but there is thought to be significant contribution from (1) shearing and torsion forces causing direct trauma to the contacting articulations, (2) unequal repetitive loading forces resulting in abnormal bone turnover at specific joint regions, and (3) immunologically mediated inflammatory responses to microtrauma.[10]

The examples given in Table 47.2 and above demonstrate how the principles of movement analysis can be applied within a clinical context, such that the clinician is able to make a judgement about the relative impact of disease or adverse biomechanics on the function of a single joint. It is important to remember, however, that assessing movement in a single unloaded joint is different from assessing multiple joints during gait, due to the kinematic and kinetic segmental chain effects discussed in the section on 'Evaluating gait'. However, the segmental analyses currently available are not perfect and do not account for the internal tissue responses occurring in response to chronic biomechanical stress. Future research aims to draw together clinical imaging modalities, such as MRI or ultrasound, and technology-assisted motion analysis systems within a clinical environment, in order to overcome these current limitations. The use of intrinsic joint and tissue imaging would provide beneficial information about the physical properties of joint and tissue structures, and allow for this to be integrated into the modelling

Table 47.2 Relationship between rheumatological disease manifestations and biomechanical function

Pathology	Biomechanical action	Common observation in gait
Inflammation	Perpetuates cycle of inflammatory joint destruction, thus further impeding joint congruency, internal joint loading responses and shear stresses affected, proliferation of synovium and other mechanically mediated cellular responses, upregulation of biological responses to tissue stress, perpetuation of inflammation	Pain on movement may inhibit willingness to use full joint ranges of motion; compensatory gait, offloading forces away from the affected area is common
Synovial hypertrophy	Increased internal joint forces; reduced ranges of motion during acute episodes, increased ranges of motion after chronic episodes due to distension of collateral joint architecture; altered kinetic function as tissue loading response is affected, compounded by altered synovial fluid viscosity	If knee affected: increased periods of double support phase If ankle affected: notably reduced ranges of motion
Tendonitis	Altered tensile strength of tissue, particularly with degradation of fibrillar tendon structure; abnormal force transference; altered lever action	Antalgic gait with a tendency to offload the affected region
Tendon rupture	Increased range of motion in the plane of synergist; increased internal and external loading forces; poorly controlled moments of inertia due to reduced muscular inhibition	Failure to produce active movement about the joint, passive movement is increased until inhibited by ligamentous structures; e.g. tibialis posterior tendon rupture results in increased calcaneal eversion until inhibition by the medial collateral ankle ligaments
Tendon equinus	Reduced ranges of motion in the plane of synergist	Commonly affecting the insertion of gastrocnemius; resulting in early heel lift and excessive forefoot loading
Muscle atrophy	Muscular imbalance between concentrically (mobilizers) and eccentrically (stabilizers) acting antagonistic muscle pairs; insufficient force generation to achieve movement	Poor balance, reduced stride length and cadence, tripping and falls in cases of early or rapid onset If peroneal muscle group affected: inability to sufficiently achieve forefoot ground clearance, forefoot abduction, widened base of support, reduced cadence, lateral foot loading If tibialis anterior and intrinsic dorsal extensor muscles affected: lesser digit retraction, reduced forefoot stability and limited ankle dorsiflexion
Ligament laxity	Poorly limited terminal joint ranges of motion, which may exceed those of normative ranges; altered kinetic function, with poorly regulated internal joint loading mechanisms	Increased rotational joint motions; e.g. genu varum/valgum at the knee or excessive subtalar joint pronation may be apparent. Increased accessory movement (beyond active/passive normative end ranges)

(Continued)

Table 47.2 (Continued)

Pathology	Biomechanical action	Common observation in gait
Cartilage damage	Change in articular congruency; quality, range and direction of motion affects kinematic and kinetic joint function; internal joint loading altered; kinetic joint function altered	Locking of the joint in primary ranges of motion; kinematic abnormality may be particularly evident within the frontal plane; kinetic abnormality may result in muscular imbalance
Connective tissue function (elasticity and plasticity)	Internal loading forces are moderated by the deformation rate of surrounding tissues, thus net moments are altered	Typically evidenced via alterations in reported joint stability, notable widened base of support, reductions in stride length, or increased plantar foot pressures

algorithms. Advances such as this will help to make biomechanical assessment a more realistic way to diagnose abnormal movement and direct treatment for patients with rheumatological disease.

CHAPTER 48

Innate vs acquired immunity

Reinhard E. Voll and Barbara M. Bröker

Introduction

In this chapter we introduce the reader to the basic components, mechanisms, and functions of the innate and the adaptive immune system and highlight the differences in pathogen recognition and elimination employed by the two systems. Also, we elucidate the close interactions of both arms of the immune system in the host response. B and T lymphocytes are described in detail in Chapters 49 and 50. Finally, the basis of autoinflammatory and autoimmune diseases is briefly discussed.

The immune system has evolved during evolution to defend organisms against invasion by pathogens. Moreover, the immune system allows the organism to be colonized by commensals and to live in symbiosis with billions of microorganisms while maintaining the integrity of the border to the inner milieu. The commensals do not only provide enzymes which improve the digestion of food: the residential microflora also competes with pathogens for space and nutrients and may create an uncomfortable micromilieu for many pathogens, for instance low pH generated by lactobacilli.

Host defence mechanisms are not unique to multicellular organisms or eukaryotes. Bacteria have developed mechanisms such as restriction endonucleases, which can cleave the DNA of invading bacteriophages, but preserve their own bacterial genome, which does not contain the respective restriction nuclease recognition sequences. Hence, restriction endonucleases may represent one of the phylogenetically oldest mechanisms of self—non-self discrimination.

Innate immune system

Mechanical barriers, interferons, and soluble antimicrobial factors

In multicellular organisms virtually all cells participate in the host defence. For instance, viral infections lead to production of type I interferons, which protect neighbouring cells and potently activate antigen-presenting cells (APCs). The type I interferons consist of more than 10 different interferon-α molecules and only one interferon-β molecule, which all signal via the interferon-α/β receptor. Depending on the cell type, stimulation of the interferon receptor leads to the expression of antiviral proteins including 2′-5z-oligoadenylate synthase as well as interferons themselves. In addition, major histocompatibility complex (MHC) expression and maturation of dendritic cells is induced.[1–5] Other mechanisms induce apoptotic cell death of infected cells as an attempt to inhibit viral replication and spreading.[1–4]

Multicellular organisms are protected by specialized surface cells, **epithelial cells**, with tight junctions in between providing a physical barrier. On the mucosa, **mucus** forms an additional mechanical barrier. Moreover, soluble antimicrobial proteins/peptides, also contained within the mucus, are employed to protect the organism's surfaces. Secreted enzymes such as lysozyme and phospholipase A_2 can digest the cell wall of bacteria or lyse membrane lipids, respectively. Antimicrobial peptides such as defensins damage bacterial cell membranes.[1–4] Upon invasion of bacteria the complement system can be directly activated on the pathogen's surface and marks the pathogen for efficient engulfment by complement receptor bearing phagocytes, or may directly kill the microbe by forming the membrane attack complex. During complement activation potent chemoattractants, C3a and C5a, are generated and lead to the invasion of mononuclear and polymorphonuclear phagocytes (see Chapter 64).[1–4,6]

Phagocytes

Even in early multicellular organisms, certain cells began to differentiate into specialized immune cells, phagocytes, recognizing and killing invading pathogens. Eli Metchnikoff was the first to describe phagocytic cells, which he observed in the invertebrate sea star. Mammalians have developed specialized types of phagocytes: rather short-lived polymorphonuclear granulocytes (neutrophils, eosinophils, basophils), dendritic cells (DC), and blood monocytes, which eventually differentiate into tissue macrophages. The extraordinary importance of neutrophils in fighting bacteria and fungi is obvious from neutropenic conditions or functional deficiencies such as chronic granulomatous disease resulting in a defect of oxidative burst. In particular, opsonized pathogens, meaning that they are decorated by antibodies and/or complement, are readily phagocytosed.[7] Neutrophil extracellular traps (NETs) consisting of externalized chromatin and contents of granules contribute to the elimination of bacteria.[8] Increased formation or impaired degradation of NETs can make nuclear antigens accessible to the immune system in a proinflammatory context, and may thereby foster the immunopathogenesis of systemic lupus erythematosus (SLE).[9–11] Monocytes and macrophages are critically involved in the clearance of apoptotic and necrotic cells, and regulate pro- vs anti-inflammatory outcomes.[12–14] Defective clearance of dying cells might predispose to anti-nuclear autoimmunity and SLE.[15] Opsonized bacteria

and immune complexes are efficiently taken up by macrophages and antigens can be presented to T cells. Similar to NK cells and neutrophils, monocytes/macrophages can exert antibody-dependent cellular cytotoxicity. Upon activation by interferon γ, macrophages efficiently eliminate intracellular bacteria such as mycobacteria. In rheumatoid arthritis (RA) and other inflammatory diseases, macrophages might on the one hand cause tissue damage, but on the other hand exert immunoregulatory functions.

DC represent the most powerful APCs and can efficiently activate naive T cells.[1–4] Plasmacytoid DC show an appearance similar to plasma cells and might be rather poor APCs due to low expression of MHC class II and costimulatory molecules. Upon TLR7 and TLR9 stimulation, especially with simultaneous Fcγ receptor engagement, plasmacytoid DC release high amounts of interferon α, thereby playing a role in antiviral responses, but may also contribute to the pathogenesis of SLE.[10] Important cell types of the innate immune system, which mostly belong to the myeloid lineage, and their role in the pathogenesis of diseases are summarized in Table 48.1.[1–4,7,16–18]

Pathogen receptors of the innate immune system

The numbers of receptors employed by the innate immune system is limited to a few dozens. These germline-encoded receptors recognize usually highly conserved non-protein structures, called pathogen-associated molecular patterns (PAMPs), that are common to groups of related pathogens. The respective receptors were therefore named pattern recognition receptors (PRRs).[1–4,19–20] Some of these receptors are also stimulated by endogenous molecules indicating necrotic cell death, termed damage associated molecular patterns (DAMPs) or 'alarmins'. Some heat shock proteins (HSPs) and the nuclear protein HMGB1 serve such a function and activate innate immune cells similar to PAMPs.[21] In Table 48.2

general properties of the PRRs of the innate immune system are compared with those of the B- and T-cell receptors of the adaptive immune system. Because PAMPs generally represent molecules which play an important role in the life cycles of pathogens, escape mutants from PRR, if not deadly in the first place, should strongly impair the fitness of the microorganism.

PRRs can be soluble molecules. **Lysozyme** recognizes and cleaves β(1,4) linkages between *N*-acetylglucosamine and *N*-acetylmuramic acids. **Mannose-binding lectin (MBL)** attaches to microbial glycans of many bacteria and fungi, whereas the ficolins bind to acetylated oligosaccharides. The respective oligosaccharides on the surfaces of the eukaryotic host cells are mostly masked by the attachment of sialic acid, so that the aforementioned PRRs cannot bind to them. MBL and ficolins start the complement activation on microbial surfaces (see Chapter 64).[1–4,6] Gut epithelial cells and phagocytes express Toll-like receptors (TLRs), either on the cell surface (TLR1, 2, 4, 5, 6) or in the endosomal compartment (TLR3, 7, 9) (Figure 48.1). The TLRs sense various PAMPs and DAMPs and induce a proinflammatory response within the immune cells by potently activating the transcription factor NFκB.[1–4,19,20]

In order to fight intracellular invaders such as viruses and intracellular bacteria, cytoplasmic surveillance molecules recognizing bacterial or viral components have developed during evolution (Table 48.3). The NOD-like receptor family consists of several subfamilies: the NOD proteins NOD1 and NOD2 recognizing components of bacterial cell walls, AIM2 sensing pathogens containing double-stranded DNA, and the pyrin-domain-containing NLRP subfamily. The NLRP proteins, of which the best investigated is NALP3 as a component of the NALP3-inflammasome, might not directly recognize pathogens; rather, they are activated by cellular stress responses. Upon decrease of intracellular K^+ concentrations,

Table 48.1 Cells of the innate immune system

Innate immune cell	Origin	Functions	Relevance in diseases
Neutrophil (granulocyte)	Common myeloid progenitor	Elimination of bacteria and fungi by phagocytosis, content of granules, NET formation	Deficiency results in bacterial and fungal infections; granulomatous disease. Contribution to pathogenesis of gout and RA
Eosinophil (granulocyte)	Common myeloid progenitor	Release of eosinophil cationic protein; eosinophil peroxidase; elimination of antibody-coated helminths	Asthma; Churg–Strauss syndrome*, eosinophilic fasciitis
Basophil (granulocyte)	Common myeloid progenitor	Defence against parasites; histamine and serotonin release upon FcR crosslinking	Induction of allergic inflammatory responses
Mast cell	Common myeloid progenitor	Defence against parasites; histamine and serotonin release upon FcR crosslinking	Induction of allergic inflammatory responses
Monocyte/ macrophage	Common myeloid progenitor	Clearance of apoptotic and necrotic cells; phagocytosis of bacteria, elimination of intracellular bacteria upon IFNγ activation, antigen presentation; ADCC	Overwhelming activation in macrophage activation syndrome
Dendritic cell (lymphoid, myeloid, plasmacytoid, Langerhans cell)	Common myeloid progenitor or common lymphoid progenitor	Uptake of antigen in the periphery and transport to the lymphnodes for antigen presentation to T cells; activation of T cells including naive T cells; immune regulation	T-cell activation by DC in RA and SLE; in SLE IFNα release from plasmacytoid dendritic cells,
NK cell	Common lymphoid progenitor	Killing of virus-infected and otherwise altered (e.g. malignant) cells; ADCC via FcγRIII; inhibitory receptors prevent killing of autologous MHC-expressing cells. IFNγ secretion	

ADCC, antibody-dependent cellular cytotoxicity; DC, dendritic cells; IFN, interferon; NET, neutrophil extracellular trap; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; *, Eosinophilic granulomatosis with polyangiitis.

Table 48.2 Comparison of pathogen recognition by receptors of the innate and adaptive immune systems

	Receptors of the innate immune system (PRR)	Receptors of the adaptive immune system
Genes	Germ line encoded	Somatic gene rearrangement
Diversity	Limited (~100 specificities)	Extremely high (>10^9)
Ligands	Highly conserved molecules essential for the life cycles of a pathogen, usually no proteins	TCR: individual peptides presented in MHC molecules BCR: most kinds of molecules can be recognized
Escape mutants of pathogens	Very rare, usually loss of fitness	Frequent, do not necessarily impair pathogen fitness
Specificity	Recognizing a whole class of pathogens (e.g. Gram +ve bacteria, fungi); no change in receptor specificity	TCR and BCR: usually highly specific for a single pathogen BCR: affinity maturation during infection (germinal centre reaction), isotype switch
Number of receptor bearing cells/memory	Many cells (e.g. all monocytes, neutrophils) express the same set of receptors, no dramtic changes in receptor-expressing cells; no memory	Before pathogen exposure: extremely low numbers of cells bearing the individual receptor; during infection dramatic expansion of antigen-specific clones; memory
Reactivity with self	Certain PRR recognize endogenous 'danger molecules' (alarmins such as HMGB1) causing activation of the innate immune cells and inflammation	Accidentally; may result in autoimmune diseases
Time to response	Immediate	First contact: delayed by some days Repeated contact: immediate

PRR, pattern recognition receptor.
Fig. 48.1 Toll-like receptors and their exogenous and endogenous ligands. HSPs and HMGB1 are endogenous ligands (red). Bac., bacteria; ds, double-stranded; ss, single stranded.

Table 48.3 Cytoplasmic pattern recognition receptors of the innate immune system

Cytoplasmic PRRs (cell types)	Specificity	Function
NOD-like receptors		
NOD1 (macrophages, dendritic cells)	γ-Glutamyl diaminopimelic acid (from Gram ve bacteria)	Activation of the innate immune system upon infection with intracellular bacteria (e.g. listeria, salmonella)
NOD2 (macrophages, dendritic cells, Paneth cells)	Muramyl dipeptide (from peptidoglycan of most bacteria)	Expression of α and β defensins in Paneth cells (NOD2); loss of function associated with Crohn's disease, gain of function mutants with Blau's syndrome
NLRP family (phagocytes)	? Activation upon decrease of intracellular K^+ concentration	
NALP3/cryopyrin		NALP3 is part of the inflammasome, which is activated upon cellular stress/damage (e.g. gout) and leads to IL-1β production; mutations in the NOD domain cause hereditary periodic fever syndromes including Muckle–Wells syndrome
AIM2	Recognition of dsDNA genomes (e.g. vaccinia virus)	IL-1β production in response to vaccinia virus infection; defence against *Francisella tularensis*
RIG-I-like helicases (most cells)		
RIG-I MDA5	'Uncapped' viral ssRNA, dsRNA	Defence against viral infections. Activation of type I interferon production via IRF3; production of proinflammatory cytokines via NFκB activation

dsDNA, double-stranded DNA; PRR, pattern recognition receptor; ssDNA, single stranded DNA.

NALP3 induces caspase 1 activation and interleukin (IL)-1β secretion.[1–4,19–20,22] The RIG-I-like helicases sense cytoplasmic RNAs of viral origin and potently induce interferon regulatory factors (IRFs) leading to type I interferon production with its antiviral activity.[4,5,23]

Adaptive immune system

Higher vertebrates from jawed fish onwards developed an adaptive immune system as an additional powerful level of defence. The cells of the adaptive immune system are lymphocytes and their features are summarized in Table 48.4. Somatic recombination and hypermutation generate such a huge arsenal of receptors that virtually all pathogens can be recognized by at least a few lymphocyte clones. The RAG enzymes enable the recombination of multiple gene segments.[1–4] The addition of variable numbers of nucleotides to the joining ends without a DNA template can introduce new amino acids, thereby further increasing the variability of the antigen binding sites. The basic mechanisms of receptor diversification are homologous in T and B cells.[1–4] In contrast to T cells, the antigen receptor of mature B cells can undergo affinity maturation during the germinal centre reaction.[24] After clonal expansion of the few pathogen-specific lymphocytes out of millions of different specificities, pathogen-specific cells (T lymphocytes) as well as soluble molecules (antibodies derived from B cells, especially plasma cells) mount a highly specific and efficient immune response. Most importantly, the adaptive immune system has a memory function, which can mediate a long-lasting, often lifelong protection ('immunity') against this particular pathogen.[1–4,24–26] Remarkably, this protection can be partially transferred to the offspring via active transport of IgG antibodies through the placenta to the fetus and the transfer of IgA antibodies with the milk to neonates.[1–4] However, these new, effective host defence mechanisms of the adaptive

Table 48.4 Cells of the adaptive immune system

Cell type	Origin	Immunoreceptor	Function
CD4+ T helper cell	Common lymphocyte precursor/thymus	αβTCR	T-cell help, orchestrating the specific immune response
CD4+ T regulatory cell	Common lymphocyte precursor/thymus	αβTCR	Regulation of immune responses; prevention of autoimmunity
CD8+ cytotoxic T cell	Common lymphocyte precursor/thymus	αβTCR	Elimination of virus-infected cells
γδ T cells	Common lymphocyte precursor/thymus	γδTCR	Subepithelial defence line recognizing also non-peptide ligands
B cell/ plasma cells	Common lymphocyte precursor/bone marrow	BCR/IgM, IgG, IgA	Neutralization of viruses, toxins, defence against extracellular bacteria, protection of the neonate

BCR, B-cell receptor; TCR, T-cell receptor.

immune system come at a cost: the inherent risk of autoreactivity and autoimmunity.

Immune response: joint effort of the innate and adaptive immune systems

During an immune response the innate and the adaptive immune systems cooperate closely and are connected at multiple layers. On the one hand, the APCs of the innate immune system control

activation of the adaptive immune system and guide T-cell differentiation into the direction most appropriate for the invading pathogen. On the other hand, the adaptive immune system often relies on components of the innate immune system for many effector functions, especially elimination of pathogens. For instance, antibodies activate the complement system or engage Fc receptors of phagocytes and NK cells, which eventually kill the invading microbes or the infected cells.

Containment of commensal microorganisms

It has been hypothesized that the immune system has developed in evolution to enable us to house a wealth of commensal bacteria, which colonize the inner and outer surfaces of the body. The composition of the human microbiome is highly complex, and the number of bacteria amounts to around 10^{14}, exceeding that of the eukaryotic cells by a factor of 10. The relationship with our endogenous microflora, the vast majority of which resides in the gut, is usually characterized by mutualism: The microorganisms benefit from the regular food intake and the homeostatic mechanisms of their multicellular eukaryotic host, while providing it with numerous enzymes that are not encoded in the host's genome. These can break down indigestible molecules, and it has been estimated that this allows the eukaryotic host to extract around 14% more calories from food.[27,28] In former times, which were characterized by scarceness of food, this must have conveyed a significant survival advantage. However, the happy balance between the host and its commensals is risky and requires enormous efforts to keep up. It is estimated that 10^{12} cells, i.e. one out of ten eukaryotic cells, belong to the immune system in the strict sense. At least half of them reside in the gut, one of their main tasks being the containment of the endogenous microbial flora. If it fails to control the colonizing microbes, the body immediately becomes prey to the degrading potential of its own commensals.[23,27,28] In fact, in the industrialized world around 80% of bacterial infections are of endogenous origin.

It thus seems to be appropriate to first consider the immune response at the body surfaces, namely the 2 m^2 of skin, and the mucous membranes of the respiratory system (50 m^2) and the gut (200–400 m^2).

Very few microorganisms can withstand the low pH in the stomach to reach the gut. There the mucus forms a barrier which is difficult to penetrate even for flagellated microorganisms, even more so as it is impregnated with high concentrations of antimicrobial peptides, derived from the Paneth cells at the bottom of the crypts. The mucus is continuously produced by goblet cells and then transported out of the body via the bowel movements or the action of ciliated epithelia of the respiratory tract.[1–4,27]

As a second layer of defence, numerous immune cells densely line the epithelial layers and accumulate in the lamina propria and the Peyer's patches, guarding the body's interface with the outside world. Once an adaptive immune response has been established, specific IgA is also found in high concentrations in the mucus and the bodily secretions, where it contributes to the control of the endogenous microflora.

It is fascinating that containment of the microorganisms usually proceeds in a largely non-inflammatory manner. A milieu of immune tolerance is essential for the maintenance of immunological food tolerance in the gastrointestinal system and for efficient gas exchange in the alveoli of the lung.

Reaction to microbial invasion

This peaceful scenario immediately gives way to a vigorous inflammatory response when the barriers are broken and microorganisms invade host cells or tissues. It should be stressed that both commensals and pathogens are equipped with PAMPs and are able to elicit an immune response. The hallmark of pathogens is their invasive behaviour. Upon barrier failure the PAMPs can be sensed by the immune system and trigger an immune response.[23,28] Now the task is to very quickly control and ultimately eliminate the invaders, since these are able to multiply rapidly at the host's cost. It is equally important to minimize damage to the host tissues, an inevitable side effect when the powerful effector mechanisms of the immune system are unleashed. Ideally the system reacts in a fast, focused, and effective manner, utilizing specialized functions to optimally control different types of pathogens. This is achieved by the concerted action of innate and adaptive immune systems. It is essential for health that the immune reaction is terminated and homeostasis is re-established as soon as the microbial invasion has been dealt with.

Innate immune reaction to microbial invasion

Initially, microbial invasion is sensed by the innate immune system via PRRs, which herald 'stranger anddanger', namely microbial factors and substances released upon cell and tissue damage.[23,27,28]

Wherever the attack may happen, sentinel cells—macrophages, dendritic cells, and mast cells—and complement factors are already in place, and they are called into action immediately. Macrophages are professional phagocytes, which take up the microorganisms and kill many of them. Their action is facilitated by the deposition of complement fragments on the microbial surface, since the phagocytes possess complement receptors (opsonization, or opsonophagocytosis). Some microorganisms can be killed by the membrane attack complex formed on their surface by the complement cascade (see Chapter 64).[6]

Inflammation

If the microbial challenge reaches a certain threshold, the immune system will respond with inflammation, which has been diagnosed since antiquity by four cardinal symptoms: rubor, calor, tumor, and dolor. When sensing PAMPs the sentinel cells release inflammatory cytokines, soluble mediators of the immune system, such as TNFα and CXCL8/IL-8.[1–4] These activate the endothelial cells lining the small local blood vessels at the interface between the focus of infection in the tissue and the bloodstream, which connects to the reservoirs of immune cells in the bone marrow and the peripheral lymphatic organs. The blood vessels dilate, the blood stream slows down (rubor and calor), and immune cells intensify their contact with the inner vessel wall, which has become decorated with adhesion molecules in reaction to the inflammatory cytokines.[29] A three-step process termed 'homing' guarantees that the various types of immune cells leave the blood vessels at the right time and in the proper place: (1) Selectins on the endothelium bind to their ligands on the immune cells. These molecular bonds are rapidly formed and dissociated again, so that the cells are gradually slowed down, rolling along the vessel wall. (2) This enables them to bind locally produced chemokines with their chemokine receptors, resulting in (3) conformational changes of cell surface integrin molecules. These permit high-affinity binding to integrin ligands on the activated endothelium. The immune cells now firmly attach to the endothelium and begin to leave the blood vessels by

reversibly opening the tight junctions in the endothelial layer. In the tissues they follow concentration gradients of chemokines and/or complement fragments, which guide them to the focus of infection, where they can accumulate in large numbers (tumour). When they perceive the local 'stranger anddanger' signals, the newly recruited immune cells become activated and join in the attack against the invaders.

When the inflammatory cytokines are released in high amounts they cause systemic effects such as fever, and a systemic inflammatory response syndrome (SIRS) develops. IL-6 is a key factor, triggering the liver to change its protein synthesis programme and release increased amounts of defence molecules such as lipopolysaccharide-binding protein, MBL, and components of the complement and coagulation cascades.[1–4]

Adaptive immune reaction to microbial invasion

The adaptive immune response is initiated by activated innate immune cells, and it takes several days to become effective. The complex programme is orchestrated in the peripheral lymphatic organs, which function as 'conference centres' of the immune system. Numerous components need to interact in a highly organized manner to start a primary adaptive immune response.[1–4] Take the lymph node as an example: naive T cells and B cells are recruited from the bloodstream into lymph nodes through specialized high endothelial venules via CCR7 signals. In the lymph node they home to different compartments, the primary B-cell follicles and the T-cell areas. Antigens and antigen-presenting dendritic cells reach the lymph node via the lymphatic vessels, which drain almost all tissues. DC are the sentinels of the adaptive immune system: Through macropinocytosis they sample the antigenic milieu in the tissues, and during homeostasis low numbers of non-activated dendritic cells continuously move with the lymph into the lymph nodes, where they present self-antigens to T cells in a tolerogenic, non-inflammatory fashion, contributing to the maintenance of immunological self-tolerance. Upon microbial invasion and during inflammation, however, the DC become activated by the PAMPs and DAMPs at the site of infection. They now stop the antigen uptake in order to preserve the antigenic spectrum incorporated at the site of danger, and while moving into the lymph nodes in increased numbers, they differentiate into professional APCs, which are characterized by the ability to activate naive T cells and guide their differentiation.

Antigen recognition

The activation of naive T cells is a stringently controlled process requiring the activated DC to give three types of signal: (1) MHC–peptide complexes, which the T cells recognize with their antigen-specific T-cell receptors; (2) costimulatory molecules such as CD80 and CD86 which bind to CD28 on the T-cell surface; and (3) a cytokine cocktail. This corresponds to the first phase of an adaptive immune response: antigen recognition.[1–4]

The first signal for B cells is antigen in its native, unprocessed form as it reaches the lymph nodes via the lymph vessels. The B cells recognize their antigenic epitopes with their B-cell receptors (BCR), which are membrane-anchored antibody molecules.

Clonal expansion and differentiation

Fully activated T cells divide rapidly with a generation time of around 6 hours and form a clone. Importantly, all progeny of an activated T cell express molecularly identical T-cell receptors on their surface, i.e. they are specific for the same antigen. During this process the T cells differentiate into effector T cells (Teff), of which there are different functional types (see 'Immunological tolerance' below and Chapter 49). B lymphocytes behave in a similar way upon antigen recognition, but in most cases they require T-cell help to become fully activated (see below).

Effector phase

While naive T cells can only home to the peripheral lymphoid organs, where they scan the local DC for their antigenic MHC–peptide complexes, activated T cells are able to enter the tissues having left the bloodstream via the capillaries. Upon re-encounter with their antigenic MHC–peptide complexes on local APC they exert their effector functions and contribute to the elimination of the invading microorganisms. Activated B cells differentiate into plasma blasts or plasma cells, whose most prominent effector function is the secretion of antibodies. These are soluble forms of the antigen-specific BCRs which originally triggered the activation and proliferation of the B cell and thus have the same antigen specificity (see Chapter 50).

Clonal contraction

Having eliminated the invasive microorganisms, homeostasis needs to be re-established, and the formerly expanded T-cell and B-cell clones contract again. Apoptosis is the essential mechanism at this stage of an adaptive immune response.

Memory

Having overcome the dangerous situation, not all effector cells die. In the case of T cells, around 10% develop into memory T cells, which divide very slowly once every 1–2 weeks, just enough to compensate cell loss by apoptosis. T-cell memory clones can persist for many years. The next antigenic challenge will thus be met by many more antigen-specific T cells than at the first exposure. Additionally, memory T cells have a lower activation threshold, are less demanding with regard to the second and third signals, can respond much faster than naive T cells, and, importantly, they also memorize and quickly recall their special effector functions (see below).

B cell memory consists of (1) memory B cells, which are able to rapidly respond to antigenic rechallenge with proliferation and differentiation into plasma cells, and in addition, (2) long-lived plasma cells populating special microenvironmental niches in the bone marrow, where they continuously produce antibodies, maintaining high antigen-specific antibody titres. During a secondary or memory immune response the antibodies will immediately bind to their antigen, such as invading microorganisms, and elicit their biological effector functions.[26]

Immune memory is a core competence of the adaptive immune system enabling it to react much faster and more efficiently to a re-encounter with the same antigenic stimulus. All vaccination strategies rely on this feature of the adaptive immune system. Moreover, IgG antibodies are actively transported into the fetus and provide an immediate protection to the neonate during the first weeks after birth.

T-cell help for B cells—the germinal centre reaction

Antibodies are very important effector molecules of the adaptive immune system. Their producers, the plasma cells, appear to be terminally differentiated cells that function largely 'on autopilot', and they can be very long-lived producing high amounts of specific antibodies for decades, possibly lifelong. Consequently, the

priming of a B-cell response must be stringently regulated, and this control is exerted by T lymphocytes in the germinal centre reaction. Naive T cells recognize their antigen on DC in the T-cell areas, proliferate, differentiate into effector T cells, and, guided by cytokine gradients, then move towards the edge of the B-cell follicles. Here they meet B cells, which have been activated by antigen binding to their specific BCR, which has stimulated them to migrate into the opposite direction towards the T-cell area. In this way it becomes possible for the very few antigen-specific T cells, not more than 1 out of 10 000 in a primary response, to cooperate with the very few B cells that recognize the same antigen in a process termed **cognate T cell–B cell interaction**. Only if the B cells are able to internalize the correct antigen via their BCR, process it and present it to the T cells, will the latter exert an effector function known as T-cell help. Via cell–cell contact and cytokines the T cells stimulate the B cells to enter a complex programme of (1) proliferation, (2) immunoglobulin class switch, and (3) somatic hypermutation, namely the accumulation of point mutations in the antigen binding sites. A quality control process selects those B cells whose BCR exhibit an increased affinity for the recognized antigen (affinity maturation) and allows them to develop into antibody-secreting plasma cells and memory B cells.[24] Their BCR and the secreted antibodies will have usually switched from IgM, which characterizes naive B cells, to another immunoglobulin class: IgG, IgA, or IgE. The class switch is not a random process, but is guided by the effector cytokines of the T helper cells: IFNγ favours the development of proinflammatory IgG subclasses, which can activate complement and bind to Fcγ-receptors on phagocytes and NK cells. TGFβ promotes the class switch to IgA, and IL-4 is essential for the elaboration of IgE.[1–4]

Microbial habitat and the optimal defence strategy

During coevolution microorganisms and viruses have specialized to persist or multiply in different compartments of the eukaryotic host. They have been most inventive regarding mechanisms of immune evasion, which highlights that the immune system puts them under strong pressure once they have managed to break the barriers. While there are general immune strategies in antimicrobial defence, the control of every microbial species is a story of its own.

Staphylococci, streptococci, and their toxic products, for example, are mainly found in the extracellular compartment, while mycobacteria are specialized to live in intracellular vesicles. Some bacteria—listeria and burkholderia species—have evolved mechanisms to destroy the phagosomal membrane, escape into the cytoplasm, and are even able to move from cell to cell directly. Viruses depend on the metabolism of their host cells for multiplication, and viral particles are assembled in the cytoplasm. After budding, however, they temporarily transit the extracellular space. Clearly, no single immune defence strategy can fit all these situations, and some specialized immune functions are described below. First, it is reassuring that the innate immune system can survey all the mentioned compartments with its repertoire of PRRs. For example, TLRs are found in the outer cell membrane as well as in the intracellular vesicles, while NOD-like receptors and RIG-I-like receptors recognize 'stranger and danger' in the cytoplasm (Figure 48.1, Table 48.3). MBL can be regarded as an extracellular pattern recognition molecule of the complement cascade.

Defence against extracellular microorganisms

Extracellular microorganisms, viruses, and toxins are accessible to antibodies and complement. Thus T-cell help for B cells is important for their control. Antibodies may neutralize the invaders, i.e. prevent their binding to the specific receptors, and thereby interfere with their function or cellular uptake. Neutralization is the essential function of IgA, the most abundant Ig class, which is found in high concentrations in the bodily secretions and on the mucous membranes. Importantly, antigen neutralization by IgA does not trigger inflammation.

This is different in the case of IgG, which can activate complement and bind to Fc receptors on phagocytes, both leading to enhanced phagocytosis and activation of the phagocytes, which then secrete inflammatory cytokines. In synergy with the opsonization by IgG and/or complement, Th17 cells, a T-cell subpopulation discovered only in the 21st century, mobilize neutrophils from the bone marrow and attract them to the focus on inflammation. Here they avidly phagocytose and destroy the marked microorganisms.[1–4]

Defence against intravesicular microorganisms

Some microorganisms have developed strategies to prevent phagocytes from killing them after uptake. In such cases IFNγ, a product of Th1 cells, helps macrophages to overcome this block and direct their aggressive potential, e.g. reactive oxygen and nitrogen mediators as well as proteolytic enzymes, at the invaders. The importance of the Th1 response is underlined by the fact that defects in this function, either inborn or acquired as a consequence of HIV infection, render patients highly susceptible to fulminant tuberculosis.[1–4]

Defence against intracytoplasmic microorganisms

Once microbes have managed to leave the phagosomes, they are out of reach of the effector mechanisms of the phagocytes. Intracytoplasmic PRR (see Table 48.3) can sense cytoplasmic bacteria and viruses and induce mechanisms to mark the infected cells and activate the immune system. Ultimately in case of intracellular bacterial infection, there is only one effective countermeasure: the infected cell has to be eliminated. The same is true for viral infection, which can hit any nucleated cell of the body. The elimination of cells with cytoplasmic infection is the function of NK cells and cytotoxic T lymphocytes (CTLs). These induce a cell death programme called apoptosis in the affected cells, and the apoptotic cells or their fragments are rapidly taken up and digested by macrophages. Obviously, the cytotoxic immune cells are dangerous for the organism itself, and their activation is therefore strictly controlled. Naive CD8+ T cells cannot kill before they have differentiated into CTLs. This becomes possible only after they have recognized their antigen (a complex of MHC-I molecule and antigenic peptide) on a professional APC, and in many cases T-cell help from Th1 cells is necessary in addition.[1–4]

Defence against parasites

Exposure to large numbers of ecto- and endoparasites has been an everyday reality during human evolution, and in large parts of the world it still is. These parasites are usually not immediately life threatening, and there is rarely sterile immunity, but the immune system has evolved mechanisms to reduce parasite density, e.g. by expelling worms from the intestinal tract or preventing ticks from enjoying a full blood meal. IgE, elaborated with the help of Th2

cells, is the key effector molecule of this immune defence mode. IgE binds to high-affinity Igε-receptors on mast cells and basophils even in the absence of antigen, providing the cells with antigen recognition capacity. Multivalent antigens will then bind to the specific binding sites of IgE on the cell surfaces, cross-link the attached Igε-receptors and induce the rapid release of inflammatory mediators. These enhance mucus secretion in the gut and stimulate bowel contractions, facilitating parasite expulsion. In the skin, itching directs the attention of the host to the parasite attack, and a strong oedema limits the parasite's blood meal or makes invasion more difficult. In addition, eosinophil granulocytes are recruited and activated, which enhance this response in a positive feedforward loop.

When they are misdirected at innocuous environmental antigens, the IgE-mediated defence mechanisms just described can drive allergic responses.[1–4,30]

Immunological tolerance

In a healthy individual the powerful inflammatory effector functions of the immune system are balanced by equally strong regulatory mechanisms, which ensure that a non-inflammatory state is dominant during homeostasis. Various negative feedback loops and active tolerance mechanisms stop the inflammation as soon as the microbes have been eliminated. Wound healing processes set in, the damaged tissues are repaired, and the system is reset to its non-inflammatory default status.

In this context, the adaptive immune system merits special attention because its unique capacity to recognize 'virtually everything' by means of its vast receptor repertoire continually challenges immunological self-tolerance. Since the many different receptors are assembled independently of antigen contact, the development of autoreactive T cells and B cells cannot be avoided. Adaptive immune tolerance, mediated by active and passive mechanisms, is thus vitally important. In the first instance, nascent T cells and B cells are filtered in the thymus and bone marrow, and most autoreactive clones are eliminated (central tolerance). The remaining autoreactive clones mature, and they need to be controlled for the lifetime of the organism (peripheral tolerance).

Toward the end of the 20th century it became apparent that a subpopulation of T cells known as regulatory T cells (Tregs) has a crucial role in this process. The so-called 'natural Tregs' develop in the thymus, while 'induced Tregs' differentiate from naive mature T cells under the influence of anti-inflammatory cytokines such as IL-10 and TGFβ. Upon antigen recognition Tregs suppress the activation of neighbouring naive T cells and interfere with their development into Teff cells, but they are also able to inhibit the effector functions of fully differentiated Teff cells, regardless of whether they are Th1, Th2, Th17, or follicular Th cells.[1–4]

Rare monogenetic immune defects, which interfere with the development or function of Tregs, are associated with a very severe autoimmune and allergic phenotype, which can be recapitulated in animal models. The discovery of an active mechanism of immune tolerance—the adoptive transfer of Tregs establishes tolerance in previously non-tolerant animals—has raised hopes that it may be possible to harness this cell type for therapeutic interventions in chronic immune-mediated inflammation. There is now good evidence that in allergy the specific immune therapy (SIT), which consists of the repeated application of minute allergen doses, relies largely on the induction of allergen-specific Tregs.

Autoinflammation, autoimmunity, and autoimmune disease

The inflammatory response serves the host defence and tissue repair; some collateral damage to the host tissues appears to be a necessary trade-off. However, overwhelming or self-perpetuating chronic inflammation can cause major harm to the organism. In certain pathologic conditions release or extracellular accumulation of endogenous molecules may exert a massive inflammatory response. In gout and pseudogout sodium urate or calcium pyrophosphate crystals are phagocytosed by neutrophils and lead to strong inflammasome activation. Autoinflammatory or hereditary periodic fever syndromes can be caused by defective regulatory mechanisms such as defective cleavage of the membrane-bound TNF receptor in TRAPs (TNF receptor associated periodic fever syndrome). Consequently, the natural decoy receptor for TNF is missing and even minor amounts of TNF may cause a systemic inflammatory response. In other autoinflammatory syndromes, e.g. cryopyrine-associated diseases, mutations in components of the inflammasome may lower the activation threshold of the inflammasome, resulting in spontaneous or inadequate IL-1β secretion in response to minor stimulation.[31,32]

Autoimmunity, i.e. the presence B or T cells which can react with autologous structures, is a rather frequent phenomenon. However, the mere presence of such autoreactive lymphocytes, which have escaped from negative selection during development in the bone marrow or thymus respectively, rarely results in clinically relevant autoimmune diseases. Autoreactive lymphocytes are usually well controlled by mechanisms of peripheral tolerance.[1–4] However, in certain conditions, there is an increased risk of breaking tolerance, at least transiently:

◆ During infection or tissue necrosis exogenous or endogenous 'danger signals' (PAMPs or DAMPs) activate APC of the innate immune system. Costimulatory molecules and proinflammatory cytokines are expressed. Presentation of self-peptides by fully activated APC may result in the activation of self-reactive T lymphocytes.

◆ Molecular mimicry, i.e. structures of pathogens that closely resemble those of the organism, can cause autoimmunity. However, even fully identical peptide stretches within an endogenous and a microbial protein have only a limited risk of breaking self-tolerance. Only those individuals who can process and present these peptides within their MHC molecules are at risk of developing autoimmunity due to molecular mimicry of T-cell epitopes.

Obviously, the innate immune system essentially contributes to the generation of a protective adaptive immune response as well as to the break of tolerance and autoimmune responses. These and other mechanisms leading to autoimmunity are discussed in the chapters on specific diseases.

Cellular side of acquired immunity (T cells)

Assia Eljaafari and Pierre Miossec

Introduction

Foreign invaders are recognized by cells of the innate immune system, which leads to the activation of adaptive immune responses. However, a crucial prerequisite for defence against external pathogens is the ability to discriminate self from non-self. Otherwise, the immune response can become threatening for the body, leading to autoimmunity and organ damage.

T cells are critical in the adaptive immune response. New subsets have been recently described, allowing a better understanding of the respective contribution in normal life as well as in disease. This understanding has led to new therapeutic approaches, and more options are coming.

The adaptive T-cell immune response

To initiate an adaptive immune response, a T cell has to come into tight contact with an antigen-presenting cell (APC). An immunological synapse is created to allow T cells to receive signals from APCs. Two signals play a preponderant role in T-cell activation. The first signal is provided after interaction with the cognate antigen–MHC ligand complex, through the T-cell receptor (TCR), and this gives specificity to the immune response. The second signal is antigen-independent and is delivered by the interaction of B7-1/CD80 and B7-2/CD86 costimulatory molecules on APC with the CD28 molecule on T cells.[1] This signal promotes T-cell clonal expansion, lymphokine secretion and effector functions. The combination of these two signals determines whether a T cell becomes activated or anergic. CD8/CD4 T-cell coreceptors and CD40 ligand amplify these signals by binding to HLA class I, class II, or CD40 molecules, respectively, on APC. On the other hand, CTLA4 (cytotoxic T lymphocyte antigen), a CD28 homologue, is a negative regulator of the immune response. Its expression is induced in a second step during activation, with the aim of regulating T-cell expansion by competing with the CD28 molecule for binding to B7-1 and B7-2 molecules. Moreover, this molecule was shown to play a key role in regulatory T-cell suppressive function.[2]

Dendritic cells

Dendritic cells (DCs) are the most potent professional APCs and play a critical role in the induction of adaptive immune responses and tolerance. They represent a heterogeneous population where immature DCs rather promote tolerogenic responses and mature DCs immunogenic responses. Peripheral DCs display an 'immature' phenotype characterized by expression of low surface levels of MHC II and of costimulatory molecules and induce suboptimal T-cell priming, resulting in T-cell anergy or tolerance. Immature DCs secrete interleukin (IL)-10, and promote tolerance in vivo by either deleting antigen-specific T cells or expanding regulatory T cells (Tregs). Conversely, upon stimulation, DCs undergo maturation characterized by expression of high levels of MHC class II molecules and costimulatory molecules. They induce robust T-cell activation and effector cell differentiation. Such DCs secrete high levels of IL-12.[3] However, many distinct DC subtypes, related to different routes of DC differentiation from precursors, have recently been discovered. Those DC subsets display specialized functions corresponding to particular locations.[4]

Link between innate and adaptive immunity

Adaptive immune responses depend on the microbial antigens that stimulate APC, and more particularly DC. DC express pattern-recognition receptors (PRRs). Those receptors recognize conserved structures of microbes, known as pathogen-associated molecular patterns (PAMPs). Among the PRRs are the Toll-like receptors (TLRs) and the Nod-like receptors (NLRs). TLRs are a family of 10 receptors in human and of 12 in mouse.[5] Most TLRs are expressed on the plasma membrane of myeloid cells and occasionally lymphoid leucocytes. They recognize various viruses, bacteria, fungi, and parasites. Different TLRs specialize in the recognition of particular PAMP motifs.[6] Their ligand molecules are expressed by different sets of bacteria. For example, TLR1, 2, and 6 detect lipopeptides, TLR5 detects flagelline, while TLR4 recognizes a variety of lipopolysaccharides. Among the various TLRs, TLR3, TLR7, TLR8, and TLR9 are intracellular, localized in endosomes and implicated in nucleic acid recognition. These four TLRs are expressed in leucocytes, such as DCs, macrophages, and B cells. They are involved in response against viruses, except TLR9, which recognizes demethylated CpG oligonucleotides in bacteria.[7,8]

Presentation of PAMPS through TLRs results in the activation of NFκB and interferon regulatory factor (IRF) transcription factors and this leads to increased expression of proinflammatory

cytokines.[9] On the other hand, cytosolic NLRs lead to the activation of the IRF3 transcription factor (IRF3), which induces type I interferon (IFN) production and a series of proinflammatory cytokine secretion, like interleukin (IL)-1β, IL-18, or IL-33, through activation of the inflammasome and cleavage of their immature form by caspase-1.[10] This TLR/NLR strategy allows a limited set of receptors to recognize a wide range of pathogens, rapidly inducing local inflammation and providing a link with a specific and memory immune response, i.e. the adaptive immune response (see Chapter 48).

T-cell differentiation and Th subsets

Upon interaction with their cognate antigen, naive CD4+T cells differentiate into a number of different subsets characterized by patterns of cytokines and transcription factors. Naive T cells are circulating cells, but upon encounter with APC in lymphoid tissues, they commit and migrate to inflamed non-lymphoid tissues where antigens are present at high concentrations. There they produce cytokines, proliferate, and/or directly lyse infected cells. A few memory T cells, know as central memory T cells, recirculate like naive T cells in order to rapidly proliferate and produce new T effector memory cells and effector cells, during a secondary response to the same antigen.

Mosmann and Coffman first defined Th1 and Th2 effector cells.[11] Th1 cells play a role in immunity against intracellular pathogens and are involved in delayed-type hypersensitivity responses. Their commitment from naive T cells is related to the secretion of IL-12 by APCs, and subsequent expression of the Tbet transcription factor. This results in the secretion of IFNγ, which activates macrophages and NK cells at the site of inflammation. When IL-10 instead of IL-12 is secreted by APCs, T cells rather commit into IL-4/STAT6-Th2 cells under the control of the GATA3 transcription factor. Th2 cells secrete IL-5/IL-10/IL-13, and play a role in immunity against parasites. They are implicated in allergy and asthma, through induction of IgE production, and activation of eosinophils. Importantly, Th2 cytokines, particularly IL-4, strongly inhibit Th1 differentiation, while IFNγ and IL-12 inhibit Th2 generation, thus leading to a reciprocal counter-regulation.[12]

Along with Th1 and Th2 cells, new subsets have been recently described, such as Th3, Th9, Th17, Th22, follicular helper T cells (TFh), or Tregs. Of these new subsets, Th17, Th22, and Tregs have attracted most attention, due to their implication in chronic inflammation and autoimmune diseases, such as multiple sclerosis, psoriasis, rheumatoid arthritis (RA), and inflammatory bowel disease (Figure 49.1).

Th17 cells

Characterization of the Th17 subset

Th17 cells were first characterized by the ability to secrete IL-17.[13] IL-17 (now IL-17A) is a member of the IL-17 family composed of six cytokines, A–F. IL-17A is the major actor of the Th17 cells, along with IL-17F with which it shares 50% homology. IL-17A and IL-17F signal through the IL-17RA IL-17RC receptor complex which is ubiquitously expressed.[14] IL-17A activates mitogen-activated protein kinases (MAPK) and NFκB via association with Act1 and activation of TNF receptor associated factor 6 (TRAF6).[15]

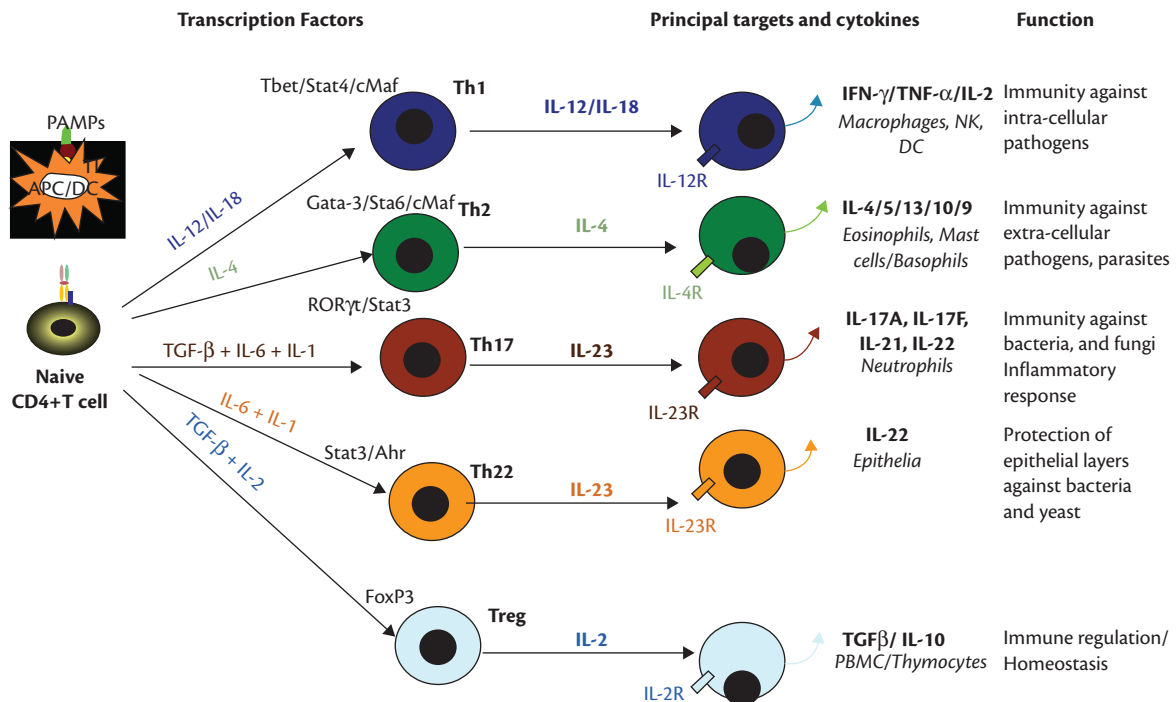
The Th17 subset was discovered through observations of the experimental autoimmune encephalitis (EAE) model, where IFNγ-deficient mice were unexpectedly found to be more susceptible to disease.[16] IL-12 is the key factor for the differentiation of Th1 cells.


Fig. 49.1 Subsets of T cells. Upon interaction with their cognate antigen, naive CD4+T cells differentiate into a number of different subsets characterized by patterns of cytokines and transcription factors. The cytokines present in the microenvironment drive this differentiation, but the profile of cytokines depends on the microbial antigens that stimulate APC, and more particularly DC which express pattern-recognition receptors (PRRs). Those receptors recognize conserved structures of microbes, named pathogen-associated molecular patterns (PAMPs).

It is made up of two subunits, p35 and p40. The p40 subunit is also one of the components of IL-23, which is a heterodimer consisting of of IL-12p40 and p19.[17] The use of mice deficient for these two molecules clearly demonstrated that IL-23 but not IL-12 was crucial for the development of EAE.[18] The discovery of a unique subset of T cells secreting IL-17 but not IFNγ or IL-4 then led to the description of a new subset, Th17, involved in inflammation and autoimmunity.

However, naive T cells do not express the IL-23 receptor, and therefore cannot be converted into Th17 cells under the sole influence of IL-23. The differentiation of Th17 cells is now seen as a three-step process. In the first step, the combination of TGFβ, IL-1β and IL-6 drives naive T cells towards the Th17 pathway; IL-6 through STAT3 triggers the activation of retinoic acid orphan receptor γ thymus (RORγT) in mouse, or RORC in human, the crucial transcription factor implicated in Th17 development.[19] TGFβ renders naive T cells sensitive to IL-23 by increasing the expression of its receptor.[20] In the second and third steps, IL-21 participates to Th17 expansion, whereas IL-23 stabilizes the Th17 phenotype.[21]

The role of TGFβ was found to be quite intriguing. TGFβ alone is involved in generation of Tregs through FoxP3. However, in the presence of IL-1β and IL-6, this cytokine activates Th17 differentiation. Since IL-6 inhibits FoxP3, this suggests that Tregs and Th17 cells are developmentally regulated.[22] Supporting the existence of such a balance is the recent finding that IL-2, a growth factor important for Treg expansion and activation, inhibits Th17 promotion. Thus Th17 cells are promoted when IL-2 is consumed, notably by Tregs. This inhibition of IL-17A production is related to the competitive inhibition of STAT-3 and STAT-5 for binding to the IL-17-enhancer element (Figure 49.2).[23]

Another balance between Th1 and Th17 cells has also been described. IFNγ inhibits Th17 promotion in different models[24] and, conversely IL-17A inhibits Th1 cells by blocking the expression of the IL-12Rβ chain, the IL-12 specific chain of the IL-12 receptor.[25] In reality, the situation is probably more complex. Th17 cells were shown to produce IFNγ by themselves, particularly in the presence of IL-12, or in the absence of IL-23 and the presence of IL-2 in vitro.[26] Moreover, Th17 cells expressing both Tbet and RORγt were found in the brain of mice with EAE, and were described as more pathogenic.[27] Such plasticity of Th17 cells does not seem to be restricted to the Th1 pathway, with studies demonstrating the ability of Th17 cells to secrete IL-10 in the presence of TGFβ. These TGFβ-induced Th17 cells expressing IL-10 are, however, likely to have limited pathological potential.[28]

Role of Th17 cells in disease
Response to infectious agents
IL-17A and IL-17F induce the recruitment of neutrophils to the site of inflammation, through the release of chemokines, like CXC-chemokine ligand-1 (CXCL1), CXCL2, IL-8, or GCP2/CXCL6.[29] Administration of IL-17A induces accumulation of neutrophils in the br onchoalveolar and joint areas. IL-17A increases neutrophil elastase and myeloperoxidase (MPO) activity and plays an important role in defence against bacteria and fungi that are not cleared by Th1 or Th2 cells, such as *Propionibacterium acnes*, *Klebsiella pneumoniae*, *Citrobacter rodentium*, *Borrelia burgdorferi*, or *Candida albicans*. In the hyper-IgE syndrome, a mutation in *STAT3* results in a defect in Th17 cells with recurrent *C. albicans* and *Staphylococcus aureus* skin and lung infections.[30]

Chronic inflammation and autoimmunity
IL-17A was found to mediate local tissue inflammation by inducing the release of proinflammatory cytokines (such as IL-1, TNFα, and IL-6) and the activation of metalloproteases in fibroblasts or epithelial cells.[31] In addition to neutrophil chemokines, the local release of granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF), monocyte
Fig. 49.2 Reciprocal balance between Th17 cells and Tregs. The combination of TGFβ, IL-1β and IL-6 drives naive T cells towards the Th17 pathway; IL-6 triggers the activation of RORγT in mouse, or RORC in human, the crucial Th17 transcription factor. TGFβ alone is involved in Treg generation through FoxP3. But, in the presence of IL-1β and IL-6, TGFβ induces Th17 differentiation. IL-6 inhibits FoxP3 activation, and thus Treg generation. Reciprocally, IL-2, a growth factor important for Treg expansion and activation, inhibits Th17 promotion. Thus Th17 cells are promoted when IL-2 is consumed, notably by Tregs. Tregs and Th17 cells are therefore developmentally regulated. A dysregulation of the Treg/Th17 balance leads to autoimmune diseases.

chemokine protein (MCP-1), or CCL20 attracts mononuclear cells such as monocytes, DCs, or Th17 cells to the site of inflammation. Therefore, Th17 cells were suggested to promote autoimmunity and chronic inflammation. In RA, IL-17A and IL-17F were found to trigger bone resorption, through extracellular matrix destruction, and stimulation of the RANK/RANKL interaction leading to osteoclast activation.[32] TNFα and IL-1β were found to act synergistically with IL-17A, in the release and activation of inflammatory cytokines or enzymes. In addition in RA, Th17 cells were found to accumulate in the tissues of patients suffering from psoriasis, multiple sclerosis, or bowel diseases.[33] IL-17A was found elevated in the serum and synovial fluid of RA patients, or cerebrospinal fluid of multiple sclerosis patients. It was suggested in the latter case that Th17 cells infiltrate the blood brain–barrier as a result of CCL20 attraction through their CCR6 expression.[34]

Th22 cells

Characterization of the Th22 subset

IL-22 is a member of the IL-10 family, which is subdivided into three subgroups. IL-10 is an immunomodulatory and anti-inflammatory cytokine, and IL-22 belongs to the IL-20 subfamily, together with IL-19, IL-20, IL-24, and IL-26. These cytokines, especially IL-22, protect epithelial cells from invasion by extracellular pathogens such as bacteria and yeast and contribute to tissue remodelling and wound healing. This family of cytokines maintains tissue integrity and restores homeostasis of epithelial layers during infection and inflammatory responses. The third group contains IL-28A, and IL-28B and IL-29, which protect epithelial cells from viral infections by synergizing with type I IFN to boost host antiviral response.[35] Stat3 is the key downstream transcription factor used by IL-10 and IL-20 subfamily cytokines, but Stat3 is also critical for Th17 cell differentiation in mouse and human. IL-22 is indeed an effector cytokine of Th17 cells. However, IL-22 and IL-17 are not always coexpressed and their regulation is different. Notably TGFβ, which contributes to IL-17 production, is a potent inhibitor of IL-22 production, while it drives IL-10 production by Th17 cells.[36] Therefore TGFβ controls the production of IL-22 but drives against IL-10 by Th17 cells. Accordingly IL-22 is induced by IL6/IL23/IL1β, while IL-10 is rather induced by TGFβ/IL-6. Thus, IL-10 and IL-22 are rarely expressed by the same cell. Stat3, which is triggered by IL-6, IL-1, and IL-23, is crucial for RORγT expression and IL-17 secretion but is not sufficient alone to lead to IL-22 production in Th17 cells. This may be related to the aryl hydrocarbon receptor (AhR), a transcription factor which plays an essential role in IL-22 expression by Th17 cells. While Stat-3 deficient mice are impaired in IL-22 expression, Th cells from AhR deficient mice fail to secrete IL-22, but still produce IL-17.[37]

Th22 cells and autoimmune diseases
Exacerbating role

IL-10 and the IL-20 subfamily cytokines are upregulated in RA synovial fluid. IL-19 and IL-22 are produced by synovial fibroblast and macrophages, whereas IL-20 and IL-24 are expressed by mononuclear and endothelial cells. The increased IL-22 production in RA synovium may also be the result of increased accumulation of Th17 cells which contribute to IL-22 production. IL-19 increases the production of IL-6 by RA synovium and decreases apoptosis of the synovial cells, whereas IL-22 enhances proliferation of synovial fibroblasts and secretion of chemokines.[35] The implication of IL-22 in RA has been demonstrated in IL-22-deficient mice, which showed a delayed onset of collagen-induced arthritis (CIA) and decreased synovial proinflammatory cytokine expression.[38]

IL-22 has also been implicated in the pathogenesis of psoriasis. Skin overexpression of IL-22 leads to key features of this disease, by increased recruitment of leucocytes through secretion of proinflammatory cytokines and chemokines, and increased keratinocyte proliferation and differentiation.[39] Mice overexpressing IL-22 die within a few days, but exhibit a thickened epidermis with hallmarks of psoriasis. IL-22 injection into the skin of normal mice induces keratinocyte hyperplasia and secretion of defensins.[35]

Protective role

Contrasting with their exacerbating role in RA or psoriasis, Th22 cells appear to play a protective role in some autoimmune diseases such as systemic lupus erythematosus (SLE), where high plasma levels of IL-22 were negatively correlated with disease activity.[40] In inflammatory bowel diseases, IL-22 contributes to protection through the secretion of inflammatory cytokines and chemokines by colonic epithelial cells and myofibroblasts, which leads to the recruitment of leucocytes that control invading pathogens. IL-22 also induces the secretion of antimicrobial peptides such as defensins, or C-type lectins from intestinal epithelial cells. Finally, it also stimulates mucosal wound healing.[35]

Regulatory T cells
Definition and functions

Intrathymic selection of T cells is a central process that ensures deletion of most of the autoreactive T cells. This is a two-step process, where a first positive selection is driven by the interaction of a self-MHC restricted TCR with its antigen presented by thymic stromal cells. The second step is a negative selection of T cells expressing TCR with high affinity for self-antigen.[41] This step is under the control of DC, which give a negative signal to T cells. Therefore negative selection is the major mechanism responsible for deletion of autoreactive T cells.[42] Some aut-reactive T cells can escape from thymus depletion, either because they express antigen-specific TCR with too low affinity for the target self-antigen, or because this antigen is not expressed in the thymus. Thus circulating autoreactive T cells are present in the periphery even of healthy individuals. To prevent autoimmunity, various mechanisms are present in the periphery, such as anergy, clonal deletion, ignorance, or silencing by Tregs. Autoimmunity can develop as the result of a failure of central or peripheral tolerance mechanisms.[43]

Regulatory T cells in autoimmune diseases

By using a combination of self-depletion and adoptive transfer experiments, Sakaguchi demonstrated the crucial role of CD4+CD25+ thymus-derived T cells to prevent and control multi-organ autoimmunity and lethal inflammatory disease. High expression of CD25, the α chain of the IL-2 receptor, allows enrichment of regulatory suppressor Tregs.[44] However, neither CD4 nor CD25 are exclusive markers for Tregs, because they are also expressed by activated T cells. But forkhead domain DNA-binding transcription factor 3 (FoxP3) is specifically expressed in Tregs in mice, and is essential for development and function of Tregs. Genetic mutation of FoxP3 leads to the lethal scurfy disease in mice, demonstrating

that this transcription factor is required for the homeostasis of the immune system.[45] In humans, the IPEX syndrome (immunodysregulation, polyendocrinopathy, enteropathy, X-linked) also indicates the crucial role of FoxP3.[46] However, FoxP3 in humans is also expressed after T-cell activation.

The emergence of autoimmune diseases can also be linked to an altered function of Tregs. In RA, although Tregs are identified in the joint, they show functional defects.[47] CTLA-4 is essential for the function of Tregs which constitutively express this molecule.[48] CTLA-4 deficiency in FoxP3+ Tregs impairs their suppressive function. CTLA-4 acts in part through the downregulation of CD80 and CD86 molecules on APC, leading to reduced stable interactions between activated T cells and APCs.[49] Polymorphisms of the *CTLA4* gene have been associated with genetic susceptibility to a variety of autoimmune diseases including RA, and may therefore account for the functional defects.[50]

Conclusion

Foreign invaders are recognized first by cells of the innate immune system. This leads to a rapid and non-specific inflammatory response, followed by induction of the adaptive and specific immune response. Different adaptive responses can be promoted, depending on the predominant effector cells that are involved, which themselves depend on the microbial/antigen stimuli. As examples, Th1 cells contribute to cell-mediated immunity against intracellular pathogens, Th2 cells protect against parasites, Th17 cells against extracellular bacteria and fungi that are not cleared by Th1 and Th2 cells. Among the new subsets, Th22 cells protect against disruption of epithelial layers secondary to invading pathogens, such as bacteria or yeast. Finally these effector subsets are regulated by Tregs. These Th subsets counteract each other to maintain the homeostasis of the immune system.

This balance can be easily disrupted, leading to chronic inflammation or autoimmune diseases. The challenge is to detect early changes in this balance, prior to its clinical expression. New molecular tools such as microarrays could be used to determine the predominant profile of the immune effector cells involved in a disease process. Such understanding should provide better therapeutic tools to counteract dysregulated effector cells.

CHAPTER 50

Cellular side of acquired immunity (B cells)

Thomas Dörner and Peter E. Lipsky

Introduction

The traditional model of rheumatoid arthritis (RA) pathogenesis postulated a central role for CD4+ T cells and macrophages.[1] Therefore, early therapeutic trials employed anti-CD4 therapy in RA, which failed to show clinical benefit and raised questions about the central role of CD4+ T cells.[2] However, recently, the successful treatment of RA by blocking T-cell costimulation with CTLA4Ig (abatacept) has again implied a role for CD4+ T cells in RA pathogenesis, although effects of this product on cells expressing CD80/86 have not permitted a firm indication on its primary target of action.

Clinical application of anti-cytokine therapy in RA appears to be closely linked to blocking aspects of innate immunity, leaving unresolved the central role of B cells in RA pathogenesis. Despite this, it has been accepted that autoantibodies play an important amplifying role in joint inflammation and serve as diagnostic, classification, and prognostic markers. More recently, however, the success of B-cell-depleting therapy in ameliorating RA inflammation and inhibiting radiographic progression even after failure of tumour necrosis factor (TNF) blockade[3] has documented a role for B cells in RA pathogenesis. It is clear from these clinical results that CD4+ T cells, B cells, and the innate immune system all may play important roles in the initiation as well as the perpetuation of RA.

Role of B cells in immune responses

B cells are an essential component of normal immune responses and are responsible for the maintenance of humoral protective memory.[4] The nature of the serologic component of protective memory is illustrated by the persisting protective antibody titres against a variety of microorganisms.[5] Interestingly, CD4+ T cells are important in instructing memory B cells to differentiate into long-lived plasma cells, whereas these long-lived non-proliferating antibody-secreting cells survive independent of antigen and further direct interaction with antigen-specific T cells.[6] However, antigen-non-specific interactions with T cells may contribute to the survival of human plasma cells in secondary lymphoid organs.[7,8]

Normal B-cell development in health

In order to understand the role of B cells in RA and also to delineate possible points for therapeutic targeting, it is important to understand the role of these cells under normal conditions. B cells follow a tightly regulated life cycle (Figure 50.1). In the bone marrow, B cells develop from stem cells through a series of precursor stages during which they rearrange their immunoglobulin genes to generate a wide range of unique antigen-binding specificities and emigrate as immature CD20+ B cells expressing surface IgM/IgD into the peripheral blood and differentiate through a series of maturational or transitional cell stages into mature naive B cells. These cells can migrate between blood and secondary lymphoid organs, able to reaction to the combination of specific B-cell-receptor stimulation and T-cell help. A summary of B-cell subsets and origins are shown in Table 50.1.

T-cell-dependent B-cell activation

After encountering their cognate antigen and receiving T-cell help in follicles in secondary lymphoid organs, B cells undergo germinal centre (GC) reactions, during which antigen-specific B cells clonally expand, somatically mutate their Ig genes to achieve avidity maturation, undergo Ig heavy-chain class switch recombination, and mature either into memory B cells or Ig-secreting plasma cells. Because of somatic hypermutation and class switch recombination, the avidity of the B-cell immunglobulin receptor can be increased and the biological function of secreted Ig altered. Important for the interaction with T cells and the generation of GC reactions are a series of ligand–receptor interactions, including those mediated by CD154/CD40 CD28/CD80-CD86, and ICOS-L/ICOS. Defects in these interactions have been shown to lead to hyper-IgM syndrome, resulting in impaired plasma cell and memory B-cell generation and adult onset of common variable hypogammaglobulinemia, respectively.[9] Some B cells can respond to specific antigens in a T-cell-independent manner (TI responses). TI responses largely induce production of IgM antibodies and do not generate post-switch memory B cells. In the mouse, these responses are thought to be restricted to CD1d+/IgM^{high} marginal zone B cells residing in the spleen which recognize polysaccharide antigens.

In addition, B cells are characteristically divided into two major lineages, B1 cells and B2 cells. It is still a matter of debate whether
Fig. 50.1 A schematic of B-cell development. B1 and B2 cell lineages seem to be independently regulated and undergo tightly controlled developmental processes. (a) B1 cells develop from haematopoietic stem cells (HSCs) in the bone marrow or fetal liver, are self-renewing, and produce natural antibodies involved in self-defence. (b) B2 cells develop from HSCs in the bone marrow. Following rearrangement of their B-cell-receptor chain genes and removal of autoreactive cells via central tolerance, immature (transitional) B2 cells relocate to the spleen. Those immature B2 cells that escape the processes of peripheral tolerance differentiate into MZ B cells or mature follicular B2 cells, which upon T-cell-dependent activation develop into long-lived plasma cells or memory B cells. B1 cells and MZ B cells are thought to be the main sources of short-lived plasma cells; the contribution of B2 cells to this population has not been delineated (as indicated by the dashed arrow). GC, germinal centre; HSC, haematopoietic stem cell; MZ, marginal zone. Dorner T, Radbruch A, Burmester GR. B-cell-directed therapies for autoimmune disease. Nature Reviews Rheumatology 2009 Aug;5(8):433–41.

Table 50.1 B-cell subsets: function and origin

B-cell subset	Function	Antibody genes	Origin	Residence	Susceptibility to superantigen-induced death	Rate of healing $(t_{1/2})^a$	Rate of decay $(t_{1/2})^b$
B1a	Natural antibodies	Often canonical without non-templated insertions	Fetal liver	Peritoneal cavity and secrete immunoglobulin in the spleen	Yes	Very slow (permanent defect?)	Very slow
B1b	Natural antibodies	Non-templated insertions ± mutations	Perinatal liver and bone marrow	Peritoneal cavity and secrete immunoglobulin in the spleen	Yes	Unknown	Unknown
Marginal zone	Anti-polysaccharide	Less common mutations	Adult bone marrow	Along the marginal sinus	Yes (early)	21 weeks	Very slow
B2 (follicular)	Protein (conventional)	Hypermutated non-templated insertions and diverse heavy-chain CDR3	Adult bone marrow	Recirculating, spleen, blood and lymph nodes	Yes (late)	13 weeks	18 weeks

[a]Rate of healing refers to studies that evaluated the time taken to replace clones in vivo after B cells were deleted by B-cell superantigen, $t_{1/2}$ represents the time taken to replace or replenish half of the affected pool.
[b]Rate of decay refers to studies in adult mice in which the capacity to generate new antibody gene rearrangements in B-cell precursors was blocked, which prevented new B cells from entering and replenishing peripheral mature B-cell compartments. These studies characterized the normal turnover of these populations when unaffected by specific challenge. CDR, complementarity-determining regions.
According to Silverman GJ, Goodyear CS. Confounding B-cell defences: lessons from a staphylococcal superantigen. *Nat Rev Immunol* 2006;6:465–475.

B1 and B2 cells are similar in mice and humans.[10] In particular, the expression of CD5 used as a marker of these cells in mice is not reliable in humans since the molecule is expressed during B-cell activation and B-cell maturation.[11] B1 cells are considered to be self-renewing and long-lived, emerging early in development, and residing in the peritoneal and pleural cavities. In mice, B1 cells produce polyreactive IgM antibodies. The natural autoantibodies produced by B1 cells are important in the clearance of apoptotic

material, senescent red blood cells and other cellular and subcellular debris. In mice the subset of B1 cells has therefore been considered to be a bridge between innate with adaptive immunity.

B2 cells or conventional B cells comprise the adaptive portion of humoral immune responses. B2 cells participate preferentially in GC reactions, during which they can hypermutate their IgV gene rearrangements, switch Ig classes, and differentiate into memory cells and long-lived plasma cells. However, B2 cells can also be activated during TI responses. B2 cells are generated in the bone marrow where there are checkpoints for removal of autoreactive cells (central tolerance). The immature survivors with functional B-cell receptors leave the marrow where they are thought to be exposed to further negative selection to remove residual autoreactive clones (peripheral tolerance). Although it has not been delineated for humans, in mice, cells at this point are routed into either a mature follicular B cell or a marginal zone B cell (MZ-B) programme.[12] Follicular B cells traffic throughout the secondary lymphoid organs, whereas MZ-B cells are specialized to reside in a compartment in the spleen that samples the bloodstream for pathogens. Both B1 and MZ-B cells are key parts of the adaptive immune system that can be activated rapidly and respond immediately to pathogens in the blood as well as the peritoneal and pleural cavities.[13] Both their responses occur independent of T-cell help and they are thought to be excluded from undergoing GC reactions and undergo Ig switch recombination and somatic hypermutation poorly and do not generate long-lived plasma cells or B-cell memory. In contrast, B2 cells respond to TD antigens, participate in GC responses, undergo extensive class switch recombination and somatic hypermutation, and generate long-lived plasma cells and memory B cells.

Fine regulation of the immune system via inhibitory and activating receptors

In this context, innate immune cells such as monocytes, macrophages, immature DCs, mast cells and neutrophils constitutively express activating and inhibitory Fc receptors that contribute to a finely balanced innate immune response.[14,15] By contrast, T cells upregulate inhibitory receptors (PD-1, CTLA-4 etc.) after activation via antigen-presenting cells (APC).[16] Finally, B cells also express constitutively inhibitory (ICOS-L, FcRIIb, CD22) and activating receptors (FcRIIa, FcRIII, BCR). Although it remains to be further elucidated and translated into clinical application, B cells share a number of receptors expressed by cells of the innate immune system (including TLR, NLR, FcRIIb) and regulatory processes and therefore could be considered as a part of both the innate and adaptive immune systems.[17] This is notable, since at the same time they represent cells with a very sophisticated surface immunoglobulin receptor with the unique capacity to recognize the universe of antigens, including (1) three-dimensional structures and (2) post-translationally modified self-proteins such as glycoproteins and polysaccharides.[13]

Role of GC-dependent B-cell activation

Naive follicular B cells encounter antigens in the secondary lymphoid organs and, after receiving T-cell help, undergo proliferation and differentiation either into plasmablasts, plasma cells, or memory B cells.[18] Newly generated plasma cells emerge after 2–3 days, providing immediate responses to a pathogen[19] which can be detected between days 6–8 in peripheral blood of humans after secondary vaccination.[20] In mice, the initial immune response

resulting in activation of antigen-specific B cells, local expansion, and the generation of short-lived plasma cells represents the extrafollicular immune response since the B cells involved migrate from the T cell–B cell interface through the bridging channels into the extrafollicular red pulp of the spleen. Subsequently in the T-cell-dependent (TD) immune response, activated B cells migrate into the B-cell follicle where a well-organized structure or 'immune unit', called a GC, is formed.[21] Establishment of these structures requires a number of precisely timed, fine-tuned cellular and humoral processes, including the action of T-follicular helper cells producing IL-21, the production of chemokines such as CXCL13, and the availability of follicular dendritic cells and antigen-specific T cells. In this regard, provision of CXCL13 by stroma cells and interaction with CXCR5 expressed by B cells and follicular helper T cells are important signals to navigate B cells into GCs where they can undergo clonal expansion and differentiation. These processes do not appear to be restricted to classical lymphoid organs and are also active in ectopic GCs, as shown for the role of CXCL13 for the RA synovium.[18,22] Once established, lymphotoxin β produced by B cells is involved in the differentiation of follicular dendritic cells into secondary lymphoid organs and the organization of an effective lymphoid architecture.

Role of B cells in animal arthritis models

B cells can function as APCs, as has been demonstrated by instructive data from animal models[23] in which a lupus-like disease developed when autoimmune-prone mice were reconstituted with B cells that lacked the ability to secrete Ig but not when they were deprived of B cells completely. Although these studies were performed in a murine lupus model, it provided data on antigen presentation by B cells.

The K/BxN model has raised particular interest for the potential role of humoral immunity in the development of arthritis.[24] In this model, spontaneous arthritis occurs in mice that express both the transgene-encoded KRN T-cell receptor and the IAg[7] MHC class II allele. The transgenic T cells have specificity for glucose-6-phosphate isomerase (G6PI) and are able to break tolerance in the B-cell compartment, resulting in the production of autoantibodies to G6PI. Affinity-purified anti-G6PI Ig from these mice can transfer joint specific inflammation to healthy recipient mice. G6PI bound to the surface of cartilage is the target for anti-G6PI binding and subsequent complement-mediated damage. However, analyses of anti-G6PI antibodies in the serum of RA patients indicate that these autoantibodies apparently do not play a significant role and confirm clearly the limitations of animal data for understanding the details of human disease.

Further involvement of B-cell activation has also been shown for antibody-mediated arthritis by coligation of TLR with the B-cell receptor (BCR) in collagen-induced arthritis with inflammatory joint destruction and CpG-induced TLR9 and BCR activation in adjuvant-induced arthritis.[25] Another model[26] was able to demonstrate the importance of antibodies against citrullinated α- and β-fibrinogen, providing additional evidence for the role of B cells and autoreactive Ig in inducing and maintaining arthritis. However, an additional murine model in which nominal antigen-expressing transgenic mice crossed to a specific T-cell receptor (TCR) developed inflammatory arthritis showed no role for B cells, in that arthritis developed when B cells were genetically absent.[27]

Role of B cells in rheumatoid arthritis

B cells are directly and indirectly involved in the regulation of certain parts of immune activation in RA. They can ultimately differentiate into antibody-producing cells known to produce IgM-rheumatoid factor (IgM-RF) and IgG-anti-CCP antibodies (ACPA) in 60–80% of patients. Higher RF and ACPA levels in synovial fluid vs serum, direct production of autoantibodies by cultured synovial organ cultures,[28] and differentiation of B cells into autoreactive plasma cells indicate that they are locally produced. Ig secretion within the synovium also results in local formation of immune complexes and activation of the complement cascade and the coagulation system with local production of anaphylatoxins and fibrin generation and induction of antibodies against citrullinated fibrin, but apparently requires a genetic predisposition of HLA-DR4 and PADI4,[29] each of which can contribute and amplify local inflammation.

Autoantibodies such IgM-RF and ACPA are the autoantibodies most frequently found in patients with RA and RF. Quantitative expression of these autoantibodies has been considered in the revised classification criteria of RA,[30] reflecting that production of autoantibodies ('humoral imprinting')[31] is associated with severe forms of RA. This emphasizes the role of the activated B-cell system in those patients.

Autoantibodies are usually taken as an indication of the breakdown of immune tolerance. The mechanisms of breaking immune tolerance are very complex, since IgM-RF usually occurs nonspecifically in many active inflammatory diseases and is associated with ageing, and therefore may have a quantitative threshold. ACPA are almost exclusively induced in patients with RA, although citrullination occurs non-specifically in many inflamed tissues,[32] and may therefore represent a qualitative biomarker of disease specific B-cell activation. Importantly, ACPA is directed against a surrogate autoantigen, being a cyclic ring of citrullinated amino acid residues that provides cross-reactivity to citrullinated antigens expressed in inflamed tissues. With regard to the citrullinated antigens expressed in inflamed sites, a central question is whether these are autoantigens or neoantigens that are widely expressed and to which there is no natural tolerance.

It remains unclear whether IgM-RF and IgG ACPA are generated using different forms of T-cell help. Moreover, RA patients also produce IgG-RF and IgA-RF which require class switch and likely are produced from progeny of B2 cells after costimulation by T cells. A substantial number of IgM-RF carries V_H gene rearrangements in germline configuration, which can frequently be found in lymphomas. By contrast, RA-associated RFs usually have somatically mutated V_H gene rearrangements and probably have developed using T-cell help. It is interesting to note that the production of ACPA is linked to the shared epitope of HLA-DR4 and PADI4 alleles, indicating that these autoantibodies are related to a defined MHC class II antigen in European patients.[32,33] Notably, this has not been found in patients in the United States.[34]

Induction of rheumatoid arthritis specific autoantibodies before the onset of disease

RF and/or anti-CCP can be found in about 50–70% of RA patients as much as 6–10 years before the onset of the clinical disease, indicating that the breakdown of immune tolerance in the B-cell system can be a very early step in disease pathogenesis.[35,36]

Seropositivity and diagnostic/therapeutic considerations

In addition to having a poorer prognosis and a greater tendency for erosive disease, it is interesting to note that patients who are positive for IgM-RF and ACPA-IgG have a two- to threefold higher likelihood to respond to B-cell depletion compared to seronegative RA patients.[3] The titre of IgM-RF decreases in about one-third of RA patients treated with B-cell-depleting therapy,[3] over varying time periods. ACPA also decreases with B-cell-depleting therapy,[37] suggesting that a portion of these specific autoantibodies derives from antibody-secreting cells that express CD20 on their surface directly or those plasma cells that require continuous replenishment from CD20+ B cells. It is likely that this subset of antibody-secreting cells is sensitive to a variety of other therapeutic agents, since glucocorticoids, methotrexate, gold,[31] and TNF blockers as well as abatacept have also been reported to reduce autoantibody levels.

Immunopathogenic functions of B cells potentially important in rheumatoid arthritis patients

Antigen presentation

Another important function of B cells is antigen presentation. This activity is especially expressed by memory B cells, and is facilitated by expression of high-avidity BCR and also MHC class II molecules on their surface.[38,39] Despite the efficiency of antigen uptake, memory B cells appear to be most effective at presenting antigen and stimulating memory T cells, whereas dendritic cells are the preferred APCs for initiating responses of naive T cells.

Antigen presentation mediated by MHC class II can be performed by cognate B cells after receiving help by autoreactive T cells that in turn have been activated by mature DCs. Thus, antigen presentation by B cells, in particular by memory B cells, may be important in the amplification and maintenance of autoimmunity after it has been initiated. In this context, enlarged pools of memory B cells have been found in RA patients,[40] and delayed repopulation of pre- and post-switched memory B cells was associated with long-term response after treatment with rituximab.[41] Since normalization of memory B-cell frequencies has also been observed under successful TNF blockade[42,43] and IL-6R inhibition,[44] this subpopulation appears to be an important amplifier of RA immunopathogenesis.

Production of proinflammatory cytokines

B cells also produce proinflammatory cytokines, such as TNF and interleukin (IL)-6, and immunoregulatory cytokines, such as IL-10. The cytokines produced by activated B cells may influence the function of antigen-presenting DCs.[17] Proinflammatory cytokines, such as TNF and IL-6, may activate macrophages, amplifying the proinflammatory signal and resulting in enhanced levels of IL-1, IL-6, and additional TNF. Although IL-6 itself is an important cytokine for B-cell growth, BAFF produced by synovial fibroblasts and regulated by TNF and IFNγ also can maintain RA synovial B cells.[45] Another important cytokine produced by B cells is IL-10, which is able to activate DCs to be more effective APCs, and with the help of T cells, to enhance the differentiation of B cells into plasma cells. The extent to which cytokines produced by B cells contribute to certain steps in immune activation in general, as well as for RA in particular, is unknown.

In addition, B cells are indirectly involved in the production of cytokines, as indicated by the loss of Th17 cells after rituximab treatment.[46] Moreover, there is a close interrelationship between B

cells and bone cells. B cells differentiate from haematopoietic stem cells in defined niches of endosteal bone areas where osteoblasts support haematopoietic stem cells (HSC) and B-cell differentiation.[47] A series of transcription factors regulates B-cell differentiation residing in these niches, and the same transcription factors appear also to be involved in maintenance of the bone phenotype based on relationships between macrophage/osteoclast and B cell differentiation. Notably, an important factor connecting B cells and bone cells is the RANKL-RANK system, with a reciprocal effect on their differentiation. It has been found that activated B cells exert a number of bony changes based on their inflammatory roles and therefore at least appear to be involved in radiographic progression in RA.

Dendritic cell differentiation and organization of the lymphatic architecture

B cells also regulate follicular DC differentiation and the organization of the lymphatic architecture. Mice that lack B cells do not develop antigen-presenting M cells in the gut. B cells are also involved in the regulation of T-cell activation, anergy, differentiation, and the expansion of T cells. B cells play an important role in T-cell activation. In humans, this conclusion is supported by recent studies in patients with systemic lupus erythematosus (SLE) that demonstrated a deactivation of T cells after selective B-cell depletion,[48] but it has not yet been shown for RA patients. However, data from experiments in which synovial tissue was transplanted into *scid*/NOD mice[49] showed that B-cell depletion by rituximab caused a substantial downregulation of T-cell activation and reduction in IFNγ occurred. These data suggest that synovial B cells are necessary for T-cell activation.

Formation of ectopic germinal centre

It is known that memory B cells and plasma cells reside in the RA synovium[50] in proximity to ectopic GCs in the affected tissue. Aggregates of CD20+ B cells have been identified in synovial tissue in about one-third of patients with RA,[50] surrounded by T cells and follicular dendritic cells (FDCs) within these GC-like structures. The role of these FDCs has not been intensively studied in the RA synovium. Specifically, it is not known whether they have the full capacity to select antigen-reactive cells appropriately as in typical GCs. Notably, ectopic GCs are detectable in only about 25–35% of RA patients, whereas there is only moderate infiltration or even slight infiltration in the remaining patients.[51] These aggregates have been found in a variety of autoimmune conditions, although it remains to be shown if these structures alone can drive autoimmunity independent of classic GCs. Although it cannot be formally excluded that synovial B and plasma cells have migrated into the site of inflammation, the presence of these cells in RA synovium likely reflects local generation in ectopic GC. Whereas higher RF levels in the synovial fluid than in blood argue for the primary role of GCs in the synovial membrane, detection of various clones of plasma cells and even the presence of anti-tetanus specific plasma
Fig. 50.2 Targets of anti-CD20 antibody therapy. Interactions between APCs and T cells are important during activation of the adaptive immune system, which leads to activation of B2 cells; the resultant memory B cells (reactive memory) and plasma cells (humoral memory) are long-lived and persist independent of the presence of antigen. Anti-CD20 antibody therapy leads to depletion of CD20+ B cells, which thereby affects memory B cells and blocks the generation of short-lived plasma cells (as highlighted by the shading in this figure). ANCA, antineutrophil cytoplasmic antibodies; APC, antigen-presenting cell; CR, complement receptor; dsDNA, double-stranded DNA; FcR, Fc receptor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; IFN, interferon; RF, rheumatoid factor; Th1, type 1 T helper cell; TLR, Toll-like receptor. cells after systemic tetanus vaccination[52] suggest that the synovial membrane may be a site of immigration of at least some plasma cells after egress from a distant site of induction, possibly the lymph nodes. Available data indicate that the formation of ectopic GCs in the RA synovium is a typical but not an essential finding of autoimmunity. One possibility is that they represent exaggerated local immune reactions, but whether the presence of these structures correlates with disease activity is not known.

Mechanisms of T-cell-independent B-cell activation and B-cell survival factors in rheumatoid arthritis

BAFF/BLyS and possibly APRIL (a proliferation-inducing ligand) which belong to the TNF family caused increased survival of most B-cell subsets as well as plasma cells. Enhanced BAFF levels could contribute to prolonged survival of autoreactive cells which otherwise would be deleted. BAFF/BLyS and APRIL, therefore, may lead to a vicious cycle of continuous antibody-mediated inflammation and tissue destruction. Fibroblast-like synoviocytes of mesenchymal origin express functional BAFF/BLyS in response to proinflammatory cytokines (TNF, IFNγ) in the synovium of patients with RA.[45] Notably, however, BAFF transgenic mice[53] develop autoimmunity, including Sjögren's-like disease, but they do not develop arthritis. BAFF/BLyS levels in autoimmune diseases, such as Sjögren's syndrome, SLE, and RA were found to be significantly increased and BAFF/BLyS levels in the RA synovial fluid are higher than in the blood.[54] Whether this increase reflects the degree of inflammation or is a primary factor in disease pathogenesis, especially in RA, is not known.

Studies blocking BAFF/BLyS alone or together with APRIL[55] in patients with RA did not show a major differentiation from placebo as with other cytokine blocking agents. Despite this, the degree to which BAFF is involved in activation or survival of certain B-cell subsets, and whether these mechanisms are operative in RA patients, is currently not clear.

Targeting B cells in rheumatoid arthritis

Recent data show that targeting B cells by depleting these cells using an anti-CD20 antibody, rituximab, provides an effective therapy with a safety profile comparable to other biologic agents. Interestingly, the ACR20, 50 and 70 response rates when rituximab was used in combination with methotrexate were very similar to those observed with other biologics, such as those directed toward TNF, IL-1, and IL-6 receptor blockade. In contrast, blocking BAFF/BLyS with the humanized antibody belimumab, as well as blocking BLys/APRIL by atacicept, did not show substantial improvements in clinical studies of RA patients. Other studies are under way, exploring whether other anti-CD20 antibodies, such as TRU015, ofatumumab, blockers of costimulation through CD80/86 by RhuDex, and inhibiting BAFF/BLys are effective and safe in RA treatment.[31]

The broadest data set of B-cell-directed therapy is currently available for rituximab (Figure 50.2). This antibody depletes CD20+ B cells by ADCC, CDC, and possibly apoptosis mechanisms and therefore does not target CD20 pro B cells and subsets of CD20 human plasma cells. With regard to apoptosis, it is notably that it occurs in vitro after binding to CD20, a molecule with a hitherto unknown function. On the other hand, anti-CD20 effects are inhibited in FcR KO mice,[56] which suggests that the 'workhorse' of rituximab is probably ADCC.

Repletion of B cells occurs within 6–8 months, although there is a trend that subsequent courses lead to longer-lasting periods of B-cell depletion, i.e. an increase from 7.5 months after the first cycle to 8.1 months after the second cycle of treatment.[41] Repletion of CD20+ B cells is also characterized by modulation of B-cell subsets with a preferential recurrence of naive B cells and a delay in the recurrence of memory B cells. In particular, the reduction of memory B cells is very striking and may reflect a 'resetting' of the immune system similar to that observed after autologous stem cell transplantation in SLE. It has also been reported that early recurrence of CD27+ memory B cells was associated with a significantly higher likelihood of an early RA flare as compared to patients maintaining predominantly naive B cells.[41] Constant production of IgA plasmablasts during peripheral B-cell depletion has been identified,[57] indicating that their precursors, which likely reside in the lamina propria, are resistant to RTX depletion.

One concern about B-cell depletion has been the consequence of depletion on protective antibody titres. There are a number of reports that have shown that anti-tetanus and anti-pneumococcus antibody titres remain stable although primary responses to pneumococcus are diminished,[37] whereas there is a decline in IgM-RF along with IgG ACPA with rituximab therapy. The difference between the protective antibody titres versus autoantibody titres is very striking. One explanation could be that the responsible plasma cell subsets are different in terms of their half-life, survival conditions, their ability to be mobilized, or their CD20 expression density.

An important consideration not only restricted to anti-CD20 therapy involves appropriate vaccination as recommended.[58,59] Patients with RA receiving rituximab have been investigated for their response to vaccination in two studies.[60,61] Any patient considered for rituximab therapy should receive all indicated vaccines (hepatitis B for at-risk population, pneumococcus, tetanus toxoid every 10 years, influenza annually) before treatment.

In one study,[37] an increase of the autoantibodies was seen before the recurrence of active RA. However, it should be noted that the declines in IgM-RF titres were initially very similar in the control group (methotrexate alone) and the patients treated with rituximab (in combination with methotrexate) likely because of the use of high-dose steroids in the first 17 days,[62] but this decrease was more long lasting and progressively greater in the latter group. The apparent effect of B-cell depletion and methotrexate on RF titres became also apparent in that patients treated with the combination of rituximab and methotrexate compared to rituximab alone[62] had substantially longer periods of RF reduction. This confirms the complexity of RA and indicates the need for effective combination therapy.

CHAPTER 51

Fibroblasts and mesenchymal cells

Andrew Filer, Maria Juarez, and Christopher Buckley

Introduction

Mesenchymal cell precursors, i.e. mesenchymal stem cells (MSC) or mesenchymal progenitor cells (MPC), are spindle-shaped cells connected to other cells in three-dimensional matrices. Mesenchymal precursor cells are able to differentiate into tissue fibroblasts, and also osteoblasts, adipocytes, chondroblasts, or myoblasts, a property termed pluripotentiality. In embryological development MSC migrate regionally, giving rise to specific tissues. The recognition that MSC and fibroblasts share morphological and functional features (including pluripotentiality) has led to the suggestion that they may indeed be the same cell type. Indeed the current definition of MSC suggested by the International Society of Cellular Therapy is incapable of distinguishing such cells from generic fibroblasts (for review see Uccelli et al.[1]).

Origin of fibroblasts

In this chapter we concentrate on the fibroblast as the prototype stromal cell. However, the stroma also consists of blood and lymphatic vessels and a wider definition of stromal cells might include endothelial cells, pericytes, and even tissue resident macrophages.

Origin in tissues

The question of the local origin of fibroblasts is an important one. Both inflammation and wound healing are characterized by formation of new tissue. There is growing evidence that fibroblasts exist as subsets of cells, often with different functions. Novel markers have recently been identified that start to demarcate such subsets with distinct functional roles.

Upon appropriate stimulation, fibroblasts can proliferate locally to regenerate new cells. However, fibroblasts may arise from other sources (Figure 51.1). The first of these is local epithelial–mesenchymal transition (EMT): upon epithelial stress such as inflammation or injury, epithelial cells lose polarity, and rearrange their F-actin fibres, transforming into mobile mesenchymal cells.

Secondly, recent research has confirmed the presence of circulating cells of a mesenchymal phenotype. These cells bear a remarkable resemblance to the synovial fibroblasts isolated from the joints of patients with rheumatoid arthritis (RA), which accumulate in enormous quantities in the inflamed joint despite little evidence of proliferation. Interestingly, Marinova-Mutafchieva and colleagues have shown that an influx of such cells precedes inflammation in a collagen-induced mouse arthritis model, suggesting a role for blood-borne stromal cell precursors in the initiation of inflammatory diseases.[2] Another circulating precursor that could account for accumulation of fibroblasts in disease is the fibrocyte. Fibrocytes elaborate matrix once in tissue, but arise from the CD14+ (monocyte) fraction in peripheral blood, and have been shown to rapidly enter sites of tissue injury and contribute to tissue remodelling in models of inflammatory lung disease.[3]

Fibroblast identity and microenvironments

Until recently, fibroblasts had been thought of as generic cells with a common phenotype. However, there is now evidence that fibroblasts from different organs have unique morphology and unique repertoires of extracellular matrix (ECM) proteins, cytokines, and chemokines. Transcriptional profiling of human fibroblasts has shown large-scale differences related to three anatomical divisions: anterior–posterior, proximal–distal, and dermal–non-dermal.[4] Recent evidence confirms epigenetic changes as effectors of these differing phenotypes. Epigenetic changes are hereditable changes in gene expression that do not result from alteration of the underlying DNA sequence.[5] They are 'switches' that control gene expression determining whether a particular gene is expressed ('on') or not ('off'). In healthy fibroblasts, expression of a non-coding RNA (termed HOTAIR) residing in the *HOXC* locus results in silencing of genes in the *HOXD* locus that are responsible for positional identity. This provides proof of epigenetic control of site-specific gene expression in fibroblasts. However there is now increasing evidence for epigenetic regulation of disease phenotypes in many cells, including fibroblasts.
Fig. 51.1 In response to persistent inflammation, increased numbers of fibroblasts accumulate within tissues: (1) Fibroblasts may proliferate locally to regenerate new cells. (2) Epithelial–mesenchymal transition: following stress, epithelial cells lose polarity and rearrange F-actin fibres transforming into mobile mesenchymal cells. (3) Blood-borne mesenchymal precursor cells may be recruited to tissues and undergo local differentiation to fibroblasts. Fibrocytes arise from the monocyte fraction of blood and then differentiate into fibroblasts within tissues.

Fibroblasts in physiology

Production, interaction, and degradation of extracellular matrix

Ensuring ECM homeostasis is one of the primary functions of fibroblasts. To fulfil this role, fibroblasts are able to produce and degrade ECM, as well as adhering to and interacting with ECM components.

Production of extracellular matrix

Fibroblasts produce a number of ECM molecules that are assembled into a 3-dimensional network. This provides a framework through which other cell types can move, a substrate for the deposition of haptotactic chemokine gradients, and stores of growth factors to direct cellular movement and behaviour in a regional fashion.[6] ECM molecular repertoires differ between tissues, reflecting fibroblast diversity. For example, dermal fibroblasts produce significant amounts of type VII collagen while fibroblasts in lung and kidney produce mainly interstitial, fibrillar collagens (types I and III).

Interaction with extracellular matrix

Integrins are key mediators of cell–matrix and cell–cell adhesive interactions. They are the main family of adhesion molecules responsible for the attachment of fibroblasts to collagen, fibronectin and vitronectin. Syndecans allow interaction with a large variety of ligands including fibroblast growth factors, vascular endothelial growth factor (VEGF), transforming growth factor beta (TGFβ), and ECM molecules such as fibronectin.

Degradation of extracellular matrix

Remodelling of the ECM requires fibroblasts to express an extensive repertoire of matrix-degrading enzymes with varying specificity.

These are crucial to tissue maintenance and repair, but inappropriate overexpression can result in joint damage in arthritis. Such enzymes fall into a number of families including matrix metalloproteinases (MMPs), tissue inhibitors of metalloproteinases (TIMPs), cathepsins, and aggrecanases. With the exception of MMP-2 and the membrane-type MMPs (MT-MMPs) which are constitutively expressed, MMP expression is regulated by extracellular signals via transcriptional activation in fibroblasts. The major groups of inducers are proinflammatory cytokines such as interleukin (IL)-1, growth factors such as fibroblast growth factor (FGF) and platelet-derived growth factor (PDGF), and matrix molecules including collagen, fibronectin, and their degradation products.[7]

Wound healing and tissue repair

Tissue injury and wound healing are accompanied by changes in the ECM, serum exposure, mechanical stress. and inflammation. These stimuli activate fibroblasts to become myofibroblasts, with expression of smooth muscle actin and secretion of high levels of ECM proteases (e.g. MMP2, MMP3, and MMP4), leading to increased ECM turnover and modified ECM composition. Growth factors (e.g. hepatocyte growth factor, FGF) that induce proliferative signals within adjacent epithelial cells are also secreted. Myofibroblasts proliferate more than their normal counterparts, but once the wound is repaired their number decreases and the resting phenotype is restored. However, evidence is accumulating that in fibrosis and cancer, fibroblasts abnormally maintain a myofibroblast phenotype resulting in organ damage, with underlying epigenetic changes driving persistence.[8]

Fibroblasts in immunity

Fibroblasts are capable of elaborating a broad repertoire of inflammatory mediators, which fully justifies their classification as

immune sentinel cells. Through expression of Toll-like receptors (TLR) 2, 3, and 4, fibroblasts respond to bacterial products such as lipopolysaccharide (LPS) by activating the classical NFκB and AP-1 inflammatory pathways, generating chemokines capable of recruiting inflammatory cells, and MMPs capable of degrading matrix. Furthermore, fibroblasts are capable of bridging innate and adaptive immune responses through expression of the molecule CD40. Engagement of CD40 by its ligand CD40L expressed on a restricted population of immune cells including activated T lymphocytes is critical for the further induction of proinflammatory cytokines and chemokines from fibroblasts during an immune response.

Fibroblast-like synoviocytes in normal synovium

The normal synovium provides an excellent example of fibroblast heterogeneity within tissues. In health, the synovium is a thin structure divided into two layers: the lining and the sublining. The lining layer is a 1–2 cell thick layer formed in roughly equal proportions of CD68+ type A macrophage-like synoviocytes and type B mesenchymal, fibroblast-like synoviocytes. The sublining layer is composed of less densely packed fibroblasts and macrophages in a loose tissue matrix along with blood vessel networks. Fibroblasts of the lining layer express a number of cellular markers, including CD55 (decay accelerating factor, DAF), (vascular cell adhesion molecule-1 (VCAM-1), uridine diphosphoglucose dehydrogenase (UDPGD), and the novel marker GP38 (also expressed in sublining lymphatic cells and pericytes). Sublining fibroblasts express the non-specific cellular marker CD90 (also expressed by endothelial cells) and the recently discovered marker CD248 (also expressed by pericytes). Fibroblasts of the lining layer subserve a barrier function that is unsupported by a basement membrane, conventional tight junctions or desmosomes; instead, the strong homophilic/homotypic adhesion between synoviocytes is mediated by cadherin-11.[9]

Fibroblasts in rheumatoid arthritis

Persistence of inflammation within joints is a hallmark feature of RA. Although it is recognized that in RA persistent inflammation results from complex interactions between haematopoietic and stromal cells, research into the pathogenesis of the disease has traditionally concentrated on cells and cytokines of the immune system, neglecting the role of stromal cells. As a consequence, biological treatments have been developed that have led to a step-change in the management of the disease. Nevertheless, these treatments neither reverse tissue damage nor lead to disease cure. At best they induce a significant clinical response (ACR70) in less than 60% of patients, most of whom will relapse on treatment withdrawal, suggesting that additional therapeutic targets, responsible for persistence of inflammation, remain to be discovered. An increasing body of evidence implicates RA synovial fibroblasts in driving the persistent and destructive characteristics of the disease.

RA synovial fibroblasts exhibit a persistent, activated phenotype that is maintained in the absence of exogenous stimulation and remains stable even after multiple passages in vitro. Activated RA synovial fibroblasts (RASFs) play crucial roles in determining the site at which inflammation occurs, and in the subsequent maintenance of persistent inflammation, and are key mediators of cartilage and bone destruction.

Fibroblasts and the switch to persistent disease

In order for an inflammatory lesion to resolve, dead or redundant cells that were recruited and expanded during the active phases of the response must be removed. The 'switch to resolution' is an important signal that permits tissue repair to take place and enables immune cells to return to draining lymphoid nodes in order for immunological memory to become established. However, in RA, fibroblasts become persistently activated, leading to tissue-specific initiation and subsequent relapse of chronic persistent inflammatory disease; effectively a 'switch to persistence'.

The synovial microenvironment in rheumatoid arthritis

In RA, the synovium undergoes radical change. The lining layer undergoes dramatic hyperplasia, becoming a mass of 'pannus' tissue rich in fibroblasts, macrophages, and osteoclasts, which aggressively invades the adjacent articular cartilage and subchondral bone. The sublining layer also undergoes expansion, with huge infiltrates of inflammatory cells (macrophages, T and B cells, mast cells, plasma cells and dendritic cells). T and B lineage cells may remain in diffuse infiltrates, or may coalesce into aggregates of cells varying from simple perivascular 'cuffs' to structures resembling B-cell follicles in up to 20% of samples (tertiary lymphoid structures).[10] In this abnormal microenvironment, activated RASFs actively maintain chronic inflammation by distorting the homeostatic balance between leukocyte recruitment, proliferation, emigration, and death (Figure 51.2).

Recruitment of inflammatory infiltrates into the joint

Activated RASFs produce inflammatory chemokines implicated in leukocyte recruitment to diseased synovium. Neutrophil attracting chemokines are expressed at high levels by stimulated fibroblasts and include CXCL8 (IL-8), CXCL5, and CXCL1.[11] Monocytes and T cells are recruited by a range of chemokines found at high levels in the synovium; CXCL10 and CXCL9 are highly expressed in synovial tissue and fluid. CXCL16 is also highly expressed in the RA synovium and acts as a potent chemoattractant for T cells. CCL2 is found in synovial fluid and known to be produced by synovial fibroblasts; it is considered to be a pivotal chemokine for the recruitment of monocytes. CCL3, CCL4, and CCL5 (RANTES) are chemotactic for monocytes and lymphocytes, and are products of synovial fibroblasts. CX3CL1 (Fractalkine) is also widely expressed in the rheumatoid synovium. The expression of some chemokine receptors differs between peripheral blood and synovial leucocytes, suggesting enrichment in the synovium either through selective recruitment by chemokines, or following upregulation by the microenvironment after recruitment.

Fibroblast support for leucocyte survival

In RA the resolution phase of inflammation becomes disordered.[12] Failure of synovial T cells to undergo apoptosis contributes to the persistence of the inflammatory infiltrate. Type I interferons (interferons α and β), produced by RASFs and macrophages, promote this prolonged T-cell survival in the rheumatoid joint. Similarly, fibroblast-expressed BAFF, VCAM-1, and CXCL12 promote B-cell survival.[13] Fibroblasts have also been shown to support NK cell and neutrophil survival in the synovium.[14,15]

Fibroblast-mediated leucocyte retention

Inhibition of leucocyte death by stromal cells at sites of chronic inflammation is unlikely to be the only mechanism underlying accumulation, because lymphocytes should also be able to leave
Fig. 51.2 Fibroblasts direct chronic inflammation in rheumatoid arthritis. The maintenance of persistent leukocyte infiltrates results from a distorted homeostatic balance between lymphocyte recruitment, proliferation, emigration and death. Activated RASFs produce inflammatory chemokines (CCL5, CCL2) implicated in lymphocyte recruitment to diseased synovium, survival factors (type I interferon, IL-15, BAFF) and constitutive chemokines (e.g. CXCL12, CCL21). The net result is the chronic accumulation, survival, and retention of lymphocytes at sites of disease.

inflamed tissue, even if their death is inhibited. However, constitutive chemokines that in health regulate the traffic of leucocytes are ectopically expressed by RASF. For example, the constitutive chemokine CXCL12 and its receptor CXCR4 play an important role in the recruitment and retention of haemopoietic cells within the bone marrow. Activated T lymphocytes in the RA synovium express CXCR4 receptors at abnormally high levels as a result of RASF-derived TGFβ,[16] while the ligand CXCL12 is highly expressed on endothelial cells and fibroblasts. The stability of lymphocyte infiltrates is reinforced by a positive feedback loop: tissue CXCL12 promotes CD40 ligand expression on T cells, which in turn stimulates further CXCL12 production by CD40 expressing synovial fibroblasts, further enhanced by T-cell IL-17 production.[17]

Lymphoid neogenesis

The genesis of 'tertiary' lymphoid follicular structures in RA also relies upon ectopic stromal expression of constitutive chemokines such as CCL19, CXCL13, and CCL21, in association with the lymphotoxins alpha and beta (LTα and LTβ) and tumour necrosis factor alpha (TNFα). The degree of lymphoid organization seen in the rheumatoid synovium has been shown to correlate with expression of the chemokines CCL21 and CXCL13, while transgenic mice overexpressing TNFα develop a chronic arthritis similar to RA and display increased formation of focal lymphoid aggregates.[18]

Fibroblasts and cartilage destruction

In addition to their extensive role in the perpetuation of the inflammatory response, activated RASFs are key mediators of joint damage. In the early RA joint, activated RASFs attach to and overgrow the cartilage surface, then invade and destroy cartilage and induce bone resorption. They act both directly via

secretion of multiple MMPs and cathepsins that degrade cartilage and indirectly by regulating monocyte to osteoclast differentiation resulting in bone damage. In-vitro functional assays such as the matrigel invasion assay have demonstrated that the degree of invasion with a given in-vitro cultured fibroblast sample correlates with the degree of radiographic progression seen in the joints of the patient from whose samples the fibroblasts were initially cultured.[19] Active degradation of cartilage in vivo has been elegantly demonstrated in the SCID mouse model of arthritis. Here, cultured fibroblasts with human cartilage are implanted under the kidney capsule forming a tissue construct in mice with no functioning adaptive immune response. RASFs but not normal or osteoarthritis synovial fibroblasts attach to and invade coimplanted healthy human cartilage in the absence of cells of the immune system. This experiment not only confirms that these cells have an invasive phenotype that is responsible for cartilage damage but also that such phenotype is stable after multiple in-vitro passages and disease specific.[20] This model has been used to explore the in-vivo mechanisms governing invasiveness. For instance, targeting MMP1 and cathepsin L using ribozymes was shown to inhibit cartilage destruction.

Fibroblast migration in vivo

Recently, it has been demonstrated that fibroblasts implanted in SCID mice with cartilage will migrate to a contralateral cell-free implant, and that subcutaneously, intraperitoneally, and intravenously injected fibroblasts will also migrate to sections of human cartilage, suggesting a tropism to damaged cartilage tissue.[21] This finding has significant implications for the study of synovial fibroblasts in arthritis, as the nature of systemic disease and the specific patterns of joint disease observed in different diagnostic groups (RA and psoriatic arthritis, for instance), could be partly explained by the trafficking of stromal cells around the body.

Acquisition of the RASF phenotype

One of the key questions arising from these observations is: how do RASFs become persistently activated? It has been proposed that activation could arise from molecular cross-talk between RASFs and other cells of the synovial microenvironment early in disease. Toll-like receptors have been shown to be involved in the initial stages of synovial activation.[22] It is thought that microbial components or endogenous ligands present in the RA synovium activate RASFs through TLR signalling and lead to upregulated expression of proinflammatory cytokines and chemokines which in turn cause attraction and accumulation of immune cells in the synovium and, through a stimulatory loop, lead to persistent inflammation.[23] In RA, synovial fibroblasts exhibit excessive responses to stimuli such as TLR ligands and persistently upregulate expression of adhesion molecules (VLA-3, VLA-4, VLA-5), matrix MMPs (MMP13, MT-MMP) and proto-oncogenes (c-*myc*) while displaying low expression or mutations of tumour suppressor genes (e.g. *PTEN*, *p53*).[24] These persistent changes in transcription are important contributors to their aggressive behaviour.

Epigenetic modifications have been proposed as determinants of this distinctive RASF phenotype. The most studied epigenetic modifications to date are non-coding RNA, DNA methylation, and histone modifications. RASFs display global genomic DNA hypomethylation, an epigenetic change associated with upregulation of gene expression of disease relevant genes (growth factors, adhesion molecules, and MMPs). Notably, treatment of normal synovial fibroblasts with the DNA hypomethylator 5-aza-2′-deoxycytidine resulted in their transformation into cells resembling activated RASFs.[25]

This example illustrates how the epigenetic hypothesis may not only provide a mechanistic explanation for this phenotype but also a tool to modify it. Both the addition and the removal of epigenetic modifications are enzymatically mediated processes and thus present attractive targets for future therapies in RA.[26]

Fibroblasts as therapeutic targets in cancer and arthritis

The importance of the stromal microenvironment in cancer has been recognized for some years (for review see Kalluri and Zeisberg[27]). It is now widely accepted that cancer is a disease that develops as a result of genetic and epigenetic alterations in clonal cells, but that the growth, survival, and metastasis of these cells are regulated by stromal–cancer cell interactions. Studies in human lung, breast, colon, and prostate cancer have demonstrated a key role of stromal cells—termed cancer-associated fibroblasts (CAFs)—in initiation and progression of disease. The term 'cancer stroma' has been coined to refer to macroscopic and functional differences between this and the corresponding normal tissues. Cancer stroma is characterized by a modified ECM composition, increased microvessel density, inflammatory cells, and activated fibroblasts. PDGF and TFGβ are the most important factors in the process of CAF activation.[28,29] In parallel with observations of RASFs, in-vivo studies have demonstrated persistent phenotypes in CAFs: for instance, coimplantation of prostate tumour fibroblasts (but not normal fibroblasts) with normal epithelial prostate cells leads to malignant transformation and proliferation of epithelial cells.[30] Obvious parallels can be drawn between CAFs and RASFs, leading to common therapeutic approaches.

Targeting signals responsible for activation of fibroblasts

Inhibitors of PDGF and TGFβ, which promote activation of CAFs, are being used successfully in the treatment of cancer. Imatinib inhibits tyrosine kinases including the PDGF receptor and is an effective treatment in chronic myeloid leukaemia.[31] TGFβ inhibitors are currently in development (e.g. lerdelimumab, metelimumab).[32] In RA, therapies such as anti-TNF and anti-IL-6 receptor (tocilizumab) have indirectly targeted stromal cells either by targeting cytokines impacting upon fibroblasts or by blocking their significant products respectively. These share the shortcomings of existing biologicals, inhibiting key pleiotropic proinflammatory cytokines leading to significant adverse events while on the other hand failing to address persistence of disease. Cellular MAPKinase and NFκB signalling pathways are heavily implicated in the proinflammatory and cartilage-damaging activities of synovial fibroblasts. Inhibiting such generic pathways carries significant risks of off-target effects.[33] However, imatinib shows promise as a therapy in RA that has been shown to modulate synovial fibroblast proliferation rates.[34,35]

Targeting fibroblast-expressed exoenzymes

Many cells express enzymes bound to the surface plasma membrane which have roles including receptor signalling and ECM engagement. Such enzymes can be initially targeted with antibodies as proof of concept; however, ultimately their enzymatic activity may be pharmacologically inhibited in order to provide more selective inhibition. An example of the first approach is the use a humanized monoclonal antibody (sibrotuzumab) against the fibroblast activation protein (FAP), a membrane-bound glycoprotein with serine protease activity and thus an exoenzyme. It is highly expressed in the tumour stroma and has been shown to enhance tumour growth in vivo. A phase I study using sibrotuzumab in patients with metastatic colorectal and lung cancer demonstrated repeat infusions of sibrotuzumab to be safe and well tolerated,[36] although a phase II study in metastatic colorectal cancer with less dramatic impact has now prompted further research.[37] Similarly, PBEF (visfatin) is an exoenzyme highly expressed on RASF in the lining layer of the pathological rheumatoid joint. Specific inhibitors exist to this molecule, although exploring their use in arthritis is at an early stage.[38,39] PBEF is of particular interest as part of the adipokine family. Serum and synovial fluid concentrations are closely linked to clinical disease activity, and PBEF induces proinflammatory cytokine and MMP production by RASFs in vitro.

Novel fibroblast markers

More specific targeting will result from recent discoveries of novel markers for stromal subpopulations, such as FAP. In RA, cadherin 11 is expressed by synovial fibroblasts of the lining layer. Cadherin 11 knockout mice subjected to models of inflammatory arthritis show less cartilage damage than their wild-type counterparts.[40] Although not a realistic therapeutic target, this provides proof of concept that stromal subset deletion could impact on progression of disease. Further synovial stromal markers have been identified, including the sublining marker CD248, a cell surface protein marker (endosialin) with restricted expression, and important roles in cancer progression. Maia et al. have shown that knockouts of CD248 result in amelioration of murine arthritis induced by anti-collagen antibodies, suggesting potential as a therapeutic target.[41]

Epigenetic therapies

CAFs in human gastric carcinomas have been shown to exhibit global DNA hypomethylation and, more broadly, cancerous epithelial cells are characterized on the one hand by global DNA hypomethylation that promotes chromosomal instability and activates proto-oncogenes, and on the other by regional promoter hypermethylation resulting in downregulation of tumour suppressor genes. Understanding of the molecular basis of these epigenetic mechanisms has led to the development of epigenetic therapies. The DNA methylation inhibitor 5-aza-2′-deoxycytidine is used for the treatment of myelodysplastic syndromes, acting by reversing pathological hypermethylation of the tumour suppressor gene and cell cycle regulator CDKN2B in affected cells, and also shows promise when used in combination with conventional chemotherapy.[42,43] In-vitro and in-vivo studies of the use of epigenetic therapies in arthritis have also started to emerge. Histone acetylation/deacetylation are epigenetic modifications that have a critical role in regulation of gene transcription by altering chromatin structure. Jüngel and colleagues[44] treated RASFs with the histone deacetylase inhibitor trichostatin A (TSA), resulting in inhibition of their proliferation and sensitization to TNF-related apoptosis-inducing ligand (TRAIL)-induced apoptosis. Subsequently, Nasu and colleagues[45] conducted an in-vivo study to analyse the effects of TSA treatment in the collagen antibody-induced arthritis (CAIA) mouse model leading to dose-dependent amelioration of disease. Non-coding RNA species such as microRNAs (miRs) are also becoming recognized as relatively specific controllers of aberrant gene expression and are frequently under epigenetic regulation. One such example in arthritis is miR203. This molecule is under the direct control of DNA methylation, and drives expression of IL-6 and MMP production by synovial fibroblasts.[46] These studies suggest that epigenetic therapies may become a reality for the treatment of arthritis in the near future.

Synovial pathology

Costantino Pitzalis, Frances
Humby, and Michael P. Seed

Introduction

The understanding of synovial pathology is becoming considerably more advanced through access to synovial tissues at earlier stages of disease via minimally invasive tissue microsampling and new molecular techniques. Internationally agreed recommendations have been published for the standardization of biopsy techniques for clinical trials[1]: 6–8 samples from within a joint provide data with less than 10% variance for T cells, B cells, macrophages, and activation markers, as well as a twofold difference in gene expression (via PCR). Wrist and knee joints appear comparable, though metacarpal joints may differ. Unfortunately, the availability of therapeutically naive tissues, and patient and tissue heterogeneity, continue to confound.

The synovium is made up of a surface, or lining, layer of overlapping cells. Unlike other serosal surfaces, this intimal lining lacks epithelial cells and basement membrane, and has no tight junctions (reviewed by Edwards[2]; Figure 52.1). The synovial lining layer is 2–3 cells thick and consists of type A (CD14, CD18 macrophage) and type B (uridine diphosphoglucose dehydrogenase, UDPGD-expressing fibroblast) synoviocytes. The macrophages are in the minority, with fibroblasts separating them by 100 μm. The intimal layer overlies a connective tissue stroma, termed the subintima (reviewed by Edwards and Wilkinson[3]). The subintima comprises a network of capillaries, fibroblasts, scattered macrophages, and mast cells. It is innervated, and in large joints contains adipose tissue. The lining contains collagen types III, V, and VI, tenascin, and decorin synthesized by the type B synoviocytes, in addition to hyaluronic acid via UDPGD. Synovial fluid hyaluronan permits free flow of synovium over its own folds as well as the cartilage surface. Synovitis, inflammation of the synovium, is characterized by a thickening of the synovial lining layer from two to up to six cells thick (Figure 52.1). Effusion into the joints occurs through endothelial cell gaps.

In rheumatoid arthritis (RA) this picture can be florid (Figure 52.2), as it can occasionally be with osteoarthritis (OA; see Figure 52.6 below), with neoangiogenesis and a profoundly inflamed soft tissue which develops into a granulomatous tissue of fibroblasts and macrophages invading the joint space as villous fronds, or an invasive tissue that erodes into cartilage and bone. Pannus erodes the joints by encroaching over cartilage, or under

it by eroding through subchondral bone into the medullary space, or both.[4] The tissue is innervated and is thus a significant source of the inflammatory pain experienced by RA sufferers. The cells of the sublining layer can become organized into loose or more structured aggregates termed ectopic lymphoid structures (ELS).

The initiating stimulus for the synovial response in RA remains unknown. Although circulating rheumatoid factor (RF) and/or anti-citrullinated protein antibodies (ACPA) antibodies predicts high risk for disease, synovium from these patients taken before the onset of symptoms does not show subclinical inflammation.[5] A secondary 'hit' of unknown origin, probably inflammatory,[6] is required.

Intimal lining layer

The first responses of the synovium in RA are tissue oedema and fibrin deposition.[4] As the plasma exudes and neutrophil accumulation occurs in the synovial fluid, fibrin is deposited. The synovial lining layer in RA[3] thickens with synoviocytes increasing in depth from two to up to six cells thick (Figure 52.1). Type A macrophage-like cells are derived from bone marrow,[7] and their expansion in synovitis is through cell recruitment from the circulation. Mitotic figures are thus rare, and DNA synthesis does not reflect that of a proliferative tissue. Lining-layer macrophage numbers are increased within the first 2 days of symptoms and in uninvolved joints. Their proportion increases to dominate the subintimal layer, and it becomes stratified with macrophages overlying and underlying the fibroblast-like synoviocytes (FLS). Lining-layer macrophages and FLS interact either through direct molecular interactions such as CD97/C55, or indirectly.

Matrix metalloproteinase-1 (*MMP1*) gene expression is seen within 2 weeks of diagnosis and correlates with CD68 macrophage numbers in the lining and sublining layers. The supporting matrix becomes diffuse, with collagen types II and III and tenascin being more widely distributed.

The invasive tissue originates from the synovial–cartilage junction.[8] This wedge-shaped tissue overlies the cartilage, and is contiguous with the synovium. It is vascular, containing fibroblasts and monocyte (CD14)-derived cells, and it is thought that it is this that migrates over the cartilage to form the erosive front. RA cartilage contains immune complexes, including RF complexes and

fibronectin, all of which are thought to act as a stimulus for cells to migrate and erode the cartilage. Without these, the anionic cartilage surface rejects cell adhesion and is protected from synoviocyte invasion by synovium-derived products such as lubricin, which is deficient in RA. As to which cells are involved in the erosion of cartilage at the cartilage–pannus junction (CPJ), neutrophils, macrophages, mast cells and fibroblast-like cells are all seen at different sites.

Fassbender first described the progression of FLS across the cartilage,[4,9] and they are seen to advance ahead of the pannus.[10] Macrophages follow by migrating between this cell layer and the cartilage-bound fibronectin, and erosion occurs under the macrophage zone. FLS feature prominently in pannus and joint erosion,[11] and are highly proliferative. Fassbender also first noted differences in fibroblast phenotypes in RA pannus, namely the presence of fibrocytes as well as classical fibroblasts. Fibrocytes are bone-marrow-derived myeloid cells involved in angiogenesis and tissue repair. They can function as antigen-presenting cells, or play a similar role to fibroblasts. Fibrocytes provide a role as a tissue scaffold, and are active in inflammatory cell traffic and erosion. There are subtypes, those with a myofibroblast gene pattern in inflammatory pannus and insulin type growth factor (IGF)-regulated fibroblasts in areas of low inflammation.[12] Fibroblast invasiveness *ex vivo* correlates with the rate of joint destruction, and in turn correlates with *MMP-1*, *MMP-3*, *MMP-10*, and *MMP14* expression. Indeed, the fibroblast phenotype appears to be involved in aggressive erosion. Subcutaneous implantation of RA fibroblasts in juxtaposition with RA cartilage in mice results in its erosion, and the fibroblasts can circulate to contralateral implants to form erosive aggregates.

There are two distinct forms of CPJ. Cartilage proteoglycan and chondrocyte depletion occurs under the invasive cellular form of CPJ, unlike under the quiescent or 'indistinct' CPJ (Figure 52.3).[8] These observations correlate with interleukin (IL)-1α and tumour necrosis factor alpha (TNFα)-expressing CD68 macrophages present in the invasive form and transforming growth factor beta (TGFβ) in the indistinct form. Other cells can occasionally be seen in the active cellular form, namely neutrophils, mast cells, dendritic cells, and plasma cells.[13] In mature pannus, there is a correlation between the inflammatory activity of the subintimal layer and the erosive activity of the underlying CPJ.

Synovial sublining layer

The general microscopic view of RA synovitis is one of a frank and vigorous chronic inflammatory tissue made up of monocytes, macrophages, lymphocytes (T and B cells) plasma cells, dendritic cells, and fibroblasts.

Cell recruitment is evidenced by perivascular cell aggregates, and the formation of specialized vasculature with high endothelial venule (HEV) morphology as well as new blood vessels (neo-angiogenesis) driven by high levels of vascular endothelial growth factor (VEGF) and VEGF receptors expressed in the endothelium and pericyte layers. The vessels express adhesion molecules, induced by interstitial macrophage cytokines. The tissue can develop a lymphatic system, with lymphangiogenesis. Thus not only is there active recruitment of monocytes, lymphocytes, and neutrophils, there is a chemokine imbalance between the lymphatic and blood vessel systems that results in the retention of cells once recruited, impairing lymphatic return.

The characterization of migrated cells shows distinct T-cell distribution profiles, with CD4 helper T cells accumulating in perivascular cuffs, and diffuse CD8 cytotoxic T cells. Joint disease activity and systemic inflammation correlate well with the presence of the major inflammatory cell type, the CD68 macrophage.[14,15] CD68 serves as a useful biomarker for synovial macrophages, as Toll-like receptors (TLRs) and Fc IgG receptors may vary between sites. Earlier macrophages reside in the sublining layer, and more mature macrophages are found in the synovial lining layer, suggesting recruitment of monocytes through vasculature of the sublining followed by residence in the lining. The greater the macrophage cellularity of the sublining layer, the greater the cellularity of the lining layer. In turn the degree of erosion and pain scores directly correlates with macrophage density, as opposed to T and B lymphocyte populations.[14] Plasma cells can be widely distributed as well as surrounding aggregates, while B cells, if they are present, are found within ELS aggregates. Neutrophils are sparse, but when they are seen they are seen between blood vessels and the intimal surface and assumed to be *en passant* to the synovial fluid.

Synovitis also comprises of T and B cells which can be seen in aggregates, compartmentalizing into B- and T-cell areas with macrophages and dendritic cells. Myofibroblasts are present and produce cytokines and chemokines that orchestrate the migration and
Fig. 52.2 The florid inflammatory nature of rheumatoid synovium, and the formation of ELS: (A) Normal synovium. (B) Rheumatoid picture, showing a profound diffuse inflammatory sublining with neoangiogenesis. The synovia (C–E) have been graded according to the radial cell count taken from the blood vessel to the periphery. The determination is made at the point of widest infiltration and specimens must exhibit a synovial cell lining layer in order to be properly graded. Cell aggregates with a radial cell count of 2–5 cells are classified as grade 1 (C). Grade 2 specimens have a radial count of 6–10 cells (D), while grade 3 specimens have a radial count of more than 10 cells (E). In addition, mixed infiltrates must be predominantly lymphocytic and it must be noted if there is diffuse inflammatory infiltrate present in the tissue. Analysis of over 100 samples shows there is a gradual distribution between ELS naive and highly organized structures. 47% of RA samples exhibit lymphoid structures at some stage of development.
Courtesy of Professor C. Pitzalis and Dr R. Hands, MRC PEAC Database.

positioning of lymphocytes.[16] B cells are almost wholly confined to follicular structures, which could provide the basis for defining specific therapeutic modalities. Thus the inflammatory infiltrate can become organized into various degrees of aggregation (Figure 52.2C–E), leading to the formation of ELS.

Ectopic lymphoid structures

When considering lymphoid aggregates, it must be stressed these are not a purely pathological processes, but may result from a normal chronic immune response. The development of local immunocompetent structures has advantages over the requirement for the development of systemic immunity, not least providing immunocompetent cells at the site of infection and local adaptive response limitation. Originally thought to be a result of chronicity in RA, these structures are found in early as well as chronic RA pannus (Figure 52.4). They may form as a result of chronic antigen drive. Indeed, the cyclic nature of RA erosive activity and antigen exposure may add to the drive for their development. This has been reviewed.[17,18]

ELS are inducible non-encapsulated lymphoid structures capable of forming in mucosal or non-mucosal areas as a result of sustained immune infiltration. However, not all lymphoid structures can function as true ELS as they frequently lack the immunological and proliferative properties of secondary lymphoid tissue (SLT). They may reflect two functions, a local adaptive response to limit systemic generation, or the failure of the secondary system to limit the problem such as seen in human kidney and cardiac transplants.

The variability in reporting of aggregates is probably as a result of sampling and laboratory variables. Histomorphometric analysis has now been standardized between laboratories into a grading system (G1–3) (Figure 52.2) to permit the quantification of aggregate organization, molecular mechanisms, and clinical outcomes. G2–3 T–B lymphocyte aggregates are found in 30% of active knees[19,20]

and 44% of samples from late arthritis at arthroplasty.[21] Differences between studies can reflect the historical treatment context, as the modern treatment paradigm is early and aggressive, as well as disease stage and sampling differences.

RA synovial ELS can be functional as they possess HEV, and express peripheral lymph node addressin (PNAd) which is usually associated with SLT for lymphocyte homing, and is colocalized with CCL21 which is produced by lymph node myofibroblasts. Thus the RA ELS has the apparatus required for lymphocyte homing and trafficking. They still retain a less organized morphology than classical SLT, with blurring and even intermixing of the T- and B-cell zones. Despite this, dendritic cells are found, similar to SLT, colocalizing with CCR7-expressing cells, which raises the possibility of functional immunological synapses. Some ELS exhibit large

interfollicular activation-induced cytidine deaminase (AID)+ B cells which are usually confined to the ELS T-cell zone with dendritic morphology.[22] Gene transcripts reveal T-cell receptor (TCR) and costimulatory pathway signalling, suggestive of active antigen presentation.

It has been known for some time that RA synovial follicles display oligoclonal immunoglobulins with highly mutated V-regions similar to those found in antigen-driven germinal centres. AID is required for somatic hypermutation and Ig class switch recombination, and is found in the follicular dendritic cell (FDC) network within RA synovial ELS and is associated with the expression of class-switched ACPA.[22] These FDC networks occur in 40% of RA samples,[21] and AID transcripts in CD21L+ samples occur in a further 20%. Like classical germinal centres, the ELS contain antigen-naive, unswitched, and switched memory B cells. Thus RA ELS possess the ability to programme both memory T and B cells. B cells are important to ELS integrity, as rituximab (anti-CD20) treatment of xenograft-coimplanted SCID mice induces dissolution of the synovial architecture, and depletion of T cells and macrophages.[23] Treatment of RA patients with rituximab also reduces the prevalence of T–B-cell lymphoid aggregates, T cells, FDCs, plasma cells, and subintimal macrophages in responders.

ELS probably contribute to RF and ACPA, but the contribution of secondary lymphocyte structures to circulating antibody confounds the interpretation. For example, ACPA can be seen in ELS-negative patients[22] as well as in spondyloarthropathy and OA. ACPA occurs years prior to the development of disease.[24] Local concentrations of RF and ACPA are greater in ELS biopsies, plasma cell numbers are elevated, and IgG1/2 transcripts are greater. Synovial plasma cells in ELS synovia correlate with synovial fluid ACPA and xenotransplantation of functional ELS containing RA synovia into SCID mice results in circulating levels of human ACPA that persists for several weeks.[22]

The enhanced detection of functional ectopic structures could explain the lack of correlation between aggregates and disease severity. One trial shows that joint destruction is increased in patients with lymphoid aggregates.[25], but two others with larger sample size do not show such a correlation.[19,20] Not only this, ELS structures within the same patient can show the coexistence of various grades of ELS structure, suggesting a dynamic process.[19]

Cytokines in the synovium

Cytokine networks reflecting adaptive immune pathways are prominent,[6,26] and the state of synovial organization distinguishes them according to their cytokine profiles.[27] In general, highly granulomatous synovia have high transcription rates for IFNγ, IL-4, IL-1β, and TNFα, while those with diffuse infiltrates are lower. Those with follicular aggregates possess high IFNγ, for example. Macrophage cytokines found in synovium include IL-1, TNF, IL-6, IL-12, IL-15, IL-32, granulocyte-macrophage colony-stimulating factor (GMCSF), as well as chemokines and are seen wherever the macrophages reside. IL-1α is seen primarily in endothelial cells, IL-1β predominantly in macrophages and also fibroblasts. TNFα is found in cells of the lining layer, in scattered macrophages, around blood vessels, and highly expressed at pannus adhered to cartilage[28]; The TNFα receptor is distributed in a similar manner and its receptors are found in on CD3 T cells in lymphoid aggregates. The ubiquitous nature of TNFα, both in cells and through its receptors

with their juxtaposition with each other and positioning at the lining layer, lymphoid aggregates, and CPJ, and its positioning in macrophages, demonstrates the central role this cytokine plays in RA. IL-1α and its receptor IL-1R appear even more predominant than TNFα. Found in the same locations as TNFα, it is seen in a high proportion of cells.[28] The endogenous antagonist on the other hand, IL-1ra, is present in less than 10% of cells.

IL-6 is also abundantly expressed,[29] being localized to some synovial T cells but preponderantly in synovial macrophages in the lining layer, perivascular aggregates, and especially those in juxtaposition to plasma cells. It is also synthesized by FLS and can be considered to be as important to RA as TNFα. IL-6 induces bone resorption, autoantibody production via stimulation of helper T-cell IL-21 synthesis, endothelial cell activation, and T- and B- cell proliferation.

The presence of ELS in synovia manifests in the expression of greater amounts of IL-1, IL-6, IL12, and IL-2 than those with diffuse cellularity. IL-12, IL-15, IL-18, and IL-23 are expressed by synovial myeloid and B-cell like (plasmacytoid) dendritic cells along with HLA class II and the accessory molecules involved in antigen presentation and T-cell activation. IL-12, an essential costimulus for the proliferation of T0 cells into T-helper cells and produced by macrophages and dendritic cells, colocalizes with CD68 macrophages.

The other important cytokine in the adaptive response is IL-17. Although IL-17 is sparsely seen in RA synovitis, when present it is found in T-cell subsets. The abundance of macrophage and dendritic cell TGFβ, IL-1, IL-6, IL-21, and IL-23 is a cytokine environment that will support Th17 differentiation at the cost of T-suppressor cells.

Examination of cytokines at the CPJ shows that cytokine expression follows the different morphological types[28]: TNFα, IL-1α, IL-6, GM-CSF and TGFβ are all found in CD68 macrophages in juxtaposition to the cartilage. However, of the diffuse CPJ subtype, only TGFβ is seen in the fibroblast-like cells. None of these cytokines are seen at other quiescent areas of the CPJ. IL-1β, IFNγ, and lymphotoxin seem not to be in the CPJ.

Bone erosion

Bone is eroded by pannus advancing along the subchondral surface, as well as via the inflamed bone marrow by osteoclasts (Figure 52.5). RA synovitis and pannus play a central role both directly as well as through cytokine expression.[30] Macrophages are a major source of osteoclastogenic cytokines such as TNF, IL-1, IL-6, and IL-17, as well as prostaglandin E$_2$. Macrophages may also serve as osteoclast precursors. Lymphoidneogenic structures can be seen in bone marrow alongside osteoclast activity. However, the presence of such B-cell structures need not mean that such association is entirely destructive. Defective B-cell follicle formation in hTNFα arthritic mice is associated with reduced endosteal bone formation, but with increased pannus activity,[31] so in this scenario it appears B-cell aggregation may be reparative.

Pannus itself secretes TNFα, IL-1a, IL-6, IL-17, macrophage colony-stimulating factor (M-CSF), and RANKL. CD4 T-cells and RA fibroblasts both synthesize RANKL. The heightened expression of RANKL over its decoy receptor osteoprotegerin (OPG) results in the promotion of octeoclastogenesis and matches the observation that osteoclasts are seen at the pannus–bone junction. TNFα induces marrow stromal cells to elaborate RANKL and M-CSF, as does IL-1, and inhibits osteoblast maturation as well as differentiation, thus leaving osteoclasts
Fig. 52.5 Pannus cytokine pathways and joint destruction in rheumatoid arthritis. Immune processes in the rheumatoid synovium, and the destruction of cartilage and bone, showing the major targets of modern anti-rheumatic biological agents. Central to this process is the presentation of an antigen by antigen-presenting cells (APC) to T cells to produce a T-helper 1 (Th1) and T-helper 17 (Th17) response. This occurs primarily in lymph nodes, but sometimes in synovial ectopic lymphoid structures (ELS) that can develop into a variety of organizational states to produce B-cell (B) and T-cell (T) responses leading to antibody synthesis, T-cell activation, and memory. The production of interferon-γ (IFNγ) aggravates a pathogenic cooperation between Th1 cells and macrophages (MØ), enhanced further by ligation of complement receptors (C-R), Fc receptors (Fc-R), and Toll (T-R) receptors by their ligands to result in the production of pro-inflammatory cytokines, especially TNF, IL-6, and IL-1. These in turn mediate monocyte (M) and T-cell recruitment, angiogenesis, lymphangiogenesis, and joint destruction. Erosion occurs either directly or through synoviocyte stimulation and RANKL, the stimulation of osteoclast differentiation, and bone resorption, as well cartilage destruction through chondrocytes and pannus.

unopposed. IL-6 upregulates osteoclast differentiation through the induction of cyclooxygenase 2 and prostaglandin E_2 synthesis which in turn increases the RANKL:OPG ratio through the expression of RANKL. IL-17 is an important bone resorption factor that also acts through RANKL. These data suggest that RA bone erosion should respond to RANKL inhibition as well as anti-cytokine therapies. Indeed this is the case, with anti-TNFα, IL-1, anti-IL-6, anti-IL-17, and anti-RANKL all reducing focal bone erosions in RA, often with a better response when coadministered with methotrexate.[32]

Synovial pathology drug effects

Few clinical trials include synovial biopsies and not as primary clinical endpoints. However, biopsy has allowed the influence of the gold standard methotrexate on synovial cell composition[33] in responsive patients to be observed. T cells (CD3), cytotoxic T cells (CD8), plasma cells (CD38), and macrophages (CD68) are all significantly reduced. Non-significant reductions in helper T cells (CD4), B cells (CD22), IL2-R (CD25), and type B synoviocytes is reported. Functional changes such as reduced mitosis (Ki67), IL-1β, TNFα, E-selectin, ICAM-1, and VCAM are seen. Prednisolone treatment[34] dramatically reduces synovial lining CD68 macrophages, CD5 B and T cells, CD163 macrophages, CD4 T cells, CD38 plasma cells, and CD55 fibroblasts. Similarly affected cytokines are IL-1β and TNFα in the sublining.

Anti-TNFα therapy is not solely associated with reduced CD68 macrophage numbers, but has a wider and dramatic effect on synovial pathology.[35] The neovasculature is severely compromised, and lymphangiogenesis is increased, while lymphatic and chemokine imbalance is corrected. T cells are reduced, along with VCAM-1 and E-selectin, as is synovial TNFα.[36] It has also been demonstrated to have a modulatory effect on synovial lymphoneogenesis.[20]

The summation of both the successful and unsuccessful trials is that CD68 macrophage suppression is a common though not specific feature of response to treatment. DAS28 scores of 88 patients from a variety of trials comprising methotrexate, leflunomide, sulphasalazine (or combinations), and infliximab correlate sublining CD68 macrophage with disease suppression.[37] Furthermore, sublining macrophage number does not change following ineffective therapy[38,39] or placebo,[40] and as such is being increasingly used in early-phase clinical trials to reduce the size and duration of studies.

This predictivity does not hold well for all treatments. Anti-B-cell therapy has variable effects on the CD68 population. It was expected that synovial B-cell depletion would predict outcome, but this is not so and is not explained by fluctuations in circulating antibody levels or the presence of anti-rituximab antibodies.[41] Differences in response are seen between trials, especially with regard to CD68 macrophages and CD3 T cells.[42] Synovial cytokine levels for TNFα, IL-6, and MMP1 also remained unaffected, as do indicators of B-cell activity—APRIL, BAFF, and SDF-1. There is an association with plasma cell depletion,[43] and response is accompanied by reduced synovial IgG and IgM synthesis and local B-cell proliferation, strongly suggesting that interruption of functional synovial B-cell pathways maybe key to clinical response.

Spondyloarthritis

Spondyloarthritis differs from RA in several respects.[44] The synovial lining layer highly expresses αVβ3, involved in fibroblast activation and proliferation, while this is much lower in the sublining layer. Instead, RA synovium expresses abundant αVβ5 in the sublining layer, which may indicate the more erosive, aggressive, nature of this disease when compared to spondyloarthritis. CD20 cells are almost absent and CD3 and CD4 helper T cells are less prevalent. CD68 macrophages, are as prevalent as seen in RA, as are plasma cells and neutrophils. The vascularity is more exaggerated and tortuous, as opposed to being more linear in RA. As the global scores increase, CD168 macrophages and neutrophils become more prevalent. Ectopic structures are also less prevalent.

Psoriatic arthritis

Ectopic lymphoid neogenesis is seen in psoriatic arthritis, and mimics the features of aggregates reported in RA,[45] with T- and

B-cell segregation, with PNAd expressing HEVs associated with CXCL13 and CCL21. As in RA, their presence appears unrelated to time of synovitis. Responsive treatment with anti-TNFα results in regression of the ectopic structures, and ineffective response is accompanied by their persistence. CD68 cells are globally present in psoriatic arthritis, to a similar degree to RA, but CD14 macrophages are fewer, which could be interpreted as reduced monocyte numbers. Mast cells contribute a significant presence and the vasculature is tortuous as opposed to linear in RA. Psoriatic synovia respond to anti-TNFα with reductions in CD3 and CD4 T cells.[46,47] CD68 is reduced as a trend in the first and significantly in the second trial. Anti-IL-1 does not have this activity. It thus seems that CD3 may be the synovial cell biomarker for psoriatic arthritis.

Osteoarthritis

It is now clear that there is significant involvement of the synovium in OA, despite the definition of OA as a non-inflammatory condition. In some patients there is a significant synovitis accompanied by hyperplasia, villous projections (Figure 52.6), and fibrosis. The synovial lining layer is often thickened, with perivascular as well as diffuse lymphocytes, and the presence of plasma cells in one-quarter of specimens. A notable minority exhibit CD4 and CD8 T cells. Samples can contain large follicular aggregates as well as perivascular accumulations,[48] containing CD4 and CD8 cells with the CD80 activation marker, and indications of FDCs. Class II HLA molecules can also be seen, as can mast cells. Cartilage shards in the synovium are associated with synovitis, and the presence of giant cells in some samples shows there is an aspect of frustrated phagocytosis of degradation products.[49]

The severity of synovitis is associated with more severe degradative disease, and also arthroscopy shows that inflammation can be subclinical. The synovitis seen in OA is associated with areas of pathological bone and cartilage damage and produces MMPs and collagenase as well as cytokines such as IL-1α, VEGF, bFGF, prostaglandin E_2, and nitric oxide.[50] VEGF and bFGF both lead to angiogenesis.
Fig. 52.6 Severe synovitis in osteoarthritis, showing thickening of the intimal layer, subsynovial lining inflammation, and neoangiogenesis, and the villous projections reminiscent of those seen in rheumatoid arthritis.
(Courtesy of Professor C. Pitzalis & Dr R. Hands, MRC PEAC Database.)

In conclusion, there appears to be more overlap in the synovial pathology between mild and severe forms of inflammatory arthritides that is related to time, severity, and chronicity than previously appreciated. This is resulting in a blurring between the extremes of RA and OA, for example, which may reflect clinical experience. In RA the events that are triggered at disease onset are manifestly different from those in the chronic phases, and the perpetuation of disease is as much to do with local self-sustaining lymphoid processes as to systemic influences. The recognition that the synovitis in the severe forms of disease actively contributes to systemic RF and ACPA; the generation of epitope spreading and immune memory; coupled with the mapping of the cellular and molecular mechanisms by which this occurs and the determination of the actions of disease-modifying anti-rheumatic drugs (DMARDs) and biological agents on them, is having a dramatic impact on the research into new therapeutics.

CHAPTER 53

Bone turnover

Georg Schett

Composition of bone

Bone is a specialized connective tissue that serves (1) locomotion by providing the insertion site of the muscles, (2) protection of the internal organs and the bone marrow as well as (3) metabolic function such as storage and provision of calcium to the body. Bone consists of cells and the extracellular matrix, which is composed of type I collagen fibres and a number of non-collagenous proteins. The specific composition of the bone matrix allows its mineralization, which is a specific feature of bone.

There are two major types of bones: the flat bones, which are built by intramembraneous ossification, and the long bones, which emerge from endochondral ossification. Intramembranous bone formation is based on the condensation of mesenchymal stem cells, which directly differentiate in bone-forming osteoblasts. In contrast, during endochondral ossification of the long bones, the mesenchymal stem cells first differentiate into chondrocytes that will further be replaced by osteoblasts. Long bones consist of (1) the epiphyses, which are protrusions at the ends of the long bones, (2) the diaphysis constituting its shaft, and (3) the metaphyses, which are located between the epiphysis and the diaphysis (Figure 53.1). The metaphysis is separated from the epiphysis by the growth plate, a proliferative cartilage layer, which is essential for the longitudinal growth of bones. After finishing growth, this cartilage layer is entirely remodelled into bone.

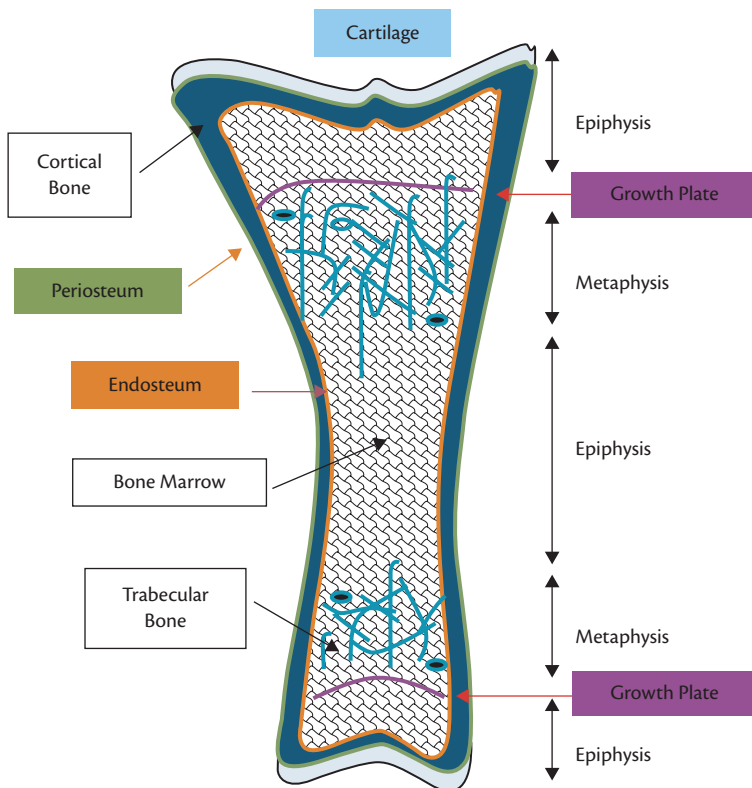
The external shape of bones is formed by a dense cortical shell (cortical or compact bone), which is particular strong along the diaphysis, where the bone marrow is located. The cortical bone shell becomes progressively thinner towards the metaphyses and epiphyses, where most of the trabecular bone is located. Trabecular


Fig. 53.1 Composition of long bones. Long bones consist of the epiphyses separated by growth plates from the metaphyses, which contain most of the trabecular bone. The outer lining of bone is the dense cortical bone, which is covered by the periosteum (outer surface) and the endosteum (inner surface). The latter connects bone to the bone marrow. The bony endplates are covered by the articular cartilage, consisting of a mineralized deep zone and a non-mineralized surface zone.

bone (also called cancellous bone) is a sponge-like network consisting of myriads of highly interconnected bony trabeculae. The outer and the inner surfaces of cortical bone are covered by layers of osteogenic cells, termed the periosteum and the endosteum, which are involved in the growth of width by bone apposition at the periosteal and bone resorption at the endosteal sites.

Although cortical and trabecular bone is composed of the same cells and same matrix components, there is a substantial difference between these two forms of skeletal tissue. Cortical bone almost exclusively consists of mineralized tissue (up to 90%) allowing it to fulfil its mechanical requirements. In contrast, only 20% of trabecular bone is mineralized tissue, whereas the bone marrow, the blood vessels and a network of mesenchymal stem cells cover the rest. As a consequence, trabecular bone shares a vast surface with the non-mineralized tissue, which is the basis for the metabolic function of bone, requiring a high level of communication between the bone surface and the non-mineralized tissue.

Bone matrix and bone remodelling

The key protein component of bone is collagen type I. Collagen fibres follow specific directions, forming the basis for the lamellar structure of bone. This lamellar structure allows a very dense packaging, resulting in optimal resistance to mechanical load. The lamellar collagen structures can be assembled in parallel (e.g. along the cortical bone surfaces and inside the bony trabeculae) or concentrically around blood vessels embedded in the haversian channels of the cortical bone. In case of rapid deposition of new bone such as during fracture healing, this lamellar structure is missing and the bone is then called woven bone. Woven bone is consecutively

remodelled into lamellar bone, which is also considered as being 'mature' bone. The composition of the collagen backbone also facilitates the deposition of spindle- or plate- shaped hydroxyapatite crystals, which contain calcium phosphate, allowing the calcification of the bone matrix. Apart from collagen type I, other, so called non-collagenous, proteins are found in bone. Some of them, such as osteocalcin, osteopontin, and fetuin, are mineralization inhibitors that make it possible to balance the degree of mineralization of the skeletal tissue. Aside from their intrinsic function in bone, non-collagenous proteins also exert important metabolic functions, such as the control of energy metabolism by osteocalcin.

Bone matrix is subject to a continuous remodelling process (Figure 53.2), which allows developmental bone growth, post-developmental maintenance, and repair of bone. Adults continuously remodel their skeleton, a process that runs even faster in the childhood and adolescence. In adults, it is considered to take 7–10 years to remodel the entire skeleton, indicating that it is fully replaced several times during a human lifetime. Most of the bone remodelling happens in the trabecular bone, which make it possible to build an optimal inner microstructure adapted to the individual mechanical demands. Trabecular bone is the leading structure in the vertebral bodies (up to two-thirds of the bone substance) and in long bones such as the femur (about 50% of the bone substance). Normal physiological circumstances ensure balance between bone formation and bone resorption to maintain skeletal homeostasis. This bone remodelling process requires a tight mutual regulation of bone resorption by osteoclasts and bone formation by osteoblasts, a phenomenon called **coupling**. Coupling is regulated on at least three different levels: (1) by a direct interaction between osteoblasts and osteoclasts; (3) by local interactions between the immune
Fig. 53.2 Bone remodelling and markers. Bone remodelling cycle with *activation* characterized by sensing of damage by osteocytes, *resorption* by osteoclast differentiation and removal of bone matrix, *migration* of bone-lining mesenchymal cells into the resorbed area, *formation* of new bone matrix by osteoblasts (cuboid cells), and *mineralization* of the newly synthesized matrix. Biomarkers reflecting the different steps of bone remodelling are indicated by black boxes.

system and bone cells; and (3) by neuroendocrine systemic control of bone metabolism.
