The entire bone remodelling process takes about 3–6 months and is controlled by the bone cells. It is initiated by so far unknown factors, which may likely be of mechanical nature and sensed by the osteocytes. Death of osteocytes and the resulting metabolic changes may govern this activation process. It is followed by a resorptive phase dominated by osteoclast-mediated degradation of the bone matrix, resulting in a resorption lacuna. The naked bone surface inside this lacuna is subsequently populated by mesenchymal cells immigrating from the neighbouring bone surface, which start differentiating into osteoblasts and produce the new bone matrix (also termed osteoid). This matrix is then mineralized and the bone returns to its resting state again. Importantly, the activity of bone cells during the remodelling process can be monitored in the peripheral blood of humans, allowing quantifying the activity of bone formation and bone resorption.

Bone cells

Osteoblasts

Osteoblasts are the bone-forming cells that derive from the mesenchymal stem cells of the bone marrow. Osteoblasts are cuboid-shaped cells that form clusters covering the bone surface. They are metabolically highly active, synthesizing the collagenous and non-collagenous bone matrix proteins, which are excreted and then deposited between the osteoblasts and the bone surface. This newly built matrix, which is not yet calcified, is termed the **osteoid**. The lag phase between osteoid deposition and its mineralization is approximately 10 days. Prostaglandin E_2 (PGE2), insulin-like growth factor (IGF)-1, parathyroid hormone (PTH), bone morphogenic proteins (BMPs) as well as Wingless and Int-1 (Wnt) proteins are key stimuli for osteoblast differentiation.[1] Osteoblast activity can be measured in the serum by assessing the production of alkaline phosphatase and osteocalcin, both of which represent specific differentiation markers of the osteoblasts, which are secreted by the differentiated cell. In addition osteoblast activity can be also determines by cleavage products of procollagen type I. These cleavage fragments of procollagen type I can be also measured in the serum and are used as markers for bone formation.

Osteocytes

Osteocytes are by far the most abundant cell type within bone. One cubic millimetre of bone contains up to 25 000 osteocytes, which are well connected with each other and the bone surface by small tubes (canaliculi) constituting a large and dense communication network inside the bone, which has similarities to the nervous system. The surface of this network of lacunae containing the osteocytes and the canaliculi containing the interconnecting filaments of the osteocytes covers an area of 1000–4000 m^2. Osteocytes are derived from osteoblasts, which subsequently are entrapped in the bone matrix. Osteocytes also start to express genes, which are specific for these cells and not found in other cells such as osteoblasts. One of the most interesting products of the osteocyte is sclerostin, a secreted molecule that binds LRPs and blocks Wnt-stimulated bone formation.[2,3] Consistent with its function as an inhibitor of bone formation, overexpression of sclerostin leads to low bone mass, whereas deletion of sclerostin leads to increased bone density and strength. Loss-of-function mutations in the human *SOST* gene

encoding sclerostin entail increased bone mass, a disease termed sclerosteosis. Several local and systemic factors have been suggested as possible regulators of sclerostin expression by osteocytes. For instance, intermittent administrations of PTH, which are associated with strong anabolic effects on the bone, potently inhibits sclerostin expression. No biomarkers for osteocyte function have yet been used in routine settings; however, measurement of sclerostin levels may close this gap in the future.

Osteoclasts

Osteoclasts are multinucleated cells containing up to 20 nuclei and are unique in their ability to resorb bone.[4,5] They are directly attached to the bone surface and build resorption lacunae (Howship lacunae). Apart from their multiple nuclei, another characteristic of the osteoclast is the ruffled border, a highly folded plasma membrane facing the bone matrix and designed to secrete and resorb proteins and ions into the space between the osteoclast and the bone surface. The space between this ruffled border and the bone surface is the place where bone resorption occurs. This area is sealed by a ring of contractible proteins and tight junctions, since it represents one of the few regions of the human body, where a highly acidic milieu is found. Bone degradation by osteoclasts comprises two major steps: (1) demineralization of inorganic bone components, and (2) removal of organic bone matrix. To demineralize bone, osteoclasts secrete hydrochloric acid through proton pumps into the resorption lacunae. This proton pump requires energy, which is provided by an ATPase allowing enriching protons in the resorption compartment, which, in fact, represents an extracellular lysosome. In addition to protons and chloride, osteoclasts release matrix-degrading enzymes, including tartrate-resistant acid phosphatase (TRAP), lysosomal cathepsin K, and other cathepsins. Cathepsin K, for instance, can effectively degrade collagens and other bone matrix proteins. Degradation products of collagen type I are the most widely used markers of bone resorption. The can be measured in the urine as well as in the serum. Both C-terminal cleavage fragments (CTX) and N-terminal cleavage fragments (NTX) are used. Moreover, TRAP and cathepsin K themselves can also be measured in the serum of humans and their level reflects the extent of bone resorption in the body.

Essential signals for osteoclast differentiation are macrophage colony stimulating factor (M-CSF) and receptor activator of NFκB ligand (RANKL). RANKL, a TNF superfamily member, is a surface molecule expressed by a large set of different cell types including pre-osteoblasts and activated T cells.[6] Under steady state conditions its expression is induced in cells of the osteoblastic lineage in response to osteotropic factors such as vitamin D, PTH, and prostaglandins. RANKL is essential for the final differentiation steps of osteoclasts as well as for their bone-resorbing capacity by engaging its receptor RANK on monocytic osteoclast-precursor cells. The interaction of RANKL with its receptor RANK is modulated by osteoprotegerin (OPG), a secreted glycoprotein, which was identified as a soluble factor that strongly suppresses osteoclast differentiation both in vitro and in vivo. Interestingly, OPG expression is induced by oestrogens, which explains the increase in osteoclast numbers and enhanced bone resorption during menopause. In accordance, RANKL-deficient mice display severe osteopetrosis due to the lack of osteoclasts. Regarding the central role of the RANKL–RANK–OPG signalling system in bone resorption, the therapeutic targeting of this system in human disease has drawn

increasing interest and recently the potent antiresorptive effect of a neutralizing RANKL antibody (denosumab) has been shown in clinical trials on postmenopausal osteoporosis.[7] Methods measuring RANKL and OPG in the serum of humans have been developed. In particular, the ratio between RANKL and OPG is considered as a marker for the bone remodelling activity in an individual.

Mineralization

Apart from these cell-controlled mechanisms of bone resorption and bone formation, which are of key importance for controlling the bone mass, it is also necessary to mineralize the bones appropriately to allow a maximum strength at certain degree of elasticity. This principle is achieved by mineralization of the bone matrix, which required sufficient supply of calcium ions. Vitamin D metabolites such as 25-hydroxycholecalciferol and its active from 1,25-dihydroxycholecalciferol are essential for maintaining calcium supply to the bone by fostering intestinal calcium uptake. Both vitamin D metabolites can be measured in the blood. Low vitamin D level due to poor UV light exposure or malnutrition is associated with impaired mineralization of the bones and decreased stability, a condition known as rickets.

Hypocalcaemia resulting from low vitamin D level is also the strongest signal for the production of PTH from the parathyroid glands, which is the key hormone in calcium homeostasis. PTH is directly regulated by blood calcium content, with low calcium levels inducing PTH production through calcium receptors.[8] Drugs mimicking calcium and binding to the calcium receptor are called calcimimetics, which are used to suppress enhanced PTH release in the case of chronic renal insufficiency.[9] PTH-mobilized calcium from the bones, by inducing osteoclasts, blocks calcium excretion through the kidneys and induces uptake of calcium in the intestinum via induction of vitamin D. Low PTH level due to impaired parathyroid gland function leads to hypocalcaemia, whereas overfunction due to hyperplasia or ademomata leads to high serum calcium levels. Measurement of PTH levels is a reliable tool to measure parathyroid function and calcium homeostasis in humans. Calcitonin is the natural antagonist of PTH and is also produced in the parathyroid glands.[10] Calcitonin can be seen as the calcium brake, as this hormone fosters the renal excretion of calcium and thus lowers calcium levels. Finally, renal derived fibroblast growth factor (FGF)-23 indirectly influences calcium homeostasis by controlling the excretion of phosphate through the kidneys.[11] Both calcitonin and FGF23 can be reliably measured in human serum and allow a detailed characterization of calcium–phosphate homeostasis in conjunction with PTH and vitamin D.

Conclusion

Bone is continuously remodelled by bone-resorbing osteoclasts and bone-forming osteoblasts. This remodelling process allows best adaptation of the bone architecture to the individual demands and tight control of calcium homeostasis.

Enthesitis

Martin Rudwaleit

Introduction

Entheses are ligaments or tendons connecting either two bones or connecting muscles and bone. Enthesitis refers to an inflammation at the site of the insertion of an enthesis or ligament to bone. Enthesitis is one of the key clinical manifestations of diseases belonging to the spectrum of spondyloarthritis (SpA) and of psoriatic arthritis. Enthesitis may occur in other inflammatory rheumatic diseases as well, such as rheumatoid arthritis (RA) or Behçet's disease, but in these conditions enthesitis is less common. In SpA, other musculoskeletal manifestations are peripheral arthritis, which is typically oligoarticular, asymmetric, and involves the lower limb; dactylitis; and inflammatory back pain. The spectrum of spondyloarthritides includes ankylosing spondylitis (AS), reactive arthritis, SpA associated with psoriasis or with inflammatory bowel disease, undifferentiated SpA, and juvenile SpA. Enthesitis in SpA is a non-infectious inflammatory process in origin, as are arthritis and inflammatory back pain. Flares of all clinical manifestations of SpA including enthesitis can be triggered by a preceding bacterial infection. Principally, enthesitis can occur at any site in the body where entheses are found, yet the most frequently affected peripheral sites in SpA are the heel (insertion of the Achilles tendon and insertion of the plantar fascia at the calcaneal bone) and the knee (patellar ligament, quadriceps ligament). Other characteristic sites in SpA are the anterior chest wall (manubriosternal junction) and the pelvis. MRI studies have revealed the presence of enthesitis also at sites such as the shoulder, sacroiliac joints, and spine.

Epidemiology

Across studies in SpA worldwide the frequency of enthesitis is about 20–50% in adults.[1–3] Similar figures of 15–53% have been reported for psoriatic arthritis.[4,5] Enthesitis in established SpA is usually accompanied by peripheral arthritis or inflammatory back pain (IBP) or both. Isolated enthesitis in SpA without concomitant arthritis or IBP may occur, in particular in the subgroup of undifferentiated SpA which may evolve later into AS or another defined subgroup of SpA.[6] In children, enthesitis is a hallmark of the subgroup of juvenile idiopathic arthritis (JIA) termed 'enthesitis-related arthritis (ERA)', a condition characterized by the presence of both peripheral enthesitis and arthritis, an age of onset of 6–9 years or older, and association with HLA B27.[7] In some children, ERA evolves to AS in adulthood.

Definitions and classification criteria

The term 'enthesitis' refers to an inflammation at the site of the enthesis insertion, whereas the term 'enthesopathy' refers to any kind of pathological abnormality of an enthesis irrespective of whether this is caused by degenerative processes, trauma, or metabolic conditions. Enthesitis of the heel has been considered as an essential and distinct clinical feature of the entire group of SpA, and was therefore included in the European Spondylarthropathy Study Group (ESSG) criteria and the Amor criteria for SpA.[8,9] In the more recent Assessment of SpondyloArthritis international Society (ASAS) criteria for axial SpA, enthesitis of the heel is one of the additional items which are required in addition to the presence of either sacroiliitis on imaging or positivity for HLA B27 in a patient with chronic back pain and age at onset of less than 45 years.[10] In the recent ASAS criteria for peripheral SpA, enthesitis of any site is one of the main entry criteria along with peripheral arthritis (asymmetric, usually involving the lower limb) and dactylitis.[11] Similarly, enthesitis is also one of the major entry criteria in the CASPAR criteria for psoriatic arthritis.[5] A child can be classified as having ERA, a subgroup of JIA best representing SpA in juveniles, if a child has either arthritis and enthesitis or has either of arthritis or enthesitis together with two more SpA features.[12] In all these sets of classification criteria the assessment of enthesitis is done clinically i.e. according to the medical history and physical examination (Table 54.1). This approach has been and still is being criticized, given uncertainties in the clinical assessment of enthesitis and lack of standardization.

Clinical picture

Enthesitis typically presents as pain or tenderness on pressure applied to the affected entheses. Pain is often most prominent after long periods of rest, in particular in the morning, and is relieved to some extent upon movement. Enthesitis in SpA most often affects the lower limb, in particular the knee and the heel. Enthesitis in SpA can also occur at the shoulder, sacroiliac joints, pelvis, and spine. In the spine, ligaments connecting the spinous processes, for example, can be affected. Many of the enthesitic sites are not visible. If visible, however, the affected enthesis can be swollen such as the Achilles tendon (Figure 54.1). Enthesitis may spontaneously resolve after some time or may run a chronic course. Accordingly, the duration of enthesitis is variable and it may last from days to

Table 54.1 Enthesitis in classification criteria

Classification criteria	Description of enthesitis in the criteria	Place of enthesitis in the criteria
ESSG criteria (1991)	Enthesiopathy: past or present spontaneous pain or tenderness at examination of the site of the insertion of the Achilles tendon or plantar fascia	Additional item
Amor criteria (1990)	Heel pain or other enthesiopathy: heel pain (but not pain originating in the Achilles tendon—non-specific) should be taken into account; pain in the anterior tibial tuberosity, midsternum pain, pain in the medial epicondyle	Additional item (2 points)
ASAS criteria for axial SpA (2009)	Enthesitis (heel): past or present spontaneous pain or tenderness at examination of the site of the insertion of the Achilles tendon or plantar fascia at the calcaneus	Additional item
ASAS criteria for peripheral SpA (2011)	Enthesitis: current enthesitis, diagnosed clinically by a physician	Main entry criterion
	Enthesitis: past or present spontaneous pain or tenderness at examination of an enthesis	Additional item (if either arthritis or dactylitis are present and considered as main entry criterion)
CASPAR criteria for psoriatic arthritis (2006)	Inflammatory articular disease (joint, spine, entheseal): no detailed description	Main entry criterion
Juvenile idiopathic arthritis; subgroup of enthesitis-related arthritis (ERA) (2004)	Enthesitis: tenderness at the insertion of a tendon, ligament, joint capsule of fascia to bone	Main entry criterion

even years. The pain can be mild or very severe and disabling. In longstanding enthesitis a bony spur can arise at the insertion site, referred to as enthesiophyte.[13]

Differential diagnosis

Pain or tenderness upon pressure on bony insertion sites of entheses can result from a variety of conditions including simple mechanical overuse and degenerative changes, trauma, metabolic conditions, and widespread pain syndromes (Box 54.1). Degenerative changes of the Achilles tendon are common and, similar to enthesitis, may lead to thickening and tenderness of the tendon. In Achilles degenerative enthesopathy the pain is often less severe than in Achilles tendon enthesitis. but this finding does not sufficiently discriminate between degeneration and inflammation. In patients with widespread pain syndromes such as fibromyalgia, the established tender points may mimic enthesitic sites upon clinical examination, making it difficult to differentiate between enthesitis and tender sites due to fibromyalgia. The distribution pattern of painful sites may be a diagnostic clue since in enthesitis associated with SpA frequently single entheses are affected, often with an asymmetric distribution, whereas in fibromyalgia multiple sites referred to as 'tender points' are affected, usually in a symmetric distribution. Thus, a careful medical history and a thorough physical examination are of great importance to distinguish these conditions. The absence of other SpA manifestations (i.e. IBP, arthritis, uveitis, limited spinal mobility), and absence of laboratory and imaging findings suggesting SpA including HLA B27, elevated C-reactive protein (CRP), and sacroiliitis on radiographs or MRI helps to rule out SpA and supports the presence of a widespread pain syndrome rather than true enthesitis. A particular diagnostic challenge is posed by secondary fibromyalgia in patients with established SpA, which has been reported to occur in at least 4–10% of patients with SpA.[14] Imaging technology such as ultrasound together with power Doppler revealing hypervascularization at the insertion site of the enthesis or MRI showing an increased signal at the insertion site corresponding to

enthesitis/osteitis may occasionally be needed for the distinction of true enthesitis from simple tender points.

Pathology and histopathology

The inflammation in enthesitis is anatomically not restricted to the enthesis as such but involves to a variable extent the bone to which the enthesis attaches. Visualization of joints and bone by MRI has revolutionized our understanding of the pathology of SpA and has stimulated research into the anatomical and histopathological characteristics of entheses and enthesitis.[13] Osteitis, a pathological hallmark of SpA, is often detected at the inflamed insertion site of an enthesis, and enthesitis and osteitis often occur together in SpA. It has been speculated that enthesitis is the key pathological element in SpA,[15,16] yet François et al. have demonstrated that in sacroiliitis, synovitis and ankylosis of the sacroiliac joints occur independent of enthesitis.[17,18] Fundamental work has been done by Benjamin, McGonagle and coworkers who studied extensively the anatomical basis of entheses and enthesitis.[19–23] Two major types of entheses can be differentiated, fibrous and fibrocartilaginous entheses. While fibrous entheses are typical for attachment of ligaments/tendons to bone in areas distant from joints, fibrocartilaginous entheses are typically found at the region of joint movement where shear and compression forces take place, such as at the Achilles tendon. At the Achilles tendon sesamoid fibrocartilage, which is found on the inner side of the tendon, protects the Achilles tendon from damage when it is compressed against the calcaneal bone, which itself is covered by periostal fibrocartilage. The subachillae bursa and the Kager fat pad further facilitate smooth movements of the tendon. Since these various anatomical structures function in an orchestrated complex way, Benjamin et al. coined the term 'enthesis organ'.[20] He also coined the terms 'functional enthesis' which refers to tendons which wrap around bony pulleys, and the term 'synovio-entheseal complex' which refers to an enthesis organ that is part of a synovial joint such as the shoulder or the knee.[21] In general, histological data on acute enthesitis is scarce because of the inaccessibility of tissue, in contrast to synovitis, and most data have been obtained from post-mortem studies.[22] In SpA preferentially fibrocartilaginous entheses are affected by the inflammatory process. Histologically, T lymphocytes, bone marrow oedema, and macrophages can be detected close to fibrocartilaginous areas. Bony erosions, entheseal calcification, and bony spurs occur in chronic enthesitis.[13] Ultrasound studies revealed that bone erosion in SpA occurred either at the proximal insertion or the superior tuberosity

Fig. 54.2 Plain radiographs of a male patient with longstanding ankylosing spondylitis showing widespread enthesitis in the pelvis with formation of fluffy enthesiophytes, particularly at the ischial bone bilaterally. In addition, symphysitis, ankylosed sacroiliac joints, and syndesmopyhtes at the spine can be seen.

of the Achilles tendon, while bony spurs occurred exclusively at the distal enthesis. In one study small bony spurs occurred in both early SpA patients and healthy controls whereas large bony spurs were found only in chronic SpA (9 of 17 patients) but in none of 20 patients with early SpA.[23] Thus, biomechanical factors likely play an important role in the pathophysiology of enthesitis associated with SpA. However, entheseal calcifications and bony spurs also occur frequently in degenerative conditions. Typical sites are the supraspinal tendon (tendinosis calcarea), the ileotibial tract, and very frequently the heel with plantar and dorsal heel spurs. Earlier work using xeroradiography suggested that fluffy and complex spurs occur more often in inflammatory conditions whereas simple spurs occur in degenerative enthesiopathy.[13]

Imaging

Enthesitis can be visualized using plain radiographs, bone scintigraphy, MRI, and ultrasonography. Plain radiographs may show the sequelae of chronic enthesitis such as calcification of tendons and bony spurs. These changes, which can be quite extensive, are often seen in longstanding AS (Figure 54.2). In recent studies, either MRI or ultrasound with power Doppler has been used for visualization of active enthesitis. For the axial skeleton MRI is most useful.[24] MRI is also highly useful for detecting enthesitis and associated osteitis at peripheral sites such as the heel and midfoot, knee, hips, anterior chest wall including the manubriosternal junctions, shoulder, and elbow (Figure 54.3). Whole-body MRI is an ideal tool to visualize widespread enthesitis, but the procedure is not widely available[25,26] and is lengthy, taking at least 45–60 minutes. On MRI, active inflammation is usually characterized by a bright signal on T2 fat-suppressed images or STIR images. Intravenous contrast agents such as gadolinium may add further important information. Furthermore, specific MRI protocols have recently been developed which may even better visualize pathological changes of entheses.[27] If MRI is unavailable bone scintigraphy can provide useful information, but the anatomical resolution is far better with MRI than with bone scans.
Fig. 54.3 MRI of the right foot of a patient with HLA B27-positive ankylosing spondylitis, peripheral arthritis of the ankle, and enthesitis. Fat-suppressed sequence after intravenous gadolinium administration. Enhanced signals are seen at the calcaneal bone at the insertion site of the plantar fascia. The Achilles tendon is not thickened and the insertion site of the Achilles tendon is normal. Effusion in the ankle joint is also seen.

For peripheral enthesitis ultrasound in conjunction with power Doppler has evolved to be of great clinical use in experienced hands.[28] Using ultrasound, features such as tendon thickening, calcifications, erosions, enlarged bursae as a sign of inflammation of the bursae, and power Doppler are being assessed. Ultrasound scoring systems have been developed for use in clinical practice and in trials.[29–31] In these scoring systems, entheses located at the lower extremity predominate and all scoring systems include the knee with the insertion of the quadriceps tendon at the patella, the patellar ligament insertion at the inferior pole of the patella and distally at the anterior tibial tuberosity, the Achilles tendon insertion, and the plantar fascia insertion at the calcaneus.

In general and across studies, ultrasound is more sensitive than the clinical examination in the detection of enthesitis. Among 18 HLA B27-positive patients with recurrent acute anterior uveitis but no other clinical signs of SpA, enthesitis by ultrasound was found in 55%, suggesting subclinical SpA in these patients.[32] Two recent diagnostic studies revealed ultrasound to be a useful tool. Among the entheseal abnormalities to be detected, the landmark of ultrasound enthesitis in SpA with the highest specificity is an increased vascularization at the insertion site.[33,34] In a study of 118 patients with suspected SpA ultrasound was performed without knowledge of clinical data. At least one vascularized enthesis was found in 76% of 51 SpA patients but in only 19% of 48 patients without SpA, yielding a positive likelihood ratio (LR+) of 4.1.[33] In contrast, entheseal abnormalities on B-mode ultrasound without power Doppler did not sufficiently differentiate between groups (86% in SpA, 60% in non-SpA, LR+ 1.4). Another diagnostic study used the semiquantitative Madrid sonography enthesitis index (MASEI). Patients with SpA (n = 113) had a significantly higher MASEI score than 23 patients without SpA (23.3 vs 16.0). A cut-off score greater than 20 yielded a sensitivity of 56%, a specificity of 89%,

and a LR+ of 5.3. Again, a positive Doppler signal had the greatest discriminative capacity among all ultrasound features.[34] In another recent diagnostic study on 51 SpA patients with or without heel pain and 24 controls, however, neither MRI nor power Doppler differentiated between SpA and control. In particular, power Doppler ultrasound did not show any difference between SpA patients and controls.[35] Thus, some controversy still exists about the exact place of ultrasound as a diagnostic tool. Ultrasound is examiner dependent and interobserver variability in detecting and scoring power Doppler signals can be substantial, as can be the interpretation of findings.[36,37] Advantages of ultrasound are the non-invasive nature of the procedure without radiation exposure. Moreover, ultrasound can visualize several entheses of interest during a single examination in contrast to MRI (except whole-body MRI).

Studies systematically comparing MRI and ultrasound in the detection of enthesitis were scarce until recently and yielded conflicting results. In an earlier study of 32 patients with SpA and clinical heel enthesitis the sensitivity of detecting entheseal abnormalities was greater using B-mode ultrasound without power Doppler (100%) than with MRI (62%; osteitis present in 40%). Inversely, in another study on 14 SpA patients retrocalcaneal bursitis was detected better by MRI (73%) than by ultrasound (only 50% of MRI bursitis was also detected by ultrasound). In recent studies, MRI was superior to ultrasound and power Doppler in the detection of tendon abnormalities.[27,35]

Clinical scoring methods

The first instrument was the Mander enthesitis index.[38] It scores 66 entheses, each in a semiquantitative way from 0–3 for the severity of pain. Since the Mander enthesitis index is complex and time-consuming for clinical use, it was modified in two ways in a data-driven approach. First, the scale from 0–3 for tenderness was reduced to 0 or 1 for each enthesis, and the number of sites was reduced according to the most often affected sides in an observational AS cohort. This modification, also referred to as the Maastricht AS enthesis score (MASES), assesses 13 entheses: first costochondral joint left/right, seventh costochondral joint left/right, posterior superior iliac spine left/right, anterior superior iliac spine left/right, iliac crest left/right, fifth lumbar spinous process, and proximal insertion of Achilles tendon left/right.[39] The Spondyloarthritis Research Consortium of Canada (SPARCC) developed and validated an enthesitis index based on MRI findings and ultrasound findings.[40] This index includes 16 peripheral entheses located at the shoulder (supraspinatus tendon), the elbow (medial and lateral epicondyles), greater trochanter, knee, and heel (Achilles tendon and plantar fascia). The Leeds enthesitis index has been developed for use in psoriatic arthritis.[41] It scores six sites: lateral epicondyle left/right, medial femoral condyle left/right, and Achilles tendon left/right. Currently, the MASES index is the most frequently used scoring instrument in clinical trials, but none of these indices is used in routine daily practice.

Treatment

Non-steroidal anti-inflammatory drugs (NSAIDs) and physiotherapy are often used for the treatment of enthesitis. In severe or refractory cases local steroid injections can be effective. Radiotherapy has been and still is applied in chronic enthesitis. Sometimes modification of physical activities and the use of ortheses can be helpful.

Several uncontrolled and controlled studies suggest that traditional disease-modifying anti-rheumatic drugs (DMARDs), in particular sulfasalazine, are ineffective for treating enthesitis. In a recent unblinded randomized study comparing etanercept and sulfasalazine in axial spondyloarthritis, improvement in the MASES score occurred in both groups equally after 48 weeks. However, improvement in MASES after 24 weeks was much greater in etanercept-treated patients than in sulfasalazine-treated patients.[42] In double-blind controlled and also in open-label clinical trials of infliximab, etanercept, and adalimumab in AS enthesitis was usually a secondary outcome parameter. In these trials, which often used one of the defined scoring instruments, enthesitis usually responded very well to anti-TNF therapy. Only one placebo-controlled trial focused on enthesitis of the heel as the primary outcome. In this study, 24 patients with heel enthesitis and MRI inflammation of the calcaneal bone at the insertion site were treated for 12 weeks with either etanercept 50 mg per week ssubcutaneously or with placebo. An improvement of at least 50% of the global patient assessment was achieved in 66% of etanercept-treated vs 8% of placebo-treated patients.[43] However, the difference between the groups regarding the reduction of the size of MRI bone marrow oedema at the heel was less impressive after 12 weeks of treatment, suggesting that maybe longer treatment periods are necessary to see significant differences.

ASAS recommends the use of anti-TNF agents in patients with axial SpA for the treatment of resistant enthesitis not responding to conventional treatment including NSAIDs and local treatment.[44,45] Similarly, the European League Against Rheumatism (EULAR) recommendations as well as the Group for Research and Assessment of Psoriasis and Psoriatic Arthritis (GRAPPA) recommendations for the management of psoriatic arthritis consider anti-TNF agents for the treatment of active enthesitis if NSAID treatment or local injections have failed.[46,47] The National Institute for Health and Clinical Excellence (NICE) has published guidance on the use of anti-TNF agents in active AS but without special reference to enthesitis.[48]

Conclusion

Enthesitis is a characteristic muskuloskeletal manifestation of all disorders of the group of SpA including including AS and psoriatic arthritis. Tremendous progress has been made in the anatomical and histological basis of entheses and enthesitis over the last decade. Enthesitis is usually assessed clinically, yet imaging by ultrasound together with power Doppler and MRI has emerged to be very useful for visualizing enthesitis. Both ultrasound and MRI represent an area of active research in enthesitis, in particular their use as diagnostic tools. Local treatment and NSAIDs are the cornerstones of standard therapy, and anti-TNF agents are effective in treatment-resistant enthesitis. Clinical trials in patients with predominant enthesitis are scarce and, apart from psoriatic arthritis, none of the anti-TNF agent has been approved for treatment of enthesitis in peripheral SpA.

CHAPTER 55

Skeletal muscle physiology and damage

Robert Dinser[†] and Ulf Müller-Ladner

Muscle structure and physiology

Structure and molecular function

Muscle fibres are huge cells formed through the fusion of many separate cells. They contain cylindrical organelles termed myofibrils, consisting of columns of sarcomeres, constituting the contractile unit. In it, thin filaments anchored at the Z-disk overlap with thick filaments (Figure 55.1). Thin filaments are formed by double-stranded helical polymers of actin. The thick filaments are positioned midway between the Z-discs and are formed by three-stranded helical polymers of the dimeric myosin organized in a hexagonal lattice.[1]

Contractions result from a transient cross-bridge between the myosin heads with actin that forms in the presence of ADP, orthophosphate, and Ca^{2+}. Once orthophosphate is released, a conformational change in the myosin heads generates the sliding force. After release of ADP, ATP dissociates myosin from actin. In the absence of Ca^{2+}, a regulatory complex of tropomyosin and troponins blocks the myosin binding site of actin.[1] Many congenital myopathies have been linked to mutations in structural muscle proteins.[2]

Contractile properties are determined by the isoformes of myosin chains and regulatory proteins they contain. Fibres are classified according to their size, speed of contraction and release, and resistance to fatigue. Different fibres may be found within a single muscle. Type I (slow) fibres are characterized by a slow but sustained contraction. Type II (fast) fibres have rapid and brief contraction times and appear whiter due to a lower content of myoglobin. Their oxidative capacity is lower and they have higher stores of glycogen. Muscle fibres are innervated by axonal branches of an α-motorneuron activated in the central nervous system. All fibres depending on one neuron are of the same type; the complex is called the motor unit. One neuron orchestrates the simultanous contraction of its depending fibres. Motor units differ in size, excitability, and patterns of excitation.

The muscle cell membrane is surrounded by a basal membrane along its entire surface. Attachment complexes consist of muscle isoforms of the transmembrane protein integrin and its receptor at the basal lamina, laminin. In addition, a specialized adhesion complex connects actin through intracellular and transmembranous proteins to the basal lamina (Figure 55.2). At the myotendinous

junction, myofibrils are separated by invaginations of the cell membrane filled with collagen arising from the tendon. The actin filaments insert at an integrin-containing cell membrane complex connected through laminin to the tendinous collagen. Mutations in the proteins involved in the adhesion complex cause destructive myopathies sch as Duchenne-type muscular dystrophy.[3]

Neuromuscular transmission

The myofibrils are separated within the muscle cells by the sarcoplasmatic reticulum (SR). The SR stores and releases Ca^{2+} to the cytosolic myofibrils, depending on the electrical activity of the cell membrane. The cell membrane is invaginated in multiple sites to form a transverse tubular network to conduct action potentials into the interior of the cell. The action potential of the axonal branch is transmitted to the dependent muscle fibre at the neuromuscular junction situated halfway along the length of the fibre. Axon-derived acetylcholine binding to its receptor at the muscular end of the synapse opens Na^+ channels, inducing a depolarization of the cell membrane. The resulting action potential is transmitted through the invaginations of the cell membrane, where dihydropyridine receptors interact with the juxtaposed ryanodine receptors of the SR to allow Ca^{2+} flux from the SR to the cytosolic myofibrils (Figure 55.3). The network of transverse tubules and the multiple sites of interaction with the SR cause an efficient excitation–contraction coupling. Disturbances of the neuromuscular junction lead to characteristic myopathies, such as Lambert–Eaton syndrome or myasthenia gravis.[4] Mutations in the ion channels also lead to muscle weakness and disturbances in excitability, such as periodic paralysis and different myotonias.[2,5]

Energy metabolism

Energy is consumed by the myosin heads cross-bridging to actin filaments, and by the Ca^{2+} pumps of the SR. The intracellular pool of ATP is small, requiring ATP production during contraction. Under
Fig. 55.3 Diagram of the network of T tubules and sarcoplasmatic reticulum reaching the proximity of myofibrils to allow electromechanical coupling.

aerobic conditions, oxidative metabolism of glycogen and triglycerides constitutes the dominant ATP-producing mechanism, generating up to 38 ATP per glucose molecule. In anaerobic settings of maximal exercise, the first source of ATP is the dephosphorylation of phosphocreatine via creatine kinase. As the exercise continues, pyruvate generated through glycolysis is converted to lactic acid, generating 2 ATP per glucose molecule. This process is faster than the aerobic metabolism, but can be sustained only for short periods of time due to the rapid depletion of glycogen stores.[6,7] Mitochondrial

dysfunction is not only the basis for muscle disease in hereditary mitochondropathies, but also a pathophysiological correlate in various diseases leading to muscle wasting[8] and fibre redistribution.

Fatigue

Intensive exercise leads to a decline in the strength generated during contraction: muscular fatigue. A key mechanism to fatigue is the failure of ryanodine receptor Ca^{2+} channels on repeated muscle activation, decreasing the availability of intracellular Ca^{2+}.[7,9] The increase in orthophosphate during contraction reduces the force of cross-bridging and Ca^{2+} sensitivity of myofilaments. Entrance of orthophosphate to the SR may lead to calcium phosphate precipitation, reducing the Ca^{2+} available for release.[9] Availability of ATP decreases during high-intensity exercise. Intracellular acidosis and accumulation of lactate in anaerobic exercise are less relevant for muscle fatigue, as the acidosis observed in severely fatigued muscles has little impact on force production. Fatigue is modulated by factors influencing the efficiency of the recruitment of motor units and inhibitory reflexes when using different muscle groups.[10] In addition to these muscle-based reasons for the development of peripheral fatigue, a failure of the motor neuron activity, mostly in situations of low-intensity exercise, is called central fatigue. The relevance of this aspect of fatigue for the decline in muscular performance during exercise is less well understood.

Muscle changes throughout life

Embryology

Skeletal muscles arise at about the sixth week of gestation. The muscles of the trunk and limbs are derived from the paraxial mesoderm, neck and head muscles from cephalic and prechordal mesoderm.[11] Induction of myogenesis depends on signals from neighbouring tissues. The developing myoblasts, precursors of the muscle cells, withdraw from the cell cycle and start to express differentiation factors like myoblast determination protein (MYOD), or myogenin. These factors drive muscle cell determination and differentiation. The process of muscle cell differentiation is modulated through the action of non-coding microRNAs (miRNAs). These miRNAs are beginning to be used as molecular markers for muscular diseases,[12] and may in the future also be used in the treatment of some muscular disorders.[13] The use of differentiation factors to improve muscle repair is an important research focus.[14]

The evolving myoblasts aggregate in columns and fuse to produce multinucleated primary myotubes which are, at their ends, attached to the developing skeleton. In these myotubes, muscle-specific proteins are formed and self-assemble in long columns of sarcomeres on cytoskeletal scaffolding. The myofibrillogenesis proceeds from the periphery to the centre of the evolving muscle fibre so that the nuclei migrate to the border of the syncytium. The number of muscle fibres is more or less constant throughout life. Growth in length is achieved through the addition of sarcomeres at the end of the fibre.[15]

Part of the difference between different muscle fibre types is determined by differing embryological origins of the myogenic precursors, involving different signalling patterns.[14] Once the nervous system begins to interact with the developing muscle at 10 weeks of gestation, the patterns of contractile activity modulate the ensuing fibre type up to the first months of postnatal life. The differences in neural activity lead to differences in intracellular Ca^{2+} levels that are sensed by calcineurin, leading to altered gene expression. Further

influence on the fibre composition is exerted through mechanical sensing of the sarcomere associated myozenins.

Repair and adaption to requirements

Some progenitor cells fail to fuse to form myotubes but remain associated to the muscle fibres. These satellite cells are enclosed by the basement membrane of the mature muscle fibre but remain outside the muscular cell membrane.[16] The satellite cells divide to provide new nuclei to damaged muscle fibres.[11] This recruitment of new satellite cell-derived muscular nuclei to existing fibres is a mechanism for an increase in sarcomeres observed in situations of increased demand.

Hormonal stimulation through androgens, leptin or insulin-like growth factor 1 (IGF-1) leads to increased muscle mass. IGF-1 is secreted as an autocrine hormone in response to mechanical stress under the control of hepatic growth hormone. It increases translational efficiency and capacity through the mammalian target of rapamycin pathway. Catabolic pathways triggered by glucocorticoids or inflammatory cytokines activate NFκB signalling.[17] In diseases like heart failure, upregulation of myostatin as negative regulator of muscle mass precipitates peripheral muscle wasting.[18]

Muscle soreness after intense muscular activity is characterized by a disruption of sarcomere structure (Figure 55.4). An increase in membrane permeability through the activation of stretch-induced ion channels leads to an impairment of excitation–contraction coupling, explaining the reduced strength immediately after damage. The ensuing local inflammatory reaction stimulates the synthesis of new sarcomeres to protect muscles on repeated activity, leading to increased muscle strength.[9]

Although it appears difficult to transform myosin heavy chain isoforms through physical exercise in healthy individuals, imposed inactivity leads to a predominance of type II fibres.[19] Training causes an increase in the number of mitochondria, resulting in an increased oxidative capacity. Exercise increases the use of fatty acids to preserve glycogen stores during prolonged exercise and improves

the uptake of glucose. Exercise may stimulate angiogenesis. Stimuli like hypoxia, increases in calcium availability, or changes in concentration of ATP influence the transcription of proteins that are relevant for the efficiency of the oxidative process.[7]

Another mechanism to contain the effects of damage is axon sprouting on denervation. Neighbouring axons grow new branches that connect to denervated muscle fibres. This increases the size of the motor unit and can lead to a switch in fibre type depending on the newly innervating neuron.

Ageing

After a peak of muscle mass in the third decade, muscle strength and bulk decrease physiologically (sarcopenia). As in pathological muscle wasting, lost muscle is replaced by adipose and connective tissue.[20]

While cycles of denervation and reinnervation are normal throughout life, increasing age is associated with a loss of α-motor neurons of type II fibres, accelerating in the seventh decade. Some fibres are reinnervated through axonal sprouting from type I fibres, leading to excessively large motor units. Later, type I fibres are lost in a comparable manner. This loss of reinnervation may be caused by a decline in neural survival factors.[20]

Damage in mitochondrial DNA with ensuing defects in the efficiency of the respiratory chain components precipitates age-related changes in muscle.[8] Part of the mitochondrial dysfunction may be caused by iron accumulation in mitochondria. Iron is central to the function of mitochondrial proteins, so that mitochondria possess their own system of regulatory proteins for iron homeostasis. Mitochondrial dysfunction leads to increased muscle cell apoptosis.

A decline in sex hormones and growth hormones with age leads to a decreased synthesis of muscle proteins and to a decrease in satellite cell proliferation.[16] While relevant signalling pathways regulating skeletal muscle mass[17] have been established, the age-associated imbalance has not been related to these pathways. A decrease in satellite cell number impairs repair capacity. Other age-associated factors not directly related to muscle physiology, such as malnutrition, also affect the loss of muscle tissue.[20]

Clinical approach to muscle disease

Clinical assessment

A useful semiquantitative system for assessing muscle strength in muscle groups and single muscles is the system of the Medical Research Council, grading strength from 0 (no contraction) to 5 (normal power). This method is insensitive but easily applied. Other methods of strength assessment include the measurement of isometric muscle strength or assessments of repetitive muscle function, like the measurement of the time required to stand up and sit down from a chair 10 times. A thorough clinical assessment of other organ systems is of utmost importance in the diagnostic workup.

Laboratory analysis

Testing for intracellular muscular enzymes reveals the extent of muscle damage. Useful are creatine kinase (CK), aldolase, myoglobin, alanine aminotransferase (ALT, GPT), aspartate aminotransferase (AST, GOT), and lactate dehydrogenase (LDH). None of these enzymes is specific for muscle.

A screening test for a suspected metabolic myopathy is the forearm ischaemic exercise test.[21] This test measures lactate as a product of anaerobic glycolysis and ammonia generated through the conversion of AMP to inosine monophosphate by the myoadenylate cyclase, allowing assessment of most glycogen storage diseases (except acid maltase deficiency) and myoadenylate cyclase deficiency. The test is performed after drawing a venous blood sample for lactate and ammonia at rest. Under conditions of suprasystolic arterial compression, the patient exercises his arm with maximal intensity for 2 minutes or until the patient cannot tolerate the discomfort. Two minutes after re-establishing arterial flow, lactate and ammonia are measured. Lactate and ammonia should rise threefold over baseline in a normal response. In the case of a glycogen storage disease, only ammonia increases, whereas in myoadenylate deficiency, only lactate levels increase. The test is valid only if maximal exercise effort has been applied. Any positive result should be confirmed by appropriate further enzyme analysis.

Electrodiagnostic studies and imaging

Electromyography and electroneurography are helpful in differentiating myopathic and neuropathic conditions and in localizing neuropathic changes to the central nervous system, anterior horn of the spinal cord, peripheral nerves, or the neuromuscular junction. Electrodiagnostic studies help in analysing muscle dysfunction but most findings are not specific for defined diseases. Over the time course of a disease, the electrodiagnostic pattern may be altered by increasing muscle fibrosis.
Fig. 55.5 MRI of a 24 year old woman with clinical myositis shows oedematous changes in distinct muscle areas of the calf (left). Haematoxylin–eosin staining characterizes the typical variability in muscle fibre size with some lymphocytic infiltrates (middle), but lacks CD8+ cells (not shown). The immunohistochemistry against dysferlin reveals a complete absence of staining (right), confirming a genetic lack of dysferlin as the origin of myopathy. A positive dysferlin staining is shown in the insert. Courtesy of Dr Anne Schänzer (Marburg).

MRI allows a clear differentiation between normal, inflamed, and atrophic muscle (Figure 55.5). It is used to characterize the distribution of a myopathy and helps determining the localization for a muscle biopsy.[22]

Histology

Histological analysis of muscle tissue is essential to establish a diagnosis. Except for enzyme deficiency diseases, specific diagnoses may not be provided by the histological analysis, but the confirmation of inflammatory disease may be decisive for treatment decisions. Several types of analysis are performed. Conventional histology from paraffin-embedded tissue can describe alterations in fibre arrangement, in the localization of nuclei, scarring, fatty replacement, and infiltrations of lymphocytes or other cells. Histochemical stains on frozen sections allow an assessment of the fibre type, glycogen and lipid stores, and the characterization of infiltrating non-muscular cells (Figure 55.5). Enzyme deficiencies can be ascertained by analysing enzyme activity in a tissue protein extract. Ultrastructural analysis by electron microscopy can identify an altered mitochondrial morphology. Both the surgeon and the pathologist need sufficient information about the suspected clinical problem in order to select an adequate specimen and to allow the correct handling of the biopsy.

CHAPTER 56

Joint biochemistry

Thomas Pap, Adelheid Korb, Marianne Heitzmann, and Jessica Bertrand

Introduction

Articular joints are key components of the musculoskeletal system that provide flexible support to neighbouring bone structures and allow for the movement in different parts of our body. This is particularly true for synovial joints that are found mainly at our extremities and constitute the structural basis for key physiological activities such as walking, climbing, and gripping. Synovial joints are composed of different morphological structures, including bone, tendons, cartilage, the synovial membrane, and the synovial space with the synovial fluid. Under physiological conditions they can be well separated, but the close functional relationship of these structures as well as the cellular and molecular interactions between the tissue components of a joint makes it seem advisable to look at synovial joints as at distinct organs. This concept becomes relevant particularly under pathological conditions such as arthritis, which not only affect joints as a whole but which are also based on complex pathological interactions between tissue components of the joints such as cartilage and synovium.

Cartilage development, biology, and metabolism

Cartilage is perhaps the key component of synovial joints. Supported by the synovial fluid, cartilage provides a smooth and low-friction surface that is needed for gliding of both bony ends. At the same time the articular cartilage functions as an elastic and load-absorbing tissue.[1] The biomechanical properties of articular cartilage are achieved by its unique structure. It is characterized by the presence of only one cell type, the chondrocytes, which are loosely embedded into a highly complex and organized extracellular matrix (Figure 56.1).[2] The articular cartilage is organized into at least four distinct zones that differ with respect to the density and orientation of the cartilage fibrils as well as the number and shape of embedded chondrocytes.[3]

Although articular cartilage is usually looked at as a covering tissue that is placed on top of the underlying bone, it actually constitutes a specific part of the cartilaginous template, from which both the joints and the long bones are formed during embryogenesis through endochondral ossification. However, articular cartilage areas are not purely remnants of the bone formation process, in which ossification comes to a halt. Rather, it has been demonstrated that articular cartilage differs from growth plate cartilage and that articular chondrocytes originate from a distinct population of mesenchymal progenitor cells that can be identified very early in limb development.[4] These cells are derived from an area called the interzone and are characterized by a specific molecular pattern including the expression of the growth factor Gdf5.[5,6] Their differentiation appears to be regulated by the concerted action of members of the Wnt family of molecules such as Wnt9a, formerly known as Wnt14, through activation of the Wnt/β-catenin signalling pathway.[7,8]

Those cells of the mesenchymal condensations that are more distant from the interzone also undergo chondrogenic differentiation and then longitudinal growth until the cartilage template is formed. Subsequently, these chondrocytes differentiate further to initiate endochondral ossification, which eventually results in the replacement of the cartilage template with trabecular bone. In addition to the transcription factor Sox-9 that is involved most prominently in chondrocyte differentiation, these steps are controlled by genes of the *Hox* family.[9,10] and regulated by the concerted action of different signalling proteins, particularly sonic hedgehog (shh), indian
Fig. 56.1 Zonal organization of cartilage. Articular cartilage can be divided into four zones. The superficial zone (also called the tangential zone, because of its structural organization) makes up about 10% of the cartilage thickness. It is in direct contact with the joint cavity. It is characterized by densely packed cartilage fibrils with long-shaped chondrocytes in between. The middle zone makes up about 40% of the articular cartilage and is also called the transitional zone. It has more round-shaped chondrocytes, which are embedded into a less densely packed extracellular matrix. The deep or radial zone is the thickest layer of articular cartilage, and the chondrocytes here are oriented perpendicular to the cartilage surface. The deep radial zone is separated by the tide mark from the calcified zone that is in direct contact with the subchondral bone.

hedgehog (ihh), and growth factors of the fibroblast growth factor (FGF) family.[11–13] Components of the extracellular matrix contribute significantly to chondrogenesis and thus to key properties of cartilage. They serve as a structuring scaffold for limb and joint development and are involved in creating gradients of growth factors. Mutations in genes encoding for heparan sulfate (HS) species such as perlecan,[14,15] or in enzymes that contribute to the assembly of HS side chains, lead to severe skeletal defects.[16,17] As a next step in endochondral ossification, chondrocytes from the middle of the cartilage template start differentiating into hypertrophic chondrocytes, which is associated with fundamental changes in their biochemical profile. Hypertrophic chondrocytes switch their collagen profile to type X collagen and are able to calcify their surrounding matrix. Moreover, hypertrophic differentiation is strongly linked to the increased expression of matrix-degrading enzymes, particularly matrix metalloproteinase (MMP)-13,[18] vascular endothelial growth factor (VEGF),[19] and transglutaminase 2.[20] These changes are controlled prominently by hypoxia, and it has been suggested that HIF-2α is a central transactivator regulating the expression of type X collagen and other catabolic genes critical for endochondral ossification.[21,22] However, this view has been challenged by the observation that endochondral bone formation is only transiently and modestly delayed in mice harbouring a homozygous loss of HIF-2α in limb bud mesenchyme.[23] Thus, while the mechanisms that regulate the differentiation of hypertrophic chondrocytes and subsequent degradation of the extracellular matrix during bone development are only partly understood, an in-depth understanding of these processes helps explain the cellular and biochemical structure of adult joints, and recent data also suggest that joint pathologies such as osteoarthritis are characterized by the (re)activation of certain parts of this embryogenic programme (Figure 56.2).

The primary function of the chondrocytes in the articular cartilage is to maintain the structure of the surrounding matrix through coordinated production and degradation of its components. The exact mechanisms that ensure the homeostatic stability of these resting chondrocytes remain elusive, but it is important to emphasize that the term 'resting chondrocytes' does not mean low metabolic activity. Rather, these cells are characterized by the high-level production of cartilage matrix components, which allows for continuous cartilage remodelling and provides the basis for the regenerative capacity of the cartilage.

The extracellular matrix of cartilage consists mainly of three structural elements: cartilage collagens, proteoglycans, and other non-collagenous proteins. The main collagen of cartilage is type II collagen. It has a triple helical structure and forms fibrillar suprastructures that includes type IX collagen as a fibril-associated collagen with interrupted triple helix (FACIT) as well as type XI collagen.[24] As has been only recently understood, these additional collagens within the collagen II fibrils are important for fibrillogenesis.[25] In addition to collagen types II, IX, and XI, other collagens such as type VI are found in the cartilage.[26] Collagens constitute the backbone of extracellular matrix in the cartilage and their turnover rate is low. Thus, the half-life of type II collagen has been estimated as to more than a human lifetime, which explains why cartilage damage can be considered largely irreversible once the integrity of the collagen network is lost. However, the regenerative capacity of cartilage is considerable, and this is largely due to the constant renewal of other key components of its extracellular matrix, namely the glycosaminoglycans and proteoglycans.

Hyaluronan (HA) is a key glycosaminoglycan in cartilage.[27] It constitutes the structural basis for the formation of large water-binding aggregates with proteoglycans, mainly aggrecan. The amount of hyaluronan in the cartilage, as determined by the rate of synthesis as well as the length of the individual hyaluronan molecules, is therefore an important determinant of the cartilage structure and its functional properties.[28] Other glycosaminoglycans in the cartilage include HS, chondroitin sulfate, and keratan sulfate, which are usually bound to proteins in specific proteoglycans.

Aside from the collagen network, such proteoglycans constitute the most important components of the cartilage matrix, with aggrecan being the most abundant proteoglycan of cartilage.[29] It can be cleaved by different metalloproteinases, including ADAMTS4 (aggrecanase-1) and ADAMTS5 (aggrecanase-2) as well as MMPs such as MMP-3 (stromelysin) and MMP-13 (collagenase-3), and contains a large number of keratan sulfate and chondroitin sulfate side chains. The specific function of the large number of highly sulfated chondroitin sulfate side chains is a matter of intense studies, particularly because several lines of evidence suggest that the sulfation pattern is not only variable but changes significantly during ageing.

Proteoglycans are also found on the surface of chondrocytes (Figure 56.3). These cell-surface proteoglycans include the families of syndecans and glypicans and are anchored to the cell either through a transmembrane domain, as characteristic for the syndecans, or through covalent binding of the C-terminus to glycosylphosphatidylinositol, as found in glypicans. They are endowed with individually characteristic numbers of heparan sulfate or
Fig. 56.2 Cell–matrix interactions in cartilage. The interaction of chondrocytes with the extracellular matrix (ECM) plays a critical role in regulating the differentiation of chondrocytes during physiological development, as in embryogenesis, but also under pathological conditions such as degenerative joint diseases (e.g. osteoarthritis) or chronic inflammatory arthritis (e.g. rheumatoid arthritis). Three classes of cell-surface molecules have been identified to contribute most prominently to the interaction of chondrocytes with ECM components: integrins, syndecans, and glypicans. The integrins and syndecans contain intracellular domains and can initiate signalling cascades both independently and in collaboration with one another.
Fig. 56.3 Fibroblast-mediated cartilage destruction in rheumatoid arthritis. Under normal conditions, the physiological function of synovial fibroblasts is to build a lining membrane that secretes lubricants and provides the joint cavity and the adjacent cartilage with nutritive plasma proteins. In addition, synovial fibroblasts are involved in matrix remodelling. In rheumatoid inflammation, cellular alterations following activation through inflammatory stimuli, chemokines, and growth factors result in a tumour-like transformation of these cells. Importantly, several lines of evidence suggest that in addition to these soluble factors, damaged cartilage contains ECM components that contribute to the stable activation of RA synovial fibroblasts. These cells exhibit a special phenotype with unique features such as reduced susceptibility to apoptosis, expression of cartilage adhesion molecules, and the increased production of matrix-degrading enzymes. At a morphological level, RA synovial fibroblasts show a rough endoplasmatic reticulum, large nuclei with prominent nucleoli, and a more rounded shape. The mechanisms that imprint these changes into transformed-looking fibroblasts are not entirely clear, but epigenetic changes have been shown to constitute an important factor in this process.

chondroitin sulfate side chains that can bind a variety of molecules including components of the extracellular matrix such as fibronectin and a growing list of soluble mediators, particularly growth factors but also cytokines and chemokines.[30] Our knowledge about the role of these cell-surface heparan sulfate proteoglycans (HSPG) in the regulation of chondrocyte differentiation and behaviour has increased dramatically in recent years, and it has been shown that the effects of growth factors such as FGF-2,[31] and also cytokines such as osteopontin[32] or chemokines such as CXCL10,[33] are regulated strongly by HSPGs such as syndecan-4. Importantly, cell-surface HSPGs can modulate the effects of soluble factors in different ways, and the role of syndecan-4 in FGF-2 signalling is best investigated in this context. Thus, it has been shown that the clustering of syndecan-4 and initiation of syndecan-4 specific PKCα signals together with altered receptor internalization contribute to syndecan-4-mediated modulation of FGF-2 signalling.[34] Whether similar mechanisms also work for other syndecan ligands and whether such independent and most likely specific signalling function of syndecans can be separated from this non-specific role is a matter of intense research.

Cartilage biochemistry and pathology in arthritis

Osteoarthritis (OA) is the most common joint disease and, at the same time a pathological condition that is most closely linked to changes in cartilage biology. It is a debilitating disorder that is characterized by the progressive destruction of articular cartilage through uncontrolled proteolysis of extracellular matrix and typically leads to a remodelling of affected joints. OA as a disease is discussed in more detail in other chapters of this book, but is

important to note at this point that although the incidence of OA increases with age, it is not a pure ageing phenomenon. Rather, OA is characterized by profound alterations to the biology of chondrocytes that shows important similarities to enchondral ossification as it occurs during embryogenesis, as described above. Recent data suggest that the triggers that initiate and drive the disease process in OA in some respect may be distinct from those in embryonic development and more influenced by inflammation, which is why the term 'osteoarthritis' has been chosen. However, accumulating evidence supports the view that OA constitutes quite a uniform way of how chondrocytes and cartilage as a whole react to stress that they are unable to compensate for. This means that although the triggers that initiate OA and the contribution of individual factors such as genetics, inflammation, mechanical stress, and others may vary considerably from patient to patient, there is an ultimately rather narrow path or programme that characterizes its pathophysiology.

Thus, during OA articular chondrocytes revert to an immature chondrocytic stage and even undergo prehypertrophic to terminal chondrocyte maturation, indicating that their differentiation state, although normally permanent, is not terminal. Losing their differentiated phenotype, the chondrocytes in affected cartilage enter an enchondral ossification-like cascade of proliferation and hypertrophic differentiation.[35] This change is accompanied by marker expression for the overt hypertrophic differentiation stage,[36] such as alkaline phosphatase and type X collagen, with subsequent apoptotic death and mineralization of the diseased cartilage.[37] Therefore, recent studies focus on the mechanisms that either stabilize the articular phenotype or induce chondrocyte dedifferentiation. It has been learnt that osteoarthritic changes are associated with the re-expression of molecules and pathways in articular chondrocytes that are characteristic for different stages of enchondral ossification. The transmembrane HSPGs mentioned earlier, particularly syndecan-4, are a prime example for this concept. Thus, it was demonstrated that syndecan-4 is re-expressed in both in human OA and in animal models of the disease and this correlates with its severity. Interestingly, the loss of synedcan-4 in genetically modified mice or its inhibition by specific antibodies prevented mice from the development of OA-like changes suggesting that, indeed, interrupting the cascade that leads to the completion of the aberrant chondrocyte differentiation programme may be of therapeutic value.[38] Likewise, it was demonstrated that the hypoxia-inducible factor HIF-2α, which (as outlined above) has been implicated strongly in enchondral ossification and in the regulation of genes involved in chondrocyte hypertrophy, also contributes to the development of OA.[39]

It has been well established that matrix-degrading enzymes, mainly metalloproteinases of the ADAMTS and the MMP families, are ultimately responsible for the breakdown of extracellular matrix in OA and, thus, for the progressive loss of articular cartilage. Among the different enzymes, particularly MMP-13 and ADAMTS-5 have been associated with chondrocyte-mediated cartilage damage, and it has been demonstrated in animal models of OA that the loss of these enzymes or inhibition of their activation results in less-severe cartilage damage. However, not only is it likely that the relevance of individual members of the MMP and ADAMTS family varies during different phases of OA, but it may also hypothesized that other MMPs, e.g. MMP-3 or MT1-MMP, which themselves are a critical activators of other MMPs and cathepsins, contribute to the loss of articular cartilage in OA. It needs to be emphasized, however, that

cartilage matrix can be degraded by these enzymes not only when they are released from chondrocytes themselves but also when there is an increased and unbalanced expression in neighbouring tissues such as the synovial membrane. The most prominent example of a disease where cartilage destruction is mediated mainly by an invading synovial membrane is rheumatoid arthritis (RA). In RA, the inflamed and hyperplastic synovial membrane that attaches to the articular cartilage grows deeply into the cartilage matrix and destroys it. Data from different animal models including the SCID mouse model of RA-like cartilage destruction and the human TNFα transgenic (hTNFtg) mouse suggest that cartilage destruction by the inflamed and hyperplastic synovium requires the attachment and, thus, the direct contact of the synovial tissue with the cartilage. Also, the early loss of proteoglycans from the cartilage, which is most likely driven by the chondrocytes themselves, appears to constitute an important prerequisite for the pannus tissue to invade. This notion has been derived not only from studying the sequence of destructive events in the hTNFtg mouse but also from experiments in which these hTNFtg mice were crossed with animals that lack interleukin (IL)-1, an important mediator of early proteoglycan loss.[40] The resulting hTNFtg/IL-1 knockout mice do develop inflammatory arthritis with pannus formation, but their cartilage is largely protected, showing no significant loss of proteoglycans and also no attachment and invasion of the pannus tissue.

Composition and biochemistry of the synovial membrane

The synovial membrane is a second specific component of synovial joints. Normally, it is only a few (~4–5) cell layers thick and consists mainly of fibroblast-like cells that through cell–cell contacts form a layer that lines up the synovial membrane against the joint cavity and the synovial fluid. The fibroblast-like synoviocytes (FLS) have a key function in providing the joint cavity and the adjacent cartilage with lubricating molecules such as hyaluronic acid as well as with plasma-derived nutrients. Unlike other bordering membranes, the synovium has no basal membrane, which makes it significantly different from the classical composition of an epithelium. Also, cellular contacts between the FLS lack tight junctions and desmosomes, which together with the absence of a basal membrane, facilitates the efflux of serum components from the small capillaries into the synovial space. However, this means that the most superficial layer of the synovial membrane, the intimal lining layer, has to take over these functions. In this context, the adhesion molecule cadherin-11 has been shown to mediate a strong homophilic adhesion between synoviocytes and to be largely responsible for their organization into a tissue.[41] This most superficial lining layer of the synovium can be separated histologically from the looser network of fibroblasts underneath, which is called the sublining. In addition to the FLS, also termed type B synoviocytes, there are macrophages in the synovial membrane, which are also called type A synoviocytes. In addition to providing the synovial cavity with nutrients and lubricating factors, production of extracellular matrix (ECM) components and cross-linking these into the specific three-dimensional structure is the main function of the cells of the synovial membrane, mainly the FLS. This is an active process in which the fibroblasts have to migrate to sites of tissue remodelling and to interact with ECM molecules through specific surface receptors (Figure 56.3).

For the interaction with ECM components, particularly collagens, integrin receptors are of special importance. They are heterodimeric molecules that consist of one α and one β chain; at least 16 different α and 8 different β chains have been identified so far. Normally, FLS use their integrins receptors to sense and interact with ECM components within the synovial membrane, but under pathological conditions they have been shown also to mediate the interaction with cartilage collagens and other cartilage components. For the attachment of synovial fibroblasts to ECM components of connective tissue and cartilage, β_1-integrins are especially important.[42] $\alpha_1\beta_1$-, $\alpha_2\beta_1$-, $\alpha_{10}\beta_1$-, and $\alpha_{11}\beta_1$-integrins are those family members that are mainly responsible for the attachment of fibroblasts to collagen. Other members of the β_1 integrin family including $\alpha_4\beta_1$- and $\alpha_5\beta_1$-integrins are responsible for the attachment of fibroblasts to fibronectin and its spliced variants. It is important to emphasize that the engagement of integrin receptors on the surface of FLS, just like on other cells, does not merely establish a cell–matrix contact but leads to the formation of adhesive cell structures that are called focal adhesions. As a consequence of their formation, intracellular signalling cascades are being activated that regulate the transcription of genes and thus control cell proliferation and survival, and secretion of certain cytokines and chemokines as well as matrix deposition and resorption. Among the molecules that transmit the signals from integrin clusters to the interior of FLS, the focal adhesion kinase (FAK) plays a central role.[43] However, many signalling pathways can also be activated by FAK-independent signalling mechanisms, particularly through growth factors but also cytokines and chemokines, and the question of how the signals from different sources, including those from focal adhesions, are coordinated into a specific cellular response is a matter of intense research.

The analysis of cell–matrix interactions of FLS is complicated by two observations. First, other and even more complex adhesive and invasive structures have been identified and characterized in recent years and the question of what role such podosome-like structures play in normal and pathological joint remodelling remain unclear. While classical podosomes are found mainly on macrophages and related cells, it has been reported that podosome-like structures such as invadopodia are also found on other cells such as fibroblasts, particularly when they are transformed.[44] The second important observation has been that in addition to integrins, syndecans are involved in the attachment of fibroblasts to ECM components as well as in their response to growth factors and cytokines. In the joint, syndecans are expressed not only on chondrocytes but also on fibroblasts. It could be demonstrated that the response of syndecan-4-deficient fibroblasts to fibronectin attachment is significantly altered[45] and that syndecan-4-deficient fibroblasts have a reduced ability to differentiate into alpha-smooth muscle actin (α-SMA) positive myofibroblasts. The exact mechanisms by which syndecans are involved in the specific functions of different fibroblast populations will soon be elucidated—it appears that syndecans are important cell-surface receptors that, due to their unique properties, integrate signals from ECM components and soluble factors.

The fibroblasts of the synovial membrane are not only responsible for the deposition of ECM molecules and their assembly, but are also prominently involved in their destruction and removal. For the degradation of ECM components, FLS produce a diversity of matrix-degrading enzymes. These include members of the metalloproteinase family, including MMPs and ADAMTS but also different cathepsins. Most MMPs are not expressed constitutively but

only upon induction by specific stimuli such as cytokines, growth factors, or ECM molecules. Among the cytokines, IL-1 is perhaps the most potent inducer of a variety of MMPs and has been shown to strongly regulate the expression of MMP-1, -3, -8, -13 and -14. Growth factors such as FGF and platelet-derived growth factor (PDGF) can also induce MMPs in fibroblasts and, thus, act synergistically with cytokines on MMP expression. The third group of MMP inducers are matrix proteins, and especially their degradation products; these activate MMP expression in fibroblasts, providing the possibility for a site-specific MMP activation in regions of matrix breakdown.[46] There are several intracellular signalling pathways that are responsible for the transcriptional activation of MMPs. Thus, bindings sites for the activator protein-1 (AP-1) are present in the promoters of nearly all MMPs, suggesting that the jun/fos transcription factors contribute prominently to the regulation of these enzymes. Indeed, there is ample evidence that all three mitogen/stress-activated protein kinase (MAPK/SAPK) families, ERK, JNK, and p38 kinase are involved in the regulation of MMP expression by integrating signals upstream of jun/fos. This has been shown particularly for MMP-1, -9 and -13.[47–49] Importantly, the promoter regions of several MMPs that have been shown to be relevant in pathologic tissue destruction also contain binding sites for NFκB,[47–49] STAT,[50] and Ets.[51]

Synovial biochemistry in arthritis

The composition, the molecular pattern, and also the biochemistry of the synovial membrane change dramatically during inflammation. This is true for acute inflammatory episodes where the accumulation of inflammatory cells with subsequent stimulation of the local mesenchyme occurs for a limited period of time, but even more so for chronic inflammation. The mechanisms that regulate the switch from acute to chronic inflammation within the synovium are not very well understood. However, it has been shown that FLS contribute significantly to this process. This has become particularly evident for RA, where these cells are a key part of the local immune system in the joints and integrate signals from different sources into a pathological tissue response. While responding to the stimuli in the chronically inflamed synovium, RA FLS undergo fundamental changes, and multiple lines of evidence suggest that the result is a stable activation, which is maintained even in the absence of continuous stimulation by inflammatory triggers. As a consequence of this stable FLS activation, the disease process is perpetuated and might progress when inflammation ameliorates. The underlying mechanisms are not entirely clear, but the chronic exposure of FLS to inflammatory cytokines, growth factors, and the ECM appears to result in the imprinting of an aggressive phenotype. However, it should be mentioned that due to their general properties, FLS are involved very prominently in regulating and modulating the local immune response in the joints. To this end, they not express a variety of cytokine receptors but also Toll-like receptors (TLRs) through which they can react to damage-associated molecular pattern (DAMP), and Fc-receptors to respond to immunglobulins.

Of note, synovial fibroblasts are not only stimulated by inflammatory and immune cells and their mediators but in turn also contribute to the accumulation of these cells. Thus, the influx of CD4+ T cells into the proliferating synovium is enhanced by RA synovial fibroblasts due to their production of CXCL16 and IL-16. RA FLS are also an important source of cytokines with IL-2-like activity,

IL-15, and IL-7, in RA joints. RA synovial fibroblasts have been shown to contribute to the attraction and accumulation of B cells in inflamed tissue. For example, the secretion of SDF-1 by synovial fibroblasts has been shown to facilitate B-cell migration and activation to the synovium. In summary, the interaction between mesenchymal, immune and inflammatory cells is mediated by a tightly regulated, extremely complex network of cytokines that results in the maintenance of inflammation.

CHAPTER 57

Vascular biology

Clare Thornton and Justin Mason

Introduction

Vascular biology involves the study not only of the physiological functions of the vasculature but also of how the vasculature may itself be a target for disease processes. Although the relevance of vascular biology to the rheumatic diseases has long been recognized, our appreciation and understanding of its importance has developed considerably over the last 15 years. The vasculature can be implicated at various levels. First, the microvasculature provides the portal of entry for leucocytes migrating to the sites of inflammation including the rheumatoid joint. Second, the vasculature may be the direct target for primary disease mechanisms in systemic sclerosis, the anti-phospholipid syndrome, and the vasculitides. The vasculature may also be a secondary target, with chronic systemic inflammation predisposing to endothelial dysfunction and increased arterial stiffness, thus escalating the risk of thrombosis and accelerated atherogenesis. Finally, the vasculature represents an important therapeutic target for disease-modifying drugs, biological therapies, and novel anti-angiogenic approaches, as well as for the deleterious effects of some agents.

Structure of the vasculature and heterogeneity of endothelium

The vasculature, composed of blood vessels, lymphatics, and the heart, originates embryologically from the mesoderm. The systemic and pulmonary circulations have the same basic organization of blood vessels, with large elastic arteries exiting the heart, followed by small muscular arteries, arterioles (the site of autoregulation of vascular tone) and then the capillary bed (the site of nutrient and waste product exchange), which feeds back into post-capillary venules (where the majority of leucocyte-endothelial cell interactions take place), and lastly large veins to return blood to the atria.

Blood vessels have walls composed of three layers (Figure 57.1), although their size and relative composition varies. The tunica intima is comprised of the endothelium, the one-cell-thick inner lining of all blood vessels, and the subendothelial basement membrane to which they are attached. The tunica media is formed from layers of fibroelastic tissue and smooth muscle in elastic arteries, and a thicker layer of smooth muscle in muscular arteries, distinctly separated from the intima by the internal elastic lamina.

Atherosclerotic plaques form between the intima and internal elastic lamina. The adventitia is made up of surrounding layers of connective tissue, through which runs the vasa vasorum: a capillary network supplying the tissues of the arterial wall. The same layers exist in veins, the main differences being a larger lumen and thinner smooth muscle layers. Capillaries consist only of endothelium and a basement membrane, in order to allow the efficient diffusion of nutrients and waste products.

The endothelium forms a continuous monolayer throughout the entire vasculature. The historical view of its function was of an inert tissue layer that maintained vessel wall permeability, but research conducted over the last 30 years reveals a biologically active tissue that carries out diverse functions, acting at the interface between blood constituents and the tissues.

The endothelium within different organs and vessels is heterogeneous. For example, brain endothelial cells (EC) are linked by tight junctions in order to maintain the blood–brain barrier, while the bone marrow has discontinuous EC to facilitate cellular trafficking, and the glomerular capillary tuft contains fenestrations to permit ultrafiltration.

EC heterogeneity may influence the spatial distribution of vascular diseases: atherosclerotic plaques preferentially occur at arterial branch points and sites of turbulent blood flow, suggesting that mechanical forces acting on EC are important in their initiation and development. Thrombus content and formation differs according to the vessel type involved. Lastly, the systemic vasculitides are classified by their predilection for blood vessels of a specific size, suggesting that there are predisposing features peculiar to each type.

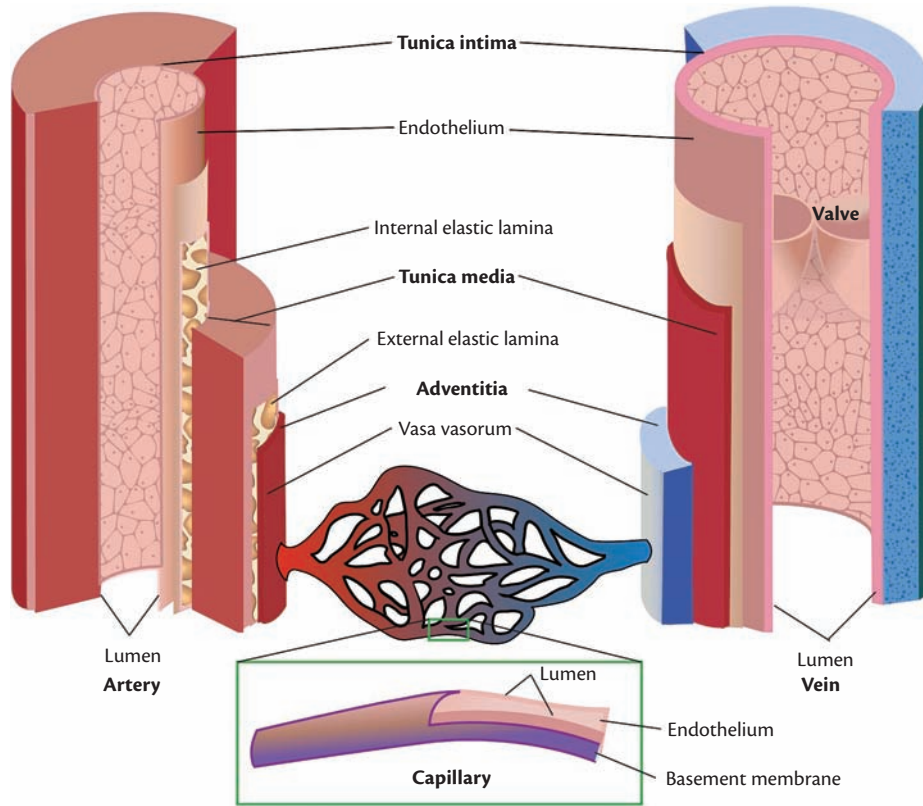
The endothelium is the focus of much vascular biology research on account of its diverse functions and because it is the site of initial injury in many vascular diseases. For example, the 'response to injury' hypothesis to explain atherogenesis suggests that this starts with endothelial injury and dysfunction,[1] while angiogenesis begins with vessel destabilization and endothelial migration. Human umbilical vein endothelial cells (HUVEC) are the predominant cell type used in in-vitro vascular biology research, although cell lines are available that represent arterial, pulmonary, and microvascular endothelium. Although it may seem counterintuitive to study the origins of vascular diseases using cells that are venous and of fetal origin, HUVEC have proved a reliable model for the study of endothelial biology as a whole.


Fig. 57.1 The structure of the vasculature and blood vessel walls.
Fig. 57.2 The leucocyte adhesion cascade. Leucocyte recruitment is a multistep process in which initial tethering and rolling of leucocytes is facilitated by low-affinity interactions between selectins and their carbohydrate ligands. Rolling allows leucocytes to sample the microenvironment and following leukocyte integrin activation by chemokines, stable cellular arrest is achieved through the interaction of β_2-integrins and their immunoglobulin superfamily ligands including ICAM-1 and VCAM-1. E-selectin, ICAM-1, and VCAM-1 expression on the endothelial surface is upregulated by proinflammatory cytokines including TNFα and IL-1. Adherent leucocytes migrate to intercellular junctions and transmigrate across the endothelial barrier and underlying basement membrane, following chemokine gradients and utilizing interactions with a variety of junctional proteins such as PECAM-1 and CD99.

Leucocyte trafficking

The vascular endothelium plays a central role in the regulation of leucocyte recruitment to sites of inflammation and infection. The multistep cascades involved in the specific recruitment of neutrophils, monocytes, and lymphocytes are now well-defined (Figure 57.2). Leucocyte recruitment is modulated by molecular interactions with EC, alongside additional direct and indirect influences from pericytes, vascular smooth muscle cells, and the extracellular matrix. The initial step, leucocyte tethering and rolling, is facilitated by the selectins: E-selectin and P-selectin expressed on the surface of cytokine-activated endothelium, and L-selectin present on the leucocyte surface. Selectins bind carbohydrate ligands including sialyl Lewis X and PSGL-1. Interactions between integrins and immunoglobulin superfamily members are principally involved in the arrest and spreading of leucocytes on the endothelial surface, a process dependent upon chemokine-mediated integrin activation. Thus, integrins including LFA-1 and $\alpha_4\beta_1$ interact with ICAM-1 and VCAM-1 respectively.[2] Leucocyte transmigration is promoted by junctional adhesion molecules (JAM) A and C, PECAM-1 (CD31), CD99, and VE-cadherin, with migration directed by a chemokine gradient.[3]

Failure to regulate the inflammatory response is a characteristic feature of chronic arthritis. The endothelium of postcapillary venules at these sites is activated, rich in cellular adhesion molecules, and provides the portal of entry to the synovium for
Fig. 57.3 The rheumatoid synovium. Photomicrograph of rheumatoid synovium stained with haematoxylin and eosin. The arrows points to inflamed high endothelial venules which act as the portal of entry for the leucocyte infiltrate.

leucocytes (Figure 57.3). These observations led to clinical trials of monoclonal antibody therapy directed at specific cellular adhesion molecules in rheumatoid arthritis (RA), which proved largely ineffective.[4] Conventional disease-modifying anti-rheumatic drugs (DMARDs) including methotrexate and mycophenolate may modulate adhesion molecule induction by proinflammatory cytokines. However, targeting upstream proinflammatory cytokines has proved particularly effective and relatively safe. This is exemplified by the tumour necrosis factor (TNF)α antagonists, which reverse vascular endothelial activation and suppress cellular adhesion molecules including E and P-selectin, ICAM, and VCAM-1.

Vascular injury

Vascular injury represents an important primary component in a variety of rheumatic diseases including systemic lupus erythematosus (SLE), vasculitides, and the anti-phospholipid syndrome. In ANCA-associated vasculitides (AAV), activated neutrophils are responsible for local disruption of the endothelial monolayer and recent studies suggest a role for complement in AAV-associated vascular injury,[5,6] which can be severe enough to result in life-threatening haemorrhage. The efficacy of B-cell-depleting monoclonal antibody therapy in AAV also suggests a direct role for B cells in pathogenesis, above and beyond their role as plasma cell precursors.[7]

The large-vessel vasculitides, giant cell arteritis (GCA) and Takayasu's arteritis, are characterized by granulomatous inflammation. The vaso vasorum acts as the portal of entry for an inflammatory infiltrate comprising activated dendritic cells, α/β and γ/δ T lymphocytes, B lymphocytes, macrophages, and multinucleated giant cells. Intimal hyperplasia is the consequence of myofibroblast proliferation, driven by growth factors including platelet-derived growth factor (PDGF), and resulting in progressive loss of the arterial lumen. Intriguing recent studies suggest that Toll-like receptors (TLR) influence the pattern of vascular injury in GCA. In a human–murine chimera model, TLR4 ligands induced a panarteritis and TLR5 ligands a periarteritis, a response related to differential dendritic cell responses, chemokine secretion, and T-cell recruitment.[8]

Endothelial dysfunction and accelerated atherosclerosis

Homeostatic mechanisms maintain a quiescent, anti-thrombotic, anti-adhesive vascular endothelium and control vasodilatation and permeability. This requires biosynthesis of nitric oxide (NO) and prostacyclin, expression of thrombomodulin, anti-apoptotic proteins including Bcl-2 and A1, and anti-oxidant/anti-inflammatory enzymes such as superoxide dismutase and haem oxygenase-1. These processes, controlled by intrinsic gene expression and external stimuli, maintain vascular integrity and initiate repair in the face of noxious stimuli including advanced glycation end products, proinflammatory cytokines, activated leucocytes, and oxidatively modified low-density lipoproteins. Prolonged systemic inflammation in RA and SLE is associated with endothelial apoptosis, inducing a local inflammatory response and endothelial dysfunction.[9] The latter, an important precursor to atherosclerosis, is potentially reversible and characterized by reduced NO biosynthesis, oxidative stress, increased permeability, and accumulation of lipoproteins and monocytes in the subintimal space.

RA and SLE are independent risk factors for accelerated atherogenesis.[10,11] Mechanisms include increased levels of oxidative stress and proinflammatory cytokines, resulting in endothelial activation, enhanced leucocyte adhesion, deleterious effects of immune complexes, anti-phospholipid antibodies, homocysteinaemia, and CD4+CD28− T cells.[12,13] Anti- high-density lipoprotein (HDL) antibodies may interfere with anti-atherogenic effects of HDL, as may anti-apolipoprotein A-I (apo A-I), as apo A-I is one of the major constituents of HDL.[14] These antibodies have been associated with reduced activity of HDL paroxonase, an anti-oxidant which prevents oxidation of low-density lipoprotein (LDL), thus contributing to the anti-atherogenic effects of HDL.

Despite the increased risk, only a subset of patients develop premature atherosclerosis and effective means for their early identification are required. Flow-mediated dilatation and pulse-wave velocity demonstrate endothelial dysfunction and aortic stiffness, and improvements with therapy have been reported.[15] High-resolution ultrasound can monitor intima-media thickness, identify early plaque, and predict risk of a cardiovascular event.[16,17] Positron emission tomography (PET) and MRI can identify microvascular dysfunction, arterial inflammation, and early asymptomatic atherogenesis in patients with RA, SLE, and Takayasu's arteritis.[18–22] However, identification of the optimal method(s) for detecting preclinical vascular disease and prospective data to demonstrate the effectiveness of this approach is required.

Thrombosis

Thrombosis is an important pathological process in many rheumatological diseases. Large-vessel thromboses, both venous and arterial, occur in Behçet's syndrome and the anti-phospholipid syndrome (APLS). Thrombosis also occurs in small vessels, principally as the end result of chronic vessel wall hyperplasia or inflammation, in diseases such as systemic sclerosis, vasculitis, and pulmonary arterial hypertension.

Activation of the coagulation cascade, leading to thrombosis, may be caused by abnormalities in the vessel wall, blood constituents, or blood flow, as described by Virchow's triad. Of most relevance to rheumatological disease is thrombosis triggered by abnormalities

in the vessel wall, i.e. the endothelium. Endothelial activation leads to expression of tissue factor on the luminal surface, which triggers the extrinsic clotting cascade pathway.

APLS is associated with thrombosis in both arteries and veins.[23] Anti-phospholipid antibodies directed against β_2-glycoprotein-1 activate EC, along with monocytes and platelets. Activated EC express adhesion molecules and upregulate tissue factor production (as do monocytes). Increased tissue factor and thromboxane A2 from platelets leads to a procoagulant state, but for thrombosis to occur, a second hit is needed. This may be provided, for example, by complement cascade activation. Anti-phospholipid antibodies may also interact with other proteins within the coagulation cascade such as prothrombin, factor X, protein C, and plasmin and may therefore adversely affect fibrinolysis.

Thrombosis is also a prominent clinical feature of Behçet's syndrome. The majority are venous, causing superficial thrombophlebitis and deep venous thromboses, including superior vena cava obstruction, cerebral vein thrombosis, and Budd–Chiari syndrome. In a small number of cases, there is a pulmonary arterial vasculitis, leading to in-situ pulmonary arterial thromboses. Although small studies have suggested that thrombosis in Behçet's syndrome is linked to the concurrent presence of a prothrombotic condition such as factor V Leiden or prothrombin mutations, this is not thought to be the cause in the majority of cases.[24] There is indirect evidence to suggest that the procoagulant state arises from an abnormally 'sticky' activated endothelium, as a result of chronic vascular inflammation.[25] Clinically, this is supported by a small trial comparing treatment of thromboses in Behçet's syndrome by anticoagulation, immunosuppression, or both together.[26] A higher proportion of patients treated by anticoagulation alone had recurrent thromboses compared to those given immunosuppression, suggesting that it is the suppression of inflammation, which would be expected to reduce the degree of endothelial activation, that minimizes the tendency to thrombosis, rather than inhibition of the coagulation cascade.

Angiogenesis

Angiogenesis is a carefully regulated multistep process driven by proangiogenic mediators including growth factors, chemokines, and cellular adhesion molecules, acting via specific receptors. In adults, angiogenesis is involved in the menstrual cycle and wound healing. Angiogenesis has been implicated in various rheumatic diseases and most widely studied in RA, with development of neovessels being one of the earliest detectable changes in the rheumatoid synovium.[27–29] In psoriatic arthropathy, angiogenic vessels can be distinguished morphologically from those in RA, with the former described as tortuous and bushy and the latter straight and branching.[30] In the vasculitides, angiogenic neovessels are found in the arterial wall in GCA, while proangiogenic growth factors are increased in the serum of patients with AAV and Kawasaki's syndrome. However, the role of angiogenesis in this setting is poorly understood.

Neovascularization permits the delivery of cells, proinflammatory mediators, and nutrients to the developing rheumatoid pannus and predisposes to joint and tendon damage. Neovessels are inherently unstable with poor EC–pericyte interactions and evidence of oxidative damage and this may contribute to persistent intra-articular hypoxia.[31] Of note, impaired vasculogenesis may be a contributory factor, with reduced, poorly functioning endothelial progenitor cells reported.[32] Likewise in systemic sclerosis impaired angiogenesis and vasculogenesis have been implicated in pathogenesis.[33]

An array of proangiogenic and angiostatic cytokines are present in the rheumatoid joint. These include vascular endothelial growth factor A (VEGF-A), basic fibroblast growth factor (FGF-2), transforming growth factor beta (TGFβ), PDGF, TNFα and CXCL8/IL-8, CXCL12/stromal-derived growth factor-α, and CXCL1/Gro-α.[34] VEGF-A, which induces EC proliferation and changes in vascular permeability, correlates with joint destruction in inflammatory arthritis.[35] Hypoxia is a key driver of VEGF synthesis, through the stabilization of hypoxia inducible factors (HIF) 1 and 2.[36]

Although there is considerable interest in anti-angiogenic therapies, further work is required to identify the most effective sites for intervention. The efficacy of an anti-angiogenic approach has been demonstrated in rodents. Thus, inhibition of $\alpha V \beta_3$ or VEGF signalling pathways attenuates rabbit and murine inflammatory arthritis respectively.[37–39] Methotrexate, sulphasalazine, and hydroxychloroquine all exert anti-angiogenic effects, at least in vitro,[28] while anti-TNFα therapy reduces proangiogenic mediators and synovial vascularity.[35,40,41] However, while development of more specific anti-angiogenic therapies may be beneficial, progress has been slow. Although anti-VEGF approaches are of interest, the significant side effects associated with the prolonged use of anti-VEGF-A monoclonal antibody (bevacizumab), including hypertension and thrombosis, may preclude its use in chronic diseases.[42,43]

Effect of drugs on the endothelium

Although it is well established that chronic inflammation leads to vascular injury and eventually atherosclerosis, much less is known about whether treating the primary inflammatory condition also reduces the associated cardiovascular disease (CVD) burden. Given that the development of atherosclerosis begins with endothelial dysfunction, an understanding of which drugs influence EC function—whether beneficially or harmfully—would assist the development of treatment regimes designed to delay or prevent vascular damage.

Statins and angiotensin converting enzyme (ACE) inhibitors—drugs commonly used in the treatment of CVD or its associated metabolic precursors—have been demonstrated to have specific beneficial effects on the vascular endothelium, in addition to their established lipid-lowering and vasodilatory actions. Likewise, several disease-modifying or immunosuppressant drugs have been investigated for their effects on endothelial function and in a few cases have been shown to reduce the incidence of CVD in chronic inflammation. Conversely, others may in fact be harmful.

Statins

The principal lipid-lowering mechanism of action of statins is inhibition of 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase in hepatocytes, leading to reduced cholesterol synthesis and hence a reduction in CVD. However, large primary prevention trials also indicate that they can reduce cardiovascular morbidity and mortality independent of changes in serum cholesterol. This pleiotropic effect arises from the inhibition of HMG-CoA reductase in EC and other cells of the immune system, which appears

Table 57.1 Summary of clinical data regarding the cardiovascular effects of various commonly prescribed immunosuppressants and DMARDs

Drug	CVD mortality	CVD incidence	Endothelial dysfunction	Carotid intima–media thickness
Methotrexate	Reduced in RA[52–54]	Reduced in RA and inflammatory arthritis[52–54]	Improved[55]; improved in responders[56]	No change[57,58]; Reduced in associated with HCQ[59]; and in associated with prednisolone[60]
Anti-TNFα therapy		Reduced[61]; reduced in responders[62]; no effect[63]	Improved[55,58,64]; improved in responders[65]	No change[57,58]
Rituximab			Improved in short term[66]	
Ciclosporin			Worsened in transplant pts[67]; worsened compared to AZA[68] or rapamycin[69]	Improved in LN[70]
Mycophenolate mofetil		Improved cardiac allograft vasculopathy[71]		No change in LN[70] or SLE[72]
Azathioprine		Use associated with CVD events in SLE but disease severity confounding[73,74]	No change in kidney transplant patients[68]	No change in LN[70]; worsened in SLE but disease severity confounding[75]
Sulphasalazine		No effect[52]; improved in combination with MTX[76]		
Hydroxychloroquine		Improved in combination with MTX and SSZ[76]; no effect[52]		Improved in combination with MTX[59]; no change in LN[70]
Glucocorticoid steroids		Increased[63]	Worsened in (juvenile) SLE but confounding disease severity[77]; low dose no change in RA[78]	Improved in combination with MTX in RA[60]; no change in LN[70]
Tocilizumab			Improved in short term[79]	
Leflunomide		Reduced[63] although 6 patients only		

AZA, azathioprine; CVD, cardiovascular disease; HCQ, hydroxychloroquine; jSLE, juvenile SLE; LN, lupus nephritis; MTX, methotrexate; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; SSZ: sulphasalazine.

to have anti-inflammatory effects. The METEOR trial examined changes in C-reactive protein (CRP) in patients taking rosuvastatin, and showed a 36% reduction,[44] while the JUPITER trial demonstrated that rosuvastatin reduced CV mortality in individuals with normal LDL concentrations but a raised CRP analysed using a high-sensitivity assay.[45] An anti-inflammatory effect was also observed in the TARA trial in which atorvastatin improved RA disease activity.[46]

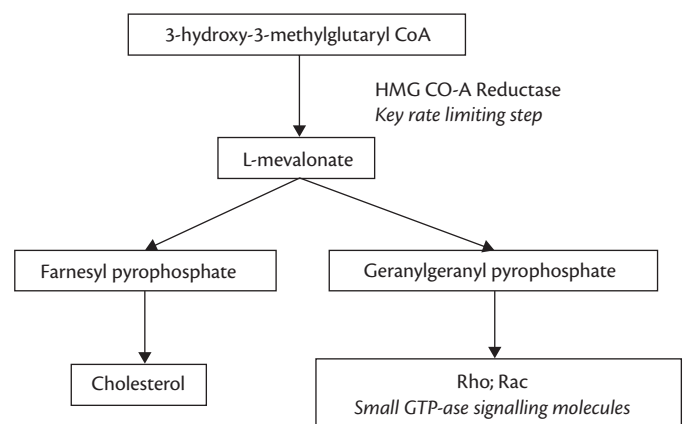
HMG-CoA reductase inhibition improves EC function in various ways. It prevents synthesis of isoprenoid intermediates such as geranylgeranyl pyrophosphate, important for the activation of small GTP-ase signalling molecules such as Rho and Rac (Figure 57.4).[47,48] Statins inhibit Rho and Rac signalling, and this leads to upregulation of endothelial NO synthase and thus increased NO biosynthesis. NO is both anti-inflammatory and vasodilatory. Disruption of Rho and Rac also modulates signalling pathways which induce cytoprotective genes such as haem oxygenase-1 and the complement inhibitory protein decay-accelerating factor (DAF).[49,50] Lastly, the anti-inflammatory effects of statins on EC also include inhibition of cellular adhesion molecules, so reducing leucocyte trafficking and potentially retarding the development of atherosclerotic plaques.[51]


Fig. 57.4 The downstream effects of HMG Co-A reductase inhibition.

Statins also affect other cells of the immune system important for atherogenesis. In macrophages, they can induce expression of the anti-inflammatory transcription factor PPARγ, and prevent IL-6 mediated induction of MCP-1. They also exhibit immunomodulatory and anti-thrombotic effects in T lymphocytes and platelets respectively.

A major caveat, however, when discussing the vasculoprotective properties of statins, is that they have largely been demonstrated using concentrations in vitro and in vivo that exceed 1 μM, several-folds higher than the concentrations achieved in patient sera. Nonetheless, these combined immunomodulatory, anti-inflammatory, and complement inhibitory actions may prove to be important mechanisms underlying the anti-rheumatic and vasculoprotective effect of statins.

DMARDs and immunosuppressant drugs

A number of DMARDs and immunosuppressant drugs have been investigated with respect to their effects on CVD, with some likely to be beneficial (methotrexate and anti-TNFα therapy) and others possibly harmful (ciclosporin). It is unknown whether these effects are due purely to their anti-inflammatory properties, or whether they have additional specific actions on the endothelium. Clinical research to date is summarized in Table 57.1, although it should be noted that some of these studies derive from the transplant literature.

Clinical evidence suggests methotrexate has a beneficial effect on vascular biology when prescribed in RA. Choi et al.[52] demonstrated a relative risk reduction of 70% in cardiovascular mortality in RA patients taking methotrexate compared to those on other DMARDs (hydroxychloroquine, sulphasalazine, gold, D-penicillamine). This has recently been reinforced by a systematic review[53] and meta-analysis,[54] although lesser degrees of relative risk reduction were found. Smaller studies have demonstrated that methotrexate improves endothelial dysfunction in patients with RA.[55,56] In-vitro work indicates that methotrexate has anti-inflammatory effects on EC: it downregulates the TNFα-induced upregulation of ICAM-1 and VCAM-1,[80] as well as increasing adenosine production (as a proportion of total nucleotides).[81] Methotrexate also reduces endothelial cell proliferation in vitro and angiogenesis in vivo[82]; hence, inhibition of synovial neovascularization may contribute to its anti-rheumatic effects.

Although the cumulative experience with anti-TNFα therapy may yet be too short to demonstrate conclusively an effect on RA cardiovascular mortality, small studies indicate it is likely to be improved. Data from the British Society for Rheumatology (BSR) Biologics Register shows that anti-TNFα responders had a lower incidence of myocardial infarction,[62] and reversal of endothelial dysfunction has also been reported.[55,64]

Ciclosporin, an immunosuppressant used in the treatment of connective tissue diseases such as polymyositis, may have deleterious effects on the vasculature, although these have largely been examined in organ transplant patients. Clinical studies suggest that it worsens endothelial dysfunction, as measured by flow-mediated dilatation, and laboratory evidence supports this.[83] Ciclosporin treatment in a rodent model of transplantation reduced endothelial NO synthase (eNOS) and endothelium-dependent relaxation, and increased endothelin-1 expression. However, tacrolimus, a related drug, may preserve endothelial function relative to ciclosporin, and it does not induce endothelin-1. Similarly, rapamycin also exhibits a more favourable vascular profile.[84]

The majority of other DMARDs and biological agents are either too new or not yet prescribed with sufficient frequency for their influence on cardiovascular risk in chronic inflammation to be determined. However, there are a few factors to take into account. Tocilizumab, an inhibitor of IL-6 signalling, might be expected to have a beneficial effect on cardiovascular risk, but this may be mitigated by its adverse effects on lipid profile. Leflunomide, while very effective in treating RA, can worsen hypertension, thus offsetting any beneficial effect on the vasculature. One family of drugs very commonly used in clinical practice, whose effects on the vasculature might be expected to be well known by now, are glucocorticoid steroids. However, they cause such a range of both beneficial and harmful effects, that no conclusive overall picture has yet been reached.

NSAIDs and COX-2 inhibitors

The effects of cyclooxygenase (COX)-2 inhibition on the vasculature has received much attention recently, due to the withdrawal of rofecoxib following concerns that it increased the rate of myocardial infarction (MI).[85] It is now understood that both traditional NSAIDs and COX-2 inhibitors may increase the risk of MI, although establishing the degree of risk and the relative safety profiles between drugs is difficult, owing to trial heterogeneity and a lack of randomized controlled trial data on older NSAIDs. A recent network meta-analysis has suggested that no traditional NSAID or COX-2 inhibitor is entirely safe, but naproxen appears least harmful.[86]

The mechanisms that explain how COX inhibition increases the risk of cardiovascular events relate to its downstream effects on synthesis of prostaglandins and thromboxane A2. COX inhibition reduces prostaglandin synthesis in the kidney, reducing renal medullary blood flow and thereby increasing water and salt retention. This can precipitate heart failure in susceptible individuals. Secondly, it alters the balance between prostacyclin production in EC, which causes vasodilation and platelet inhibition, and thromboxane-A2 production in platelets, which causes vasoconstriction and platelet activation. Perturbation of this balance may underlie the increased incidence of MI seen with most NSAIDs and COX-2 inhibitors.

Nevertheless, many questions remain, including whether COX-1 or COX-2 is the predominant source of endothelial prostacyclin. In addition, there is evidence to suggest that celecoxib may improve vascular endothelial function in men with coronary artery disease.[87] Recent in-vitro work has demonstrated that celecoxib, like atorvastatin, can induce haem oxygenase-1 in EC. This effect was independent of COX inhibition and not seen with other COX-2 inhibitors.[88] These and other reports have led to current interest in the specific COX-independent actions of celecoxib.[89]

Future approaches

In light of the cardiovascular sequelae associated with many chronic inflammatory rheumatic diseases, consideration needs to be given to the design of treatment regimens that maximize benefits to the vascular endothelium. Success can subsequently be measured as a return in cardiovascular mortality towards that seen in the general population. This ambition requires a detailed knowledge of the effects of DMARDs and immunosuppressant drugs on the vasculature, including their effects on protective pathways such as NO synthesis, anti-inflammatory and anti-oxidant gene expression, and on signalling pathways and transcription factors that control vasculoprotective genes. Furthermore, long-term clinical trials of sufficient size and with defined cardiovascular endpoints are required. It will be challenging to achieve this, particularly given the relative rarity

of many chronic inflammatory conditions. However, results from clinical trials in RA may reasonably be extrapolated to rarer diseases, so optimizing future protection from vascular injury for our patients.

CHAPTER 58

Acute-phase responses and adipocytokines

Elena Neumann, Klaus Frommer, and Ulf Müller-Ladner

Introduction

Adipose tissue is a structural component of many organs. The central function of adipose tissue in energy metabolism is well known, with adipocytes being the dominant cell type. This cell produces and secretes highly bioactive substances, the adipokines, which are also called adipocytokines, such as adiponectin, resistin, leptin, and visfatin.[1–4] In addition, adipocytes produce several proinflammatory factors including tumour necrosis factor alpha (TNFα), interleukin (IL)-6, and factors of the complement system, growth factors, and adhesion molecules. All of them contribute actively to activation of the innate immune system and modulation of the immune response.[1,3–5] There is increasing knowledge on the various effects of adipokines under different pathophysiological conditions including rheumatic diseases.[3,6] As outlined below, the potency of adipokines to modulate the immune system under healthy and chronic inflammatory pathophysiological conditions is significant and has a substantial part in the initiation and perpetuation of the respective disease entities.

Immunomodulatory adipokines

Adiponectin

Adiponectin is mainly but not exclusively produced by adipocytes and accounts for 0.05% of total serum protein in humans. Adiponectin is a complex molecule which exists in different isoforms with sometimes counteracting functions under pathophysiological conditions including rheumatic diseases.[3] The effects of the respective isoforms are most likely mediated by induction of different signalling cascades and selective receptor affinity binding.[3,7] Oligomerization and the expression levels of its receptors directly influence the effects mediated by adiponectin.[7,8]

The human adiponectin isoforms are well described, in contrast to the murine isoforms. In humans, the isoforms are formed from the adiponectin monomer leading to a 'bouquet of flowers' structure.[7] The adiponectin trimer, the low molecular weight (LMW) adiponectin isoform, is composed of three full-length adiponectin monomers that form a collagen triple helix with a C-terminal globular head domain (gC1q domain).[7] The hexamer isoform is a combination of two adiponectin trimers and called middle molecular weight (MMW) adiponectin. The high molecular weight (HMW) adiponectin consists of 12–18 monomers. The globular adiponectin isoform consists solely of the head domain of trimeric adiponectin and is formed by proteolytic cleavage.

Two adiponectin receptors with signalling function, adipoR1 and adipoR2, have been characterized. AdipoR1 has a higher affinity for globular adiponectin. AdipoR2 has a higher affinity for trimeric adiponectin and most likely the higher molecular weight isoforms.[9] In addition to the known adiponectin receptors, additional potential adiponectin receptors have been described. Among those are progestin and the adipoQ receptor family members III (PAQR3) or X (PAQR10).[3] Their affinity for the individual adiponectin isoforms and their functions are largely unknown. In addition, an integral membrane protein, T-cadherin, binds MMW and HMW adiponectin but not globular or trimeric adiponectin.[10] T-cadherin has no cytosolic signalling domain and may therefore serve as a coreceptor or accessory surface molecule. Furthermore, other surface molecules are able to modulate the function or activity of the adiponectin receptors, such as APPL1,[11] protein kinase CK2,[12] and ERp46.[13]

Besides its metabolic functions, adiponectin is involved in the modulation of several immunomodulatory pathways in different diseases.[1,4,14] Although initially mainly anti-inflammatory and antifibrotic effects have been described, there is growing evidence for a proinflammatory and prodestructive role of adiponectin under different pathophysiological conditions. Examples of the heterogeneous role of adiponectin are listed in Table 58.1.

Resistin

Similar to adiponectin, an immunomodulatory potential for resistin has also been described. In contrast to adiponectin, the main effects of resistin in the immune system seem to be proinflammatory.[15] For example, resistin induces proinflammatory cytokines in mouse and human macrophages.[3,6,16,17] and activates human endothelial cells.[16] Furthermore, cytokines as well as chemokines are induced in a variety of human cells, including fibroblasts and endothelial

Table 58.1 Examples of the heterogeneous functions of adiponectin

Effect on inflammation and joint destruction	Effect
Pro-inflammatory	Induction of proinflammatory cytokines and chemokines in RA effector cells Induction of NO synthase in chondrocytes
Anti-inflammatory	Mitigates arthritis severity in the collagen-induced arthritis mouse model Inhibition of cell proliferation
Pro-destructive	Induction of RANKL and inhibition of OPG in osteoblasts
Anti-destructive	Inhibition of osteoclast formation, increase of osteoblast mineralization activity
Anti-apoptotic	Suppression of endothelial cell apoptosis by HMW adiponectin

HMW, high molecular weight; NO, nitric oxide; OPG, osteoprotegerin; RA, rheumatoid arthritis.

cells after stimulation with resistin.[3,16] Therefore, resistin seems to be associated with inflammation and exerts proinflammatory effects on the innate and adaptive immune system.[18] Similar to adiponectin, resistin forms multimeric structures. Physiologically, resistin exists as a monomer and a dimer. The resistin monomer is a non-covalent assembly of three protomers, while the dimeric resistin consists of two such monomers joined covalently by disulfide bonds.

Leptin

Leptin is a central adipokine in energy metabolism. Leptin also has immunoregulatory functions similar to adiponectin and resistin. The leptin serum levels are altered under pathophysiological conditions including chronic inflammatory diseases.[2,3,6] Acute as well as initial proinflammatory responses are modulated by leptin.[19,20] Leptin is involved in modulation of T-cell-mediated immune responses.[2] Additionally, other cells involved in inflammation are activated by leptin including monocytes, fibroblasts, and neutrophils.[2,19,20] However, the actual role of leptin in the inflammatory adipokine network is difficult to define because of its central regulatory role in metabolism and energy homeostasis.

Visfatin/PBEF

Visfatin, also known as pre-B cell colony enhancing factor (PBEF) or Nampt because of its nicotinamide phosphoribosyl-transferase (NAmPRTase) activity, is also involved in cell metabolism. Similar to resistin, it has an immunomodulatory potential with mainly proinflammatory effects under pathophysiological conditions.[5] Visfatin/PBEF is positively correlated with serum C-reactive protein (CRP) in different diseases, including rheumatoid arthritis (RA).[3,6] Furthermore, leucocytes are activated by visfatin/PBEF resulting in increased amounts of co-stimulatory molecules on the cell surface. In lymphocytes and monocytes, it induces proinflammatory cytokines in rheumatoid arthritis.[3,5,6] Furthermore, lymphocyte proliferation is stimulated by visfatin/PBEF in RA.[3,5,6] Cells such as neutrophils are protected from

apoptosis by visfatin/PBEF under pathophysiological conditions such as atherosclerosis or sepsis.[21]

Visfatin/PBEF has been shown to be involved in inflammatory processes of different (chronic) inflammatory diseases including RA.[3,5,6,22] Visfatin/PBEF is increased under chronic inflammatory conditions and may be involved in chronification due to its potential to further increase the proinflammatory reactions within the affected tissues.

Other 'new' adipokines

Omentin

Omentin is a recently identified adipokine of the omental adipose tissue.[23,24] It is secreted as a homotrimeric glycoprotein consisting of 313 amino acids with a molecular weight of 34 kDa per monomer.[24] Omentin is differentially expressed in omental adipose tissue under pathophysiological conditions, specifically in patients with Crohn's disease.[24] It is able to mediate metabolic as well as immunological effects.[25,26] Because of functional similarities to lectins, omentin was also called intelectin. Omentin has been also discussed as lactoferrin-binding protein and thought to be a lactoferrin receptor with immunomodulatory potential.[27]

Vaspin

Vaspin, which is similar to omentin, has recently been added to the list of adipokines. It belongs to the serin protease inhibitor family and has insulin-sensitizing effects. It is predominantly expressed in visceral adipose tissue. In addition, a role in inflammation and obesity has been suggested for vaspin.[25,28]

Chemerin

Chemerin was first discovered as a chemokine[29] and was only later added to the group of adipokines.[30-32] Similar to leptin, it is involved in energy metabolism as well as metabolic syndrome.[30-32] Chemerin occurs in different isoforms[33] and is structurally related to cathelicidin precursors (antibacterial peptides). Chemerin circulates as an inactive precursor and is activated by proteolytic cleavage at the C-terminus involving proteases. After activation, it is a strong chemoattractant for immature dendritic cells and macrophages[29] and is involved in inflammatory processes.[34]

Adipokines in inflammatory rheumatic diseases

In inflammation, adipokines are induced locally under different pathophysiological conditions including rheumatic diseases.[3,6] Although an altered expression and secretion of adipokines has been described for several adipokines in rheumatic diseases,[2,3,6] knowledge about the role of the respective adipokines in the disease pathology is limited. However, there is evidence that adipokines are able to induce immunomodulatory responses in different cell types responsible for inflammation as well as tissue remodelling/destruction.[3,6,8,17,22] Interestingly, adipokines are able to induce each other, forming an 'adipokine network' potentially contributing to the early induction of inflammation as well as to chronification of the respective disease.

Adipokines in rheumatoid arthritis

Most information on the role of adipokines in rheumatic diseases is available for RA. Adipokines including adiponectin, visfatin/PBEF, resistin, leptin, chemerin, vaspin, and omentin are increased

or decreased in serum and/or synovial fluid of RA patients.[3,6,14,25] Adiponectin, resistin and visfatin serum or plasma levels, respectively, were increased in RA vs controls, although in some adiponectin studies no significant differences could be observed.[2,3,6] These different findings may be due to the increase of adiponectin especially in erosive vs mild RA, which also seems to correlate with joint erosion[2,3,6,14] and, interestingly, with vascular endothelial growth factor (VEGF) levels.[35]

Adipokines are not only produced by adipose tissue but also locally by additional cell types. The possibility of an existing adipokine network influencing the inflammatory response is reflected by the presence of different adipokines in the same compartments within the affected tissue. For example, the adipokines adiponectin, visfatin, and resistin are not only expressed by articular adipose tissue[33] and especially at the synovial lining layer and invasion zone, but also in the perivascular area, lymphocyte infiltrates, and single cells in the sublining.

In these compartments, a major source of adipokines are the RA synovial fibroblasts (RA-SF) as well as macrophages (Figure 58.1).[2,3,6,14] The adipokines produced in the synovium affect different effector cell types especially at sites of joint destruction, synovial angiogenesis, and inflammation. In addition, some knowledge is available about the effects of adipokines on the cell types localized in these areas. With regard to the early initiation of inflammation, the correlation of adipokines with inflammation markers is the first hint showing the link between adipokines and inflammation in RA. For example, CRP and other proinflammatory markers are correlated with systemic resistin and visfatin levels.[2,3,6,15]

Adiponectin has been described as being systemically increased in RA and as being associated with radiographic damage.[3,6,36,37]

A central cell type of cartilage destruction, the RA-SF, produces increased amounts of proinflammatory cytokines, growth factors and especially chemokines in response to adiponectin.[2,3,6,8,38,38a] Furthermore, chemokine production, which enhances further articular inflammation, is induced by adiponectin in endothelial cells, lymphocytes as well as chondrocytes in the synovium.[2,3,14]

However, in contrast to the above-mentioned proinflammatory effects on local synovial cells in vitro, in an in-vivo model of RA, the collagen-induced arthritis (CIA) model, application of adiponectin resulted in reduced severity of arthritis.[3,6] The reasons for the observed differences in the effects mediated by adiponectin are not completely clear. The different effects could be due to different protein (isoform) function in rodents and humans, the differences of the human and murine adiponectin (isoform) proteins, the use of different recombinant proteins with varying isoform compositions in the respective experiments, or systemic effects in vivo that are not visible in single-cell type experiments in vitro.

In contrast to the in part contradictory results on the immunomodulatory effects of adiponectin in RA, resistin and visfatin seem to be solely proinflammatory. Besides the correlation of proinflammatory markers such as CRP, IL-1ra, or TNFα with serum resistin, local resistin concentrations in the synovial fluid are higher than in the serum of the same patients.[3,6,16] Similar to adiponectin, resistin induced proinflammatory cytokines in peripheral blood mononuclear cells (PBMC)[16] and chondrocytes.[39] In turn, resistin is inducible in PBMC by proinflammatory factors showing a proinflammatory feedback loop locally active in the synovium.[16] In addition, a strong proinflammatory effect of resistin was confirmed using an in-vivo model by an intra-articular resistin injection, which led subsequently to rapid joint destruction.[16]
Fig. 58.1 Adipokines in rheumatoid arthritis (RA) synovial tissue. Adipokines such as adiponectin, resistin, visfatin/PBEF, omentin, and chemerin are expressed in the synovial lining layer. Perivascular areas, lymphocyte infiltrates, and adipocytes in the synovium express adipokines as well as single cells in the synovial sublining. Of note, in the invasion zone into cartilage, mainly consisting of invading fibroblasts, adipokines such as adiponectin and visfatin/PBEF are also expressed. Therefore, a variety of cell types involved in RA pathophysiology are exposed to adipokines and, depending on the cell type, in turn respond to these factors by releasing proinflammatory and prodestructive factors. Of note, the presence of adipokines in the synovial fluid and serum is not depicted in this figure.

Table 58.2 Adipokines in rheumatoid arthritis

	Systemic parameters	Local effects	Therapeutic effects
Adiponectin	Systemic adiponectin correlates with disease activity and severity	Proinflammatory and prodestructive factors are induced in RA-SF, chondrocytes Proinflammatory effects are induced in lymphocytes, endothelial cells	Influence of anti-TNF treatment visible but unclear Adiponectin reduces CIA severity
Visfatin	Systemic visfatin is increased in RA patients as well as in synovial fluids. Systemic visfatin correlates with systemic inflammation parameters and disease activity	Visfatin expression by RA-SF is regulated by TLRs and chemokines Visfatin induces proinflammatory and prodestructive factors in RA-SF. Visfatin protects synovial cells from apoptosis	In CIA, visfatin inhibition ameliorates arthritis severity
Resistin	Systemic resistin is increased in RA patients Systemic inflammation markers correlate with systemic resistin. Synovial fluid/serum resistin ratio is increased in RA	Proinflammatory factors are induced in RA-SF and inflammatory cells by resistin	Anti-TNF treatment reduces systemic resistin. Intra-articular resistin injection induces arthritis in rodents
Leptin	Potential association between leptin levels and RA (progression). Synovial fluid/serum ratios correlate with RA progression and activity	In RA-SF and chondrocytes, IL-8 is increased by leptin Leptin influences T cell activity and Treg proliferation	No influence of anti-TNF treatment on systemic leptin levels. Arthritis severity in leptin-deficient ob/ob mice is reduced and zymosan-induced arthritis. Acute inflammation resolution is delayed
Chemerin Omentin Vaspin	Vaspin synovial fluid levels are increased in RA, omentin levels decreased. Omentin levels correlate with serum ACPA and IgM-RF. Chemerin synovial fluid levels are higher than systemic levels	Chemerin has pro-inflammatory effects on RA-SF. Chemerin is induced by IL-1	Not available

ACPA, anti-citrullinated protein antibodies; CIA, collagen-induced arthritis; IL, interleukin; RA, rheumatoid arthritis; RA-SF, rheumatoid arthritis synovial fibroblasts; TLR, Toll-like receptors; TNF, tumour necrosis factor; Treg, regulatory T cell.

Visfatin is also increased locally in the synovial fluid of affected RA joints and in the serum as mentioned above. The proinflammatory effects on leucocytes, synovial fibroblasts, and neutrophils have been shown by different groups,[3,6,22] and seem to have an additional effect on the hyperplasia of the synovium by protection from apoptosis of synovial cells such as fibroblasts and neutrophils.[21] Similar to resistin, inhibition of visfatin results in reduced arthritis severity and anti-inflammatory responses in inflammatory cells in the CIA model, suggesting a proinflammatory role of visfatin in RA.[3,6] Taken together, these findings show that resistin, visfatin, and potentially adiponectin locally contribute to central inflammatory processes operative in RA joints.

In contrast to the findings from the above-mentioned adipokines, the function of leptin on RA inflammation and joint destruction is difficult to elucidate. Systemic levels of leptin seem to be increased in RA. However, leptin levels are influenced by body fat content, body mass index (BMI), treatment, and disease activity and progression, leading to discrepancies in the measured leptin levels in RA patients vs controls.[2,3,6] In the synovial fluid, leptin concentrations seem to be increased in comparison to the systemic leptin levels and to be correlated to joint erosion.[3,6] Interestingly, severity of arthritis in leptin-deficient ob/ob mice was reduced in comparison to controls.[3,6] In addition, detailed data on the effects of leptin on different cell types is limited. Although leptin influences the inflammatory response, especially via T cells,[2,6] and a proinflammatory effect via an increase of IL-8 in RA-SF[6] has been described,

the available information on systemic and local effects of leptin on destructive and inflammatory processes is not sufficient to confirm a clear pro- or anti-inflammatory role.

On a number of proteins recently identified as adipokines, only limited information is available about their role in RA pathophysiology. Vaspin levels in synovial fluid of RA patients were significantly higher than in osteoarthritis (OA) controls[25] as well as in serum.[40] In contrast, omentin levels in synovial fluids were reduced in RA when compared to osteoarthritis in this study. Both factors did not correlate with CRP or synovial fluid leucocyte counts. Of note, omentin but not vaspin correlated with anti-citrullinated protein antibodies (ACPA) and IgM-RF, showing a potential role in chronic RA inflammation.[25]

Interestingly, plasma concentrations of chemerin isoforms chem163S, chem158K, and chem157S are lower than synovial fluid levels in patients with RA, psoriatic arthritis, and OA, although no significant differences could be found for the respective diseases.[41] An increased expression of chemerin in the lining, sublining, and endothelial cells could be detected in RA in comparison to OA.[42,43] In addition, chemerin was identified as proinflammatory activator of RA-SF.[42,43] After proteolytic activation, it is a strong chemoattractant for immature dendritic cells and macrophages[29] but not for synovial fibroblasts,[43] although it does increase cell motility of this cell type.[42] Chemerin is secreted by adipose tissue[32] but also by other cell types including RA-SF[43] and chondrocytes.[44,45] It is found in similar concentrations in synovial fluid of patients

with RA, OA, and psoriatic arthritis[43]; however, chemerin activity is increased in synovial fluid of RA patients compared to OA patients.[29] Additionally, chemerin increased TLR4 expression and MCP-1 secretion of synovial fibroblasts,[43] and enhanced the secretion of proinflammatory factors in chondrocytes.[44] These results suggest a role of chemerin in the innate immune system-associated joint inflammation.

In summary, the data suggest a potential proinflammatory local adipokine network active in RA synovial tissue within the affected joints (Table 58.2). However, interaction and comparison of systemic to local effects are still to be evaluated to clarify the in part contradictory data available on the role of adipokines in RA pathophysiology.

Adiponectin in systemic lupus erythematosus

In contrast to RA, the knowledge on the role of adipokines in the pathogenesis of other rheumatic diseases is mainly limited to information on serum levels and correlation to inflammation markers. However, besides the increased plasma and urine adiponectin levels in patients with systemic lupus erythematosus (SLE), especially with glomerulonephritis,[3,6] a proinflammatory role of adiponectin has been identified. Recombinant full-length adiponectin (consisting of all isoforms) but not globular adiponectin induced the chemokines IL-8 and MCP-1 in microvascular endothelial cells and monocytes,[3,6] although these effects may not be completely specific for SLE.

Serum levels of leptin were negatively correlated to androstenedione in SLE as well as RA patients[3] and may be involved in RA and SLE hypoandrogenicity. In addition, leptin and a high-fat diet induced proinflammatory high-density lipoproteins in lupus-prone mice.[6] In contrast, although resistin levels did not differ between SLE patients and controls, resistin was correlated with systemic inflammation in these patients.[46]

Adiponectin in spondyloarthropathies

Although Toussirot and colleagues found no altered adiponectin serum levels detectable in ankylosing spondylitis (AS) patients,[3] Derdemezis and colleagues reported increased adiponectin but not leptin levels in AS.[47] Serum levels of resistin were increased when compared to OA controls.[3,6] In contrast, synovial fluid resistin levels were not as high as in RA or OA in this study. As in RA, the data on systemic leptin levels in AS is not clear, as increased as well as decreased leptin serum levels have been reported.[3] However, systemic leptin levels seem to be correlated with CRP and IL-6,[3] and again adjustment to BMI and other metabolic parameters may be required for these analyses. However, leptin seems to be associated with proinflammatory effects on PBMC in AS patients, due to the increased expression of leptin, IL-6, and TNF in PBMC from AS patients in comparison to healthy controls.[48]

Adiponectin in other inflammatory rheumatic diseases

In systemic sclerosis (SSc), leptin levels seem to be reduced.[3] However, no additional information is available on the effects of adipokines on SSc-related inflammation and fibrosis. Similarly, limited information is available with respect to other rheumatic diseases such as vasculitis. In ANCA-associated vasculitis, leptin levels were significantly lower in comparison to healthy controls and were negatively correlated with disease activity in this study.[49]

In contrast, in Behçet's disease, leptin concentrations during active disease were increased when compared to inactive periods as well as in patients with longer disease duration.[3] Resistin and IL-6 serum levels were significantly higher in these patients in comparison to healthy controls.[50] Although no information on the effects and local expression at sites of pathophysiological alterations are available in these diseases, a link to inflammation is to be expected. However, the anti- and proinflammatory potential of these factors remains to be clarified.

Clinical features of adipokines in rheumatic diseases

The presence of adipokines in the serum, local compartments and tissues is not only affected by the respective pathophysiological condition, it is in part influenced by therapeutic interventions potentially serving as a parameter of treatment efficiency.

For example, in RA patients, systemic adiponectin is altered by treatment with TNF inhibitors showing an increase of adiponectin serum levels after TNF blockade in two studies, although there were also studies showing decreased or unaltered adiponectin serum levels after anti-TNF therapy.[3,6] In contrast, methotrexate seems to increase adiponectin serum levels in RA patients and resistin seems to be downregulated after anti-TNF treatment whereas leptin is not influenced.[3,6] In AS, systemic adiponectin and leptin levels were not altered by anti-TNF treatment.[6]

Conclusion

Adipokines affect the immune system and may be involved in early innate immune responses in addition to processes leading to chronic inflammation. Adipokines also affect matrix remodelling depending on the respective disease in addition to their role in inflammation. Because of the pluripotent functions of adipokines, there are currently many efforts to analyse the role of an adipokine or different adipokines under pathophysiological conditions, especially in chronic inflammatory diseases. However, as adipokines are able to influence each other and show partly contrary effects depending on the tissue, organ, and pathophysiological condition analysed, it is necessary to further characterize the adipokine network before potential therapeutic interventions in central adipokine-dependent pathways can be developed. Adipokine function has to be characterized, especially as adipokines are central effectors of metabolism and systemic therapeutic intervention may lead to strong unknown side effects that are reflected in the data available in animal models. Detailed understanding of the adipokine effects on the innate and adaptive immune system are required to identify specific isoforms, adipokine interactions, or receptors which make it possible to modulate the local response of adipokines without modifying central, vital pathways. The variety of possibilities in this relatively new field of 'immunoendocrinology' offers various possibilities for interesting new insights in adipokine-oriented research for the near future.

CHAPTER 59

Pain neurophysiology

Hans-Georg Schaible and Rainer H. Straub

The nature of pain

♦ **Physiological nociceptive pain** is evoked by high-energy stimuli acting on healthy tissue which potentially or actually damage the tissue (noxious stimuli). This type of pain is a warning sensation and essential for survival because it triggers adequate protective reactions of the endangered organism. Pain treatment must not impair this type of pain.

♦ **Pathophysiological nociceptive pain** occurs during inflammation or after injury. It appears as allodynia (occurrence of pain upon an innocuous stimulus of low energy which is normally not painful) and/or hyperalgesia (increased pain during the application of noxious stimuli). Finally, resting pain (in the absence of intentional stimulation) may occur. This pain impairs normal life and requires treatment.

♦ **Neuropathic pain** is evoked by damage to the neurons of the nociceptive system. Causes are nerve damage, metabolic diseases (e.g. diabetes mellitus), infections such as herpes zoster and others. Neuropathic pain does not primarily signal noxious tissue stimulation, is often felt to be abnormal (burning or electrical character), and can be persistent or occur in short episodes (e.g. trigeminal neuralgia). It may be combined with hyperalgesia and allodynia or with sensory loss.[1]

The nociceptive system

Nociception is the encoding and processing of noxious stimuli. Neurons which encode noxious stimuli (see above) at the different levels of the neuraxis form the nociceptive system (see scheme in Figure 59.1A). It consists of the peripheral nociceptors supplying almost all organs and tissues of the body, nociceptive spinal cord neurons, which are synaptically activated by nociceptors, and nociceptive neurons in the thalamocortical system, which are activated by ascending neural tracts such as the spinothalamic tract. Furthermore, ascending tracts (the spinothalamic and spinoreticular tract) activate nociception-related nuclei in the brain stem. From there further neural projections branch into cerebral structures such as the amygdala. As shown in Figure 59.1B, some brainstem nuclei, the periaqueductal grey (PAG), and the rostral ventral medulla (RVM) and their axons, form descending systems which control the nociceptive processing at the spinal level either in an inhibitory or facilitatory fashion.[2]

Peripheral nociceptors are thinly myelinated (Aδ-fibres) or unmyelinated (C-fibres). Their sensory endings are so-called 'free nerve endings', i.e. they are not equipped with corpuscular end organs. Most of the nociceptors are polymodal, responding to noxious mechanical stimuli (painful pressure, squeezing or cutting the tissue), to noxious thermal stimuli (heat or cold), and to chemical stimuli.[3] It is highly important that a proportion of the afferent sensory nerve fibres, the **peptidergic** nociceptors, not only have an afferent function by transmitting nociceptive input to the central nervous system but that they have in addition an efferent function by releasing substance P and other neuropeptides such as calcitonin-related peptide (CGRP) and galanin into the vicinity of the peripheral nerve terminal. Upon trauma with or without infection, these afferent fibres can also induce vasodilation, plasma extravasation, and other pathophysiological effects, e.g. the attraction of macrophages or the degranulation of mast cells. This **neurogenic inflammation** is the first component of an innate inflammatory response that induces a cascade of subsequent mechanisms such as chemotaxis, upregulation of adhesion molecules, and activation of immune cells. In particular substance P is an immunostimulatory neuropeptide that activates macrophages, fibroblasts, neutrophils, lymphocytes, and other immune cells leading to secretion of proinflammatory cytokines.[4] The other subset of nociceptors is **non-peptidergic** (IB4-positive neurons). The skin is innervated by both peptidergic and IB4-positive nociceptive afferents, but the vast majority of afferents in the musculoskeletal system are peptidergic.

A single peripheral nociceptor supplies a specific site of the body such as the skin, skeletal muscle, a joint, or a visceral organ. In contrast, many **nociceptive neurons in the spinal cord** exhibit convergent inputs from nociceptors from different organs/tissues.[5] This is the basis for referred pain, i.e. pain is sometimes felt in a structure other than the stimulated one. In particular, pain originating in the visceral tissues may be felt in the somatic tissue of the same neuronal segment. Nociceptive spinal neurons are either ascending tract neurons (see above) or interneurons that are part of segmental motor or vegetative reflex pathways. However, the spinal cord through sympathetic reflexes and the brain itself through descending influences can influence diverse pathological processes in the affected tissues. This is relevant for the neuronal influences on the course of inflammation.

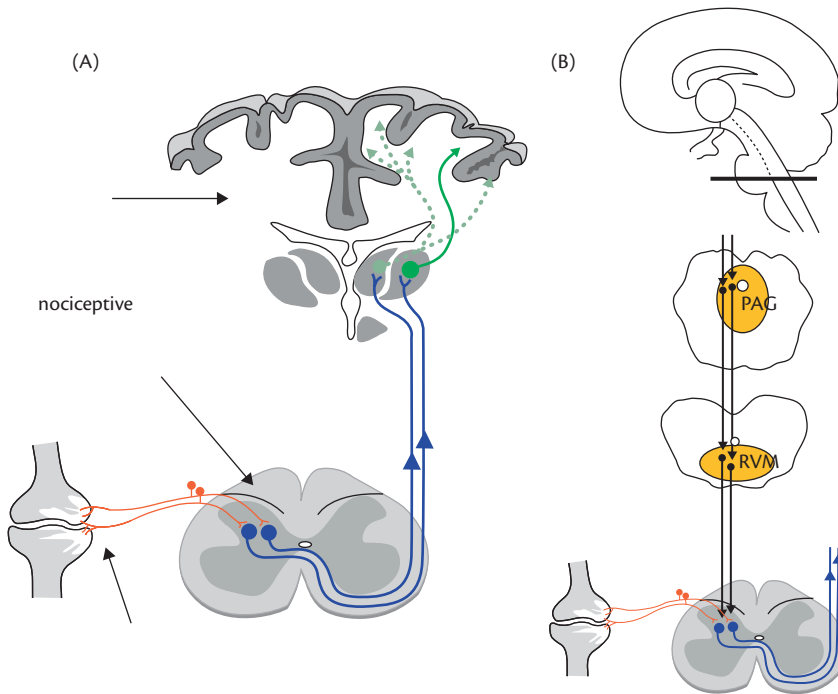
The conscious sensation of pain is generated in the thalamocortical system (Figure 59.1A). The **lateral thalamocortical system** consists of relay nuclei in the lateral thalamus and the areas SI and


Fig. 59.1 Simplified scheme of the structure of the nociceptive system and major events during inflammatory pain states. (A) Upon inflammation the sensory nociceptive system exhibits sensitization of peripheral nociceptors (peripheral sensitization) and hyperexcitability of nociceptive neurons in the spinal cord (central sensitization). The latter determines the amount of activation of the thalamocortical nociceptive system. (B) Descending systems originating in the brainstem which inhibit or facilitate the nociceptive processing at the spinal level. PAG, periaqueductal grey matter; RVM: rostroventral medulla.

SII in the postcentral gyri. In these areas the noxious stimulus is analysed for its location, duration, and intensity (sensory discriminative aspect). The **medial thalamocortical system** consists of relay nuclei in the central and medial thalamus and the anterior cingulate cortex (ACC), the insula, and the prefrontal cortex. In these structures the affective component of suffering is produced, and in particular the ACC is thought to be involved in the selection of the proper response.[6] In addition these structures contribute to the activation of the inhibitory system which descends from the brainstem to the spinal cord in the dorsolateral funiculus (see Figure 59.1B). This system is thought to be responsible for the powerful analgesic placebo effects.[2,6]

Nociceptive processing under normal and pathological conditions

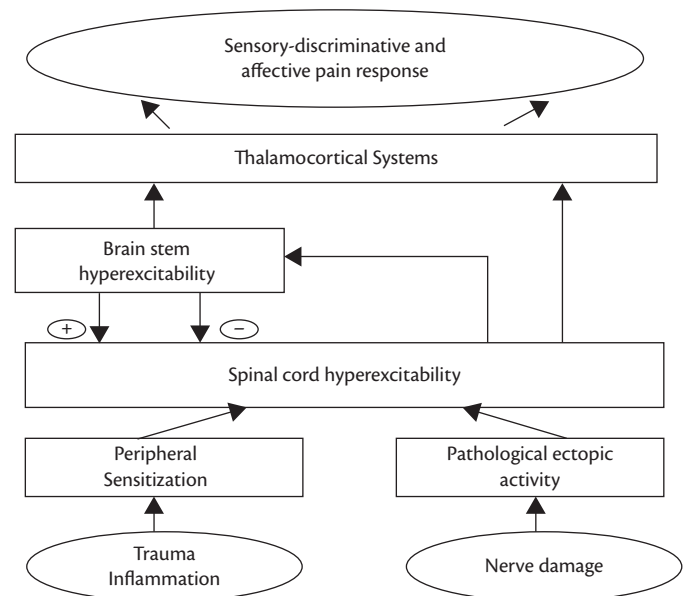
In the healthy individual, pain is only elicited by stimuli of high intensity which are potentially or actually tissue damaging (physiological nociceptive pain). During inflammation and injury of organs/tissue, the nociceptive system is sensitized (Figure 59.2), which is the neuronal basis of allodynia and hyperalgesia, main features of pathophysiological nociceptive pain. Nociceptive sensitization has a peripheral component (sensitization of nociceptors in the tissue) and a central component (development of hyperexcitability in nociceptive neurons in the central nervous system). Peripheral sensitization reduces the excitation threshold of the nociceptors such that they are excitable by stimuli of light intensity such as palpation. Nociceptors in the muscle and joint are strongly sensitized to mechanical stimuli, whereas cutaneous nociceptors are rather sensitized to thermal stimuli.[3] Furthermore, silent nociceptors, i.e. nociceptors with extremely high thresholds in normal tissue, are then activated by stimuli.[5] These processes cause an enhanced neuronal input into the spinal cord, which further activates and sensitizes spinal cord neurons. **Central**


Fig. 59.2 Schematic display of the activation of the nociceptive system by inflammation/injury and neuropathic events and elicitation of descending inhibition or facilitation of nociception.

sensitization describes a state of hyperexcitability, in which central neurons respond more readily to their peripheral inputs. It amplifies the nociceptive input from the periphery.[7]

While physiological and pathophysiological pain is induced by noxious stimulation or inflammatory conditions in the innervated organs/tissues, neuropathic pain is generated by damage or disease of injured nerve fibres themselves. Mechanistically, action

potentials in injured nerve fibres are often initiated at the nerve lesion site or in the dorsal root ganglion, i.e. they are not elicited in the sensory endings in the tissue (where this normally takes place) but in the course of the nerve fibre (thus they are called **ectopic discharges**, which may occur regularly or episodically).[1] Episodic discharges are usually not related to noxious stimuli applied to the tissue, and therefore this input is felt abnormal by the individual. Figure 59.2 shows that episodic discharges may also cause central sensitization.

Figure 59.2 also indicates that the brain stem may either reduce or aggravate the nociceptive processing at the spinal level. During short-lasting acute inflammation, the feedback is rather negative, i.e. descending inhibitory systems try to reduce central sensitization. During prolonged inflammation this descending inhibition is attenuated, and studies in pain patients have suggested that some forms of descending inhibition (in particular the descending noxious inhibitory control, DNIC) are even out of order. DNIC is a form of inhibition in which the application of painful stimuli to one site of the body reduces the pain at other sites of the body (DNIC is therefore considered to be one mechanism involved in acupuncture).[2] There is evidence that under neuropathic conditions the brainstem rather facilitates nociception at the spinal level.

Although nociceptive pain and neuropathic pain are different, there may be an overlap under certain clinical conditions. First, surgery may damage tissue and nerve fibres. Bone cancer may evoke an inflammatory component but may also invade nerve branches. In addition, nerve injury is associated with a local inflammatory reaction at the lesion site, and there is some preliminary evidence that chronic lesions such as osteoarthritis may also have a neuropathic component.

Inflammation induces a change of tissue innervation that leads to a sprouting response of sensory nerve fibres and to a parallel loss of sympathetic nerve fibres. The imbalance leads to a preponderance of substance P over sympathetic neurotransmitters, which supports the local inflammatory process but also pain processing.[8]

Molecular mechanisms of peripheral nociception and sensitization

Transduction of stimuli and generation of action potentials

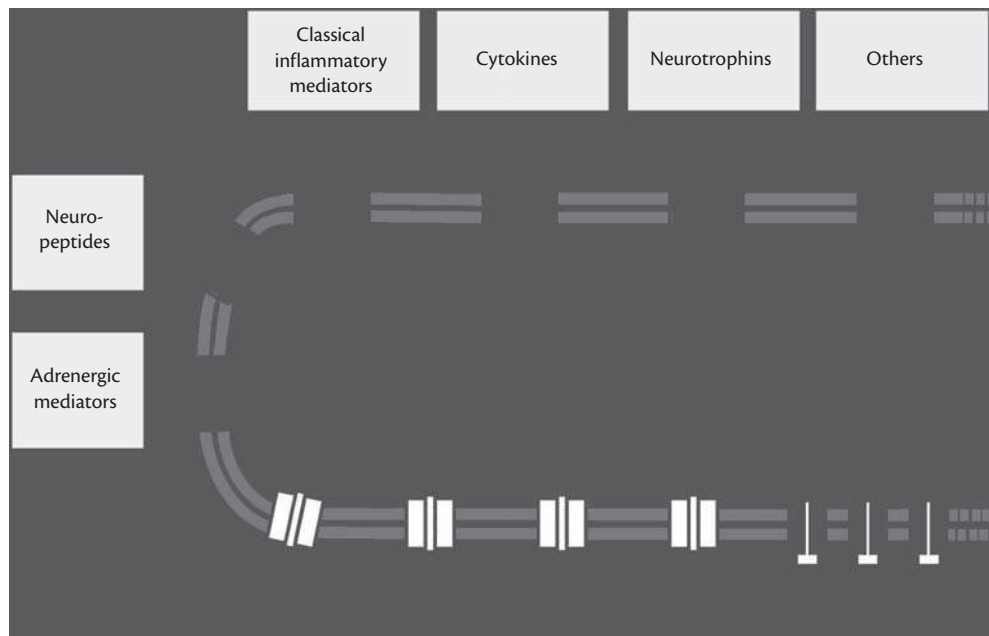
The sensory endings of nociceptors are equipped with numerous ion channels and membrane receptors (Figure 59.3). Sensor molecules in the sensory endings of nociceptors transduce mechanical, thermal, and chemical stimuli into a sensor potential, and when the amplitude of the sensor potential is sufficiently high, action potentials are triggered and conducted by the axon to the dorsal horn of the spinal cord or the brainstem. Some sensor molecules have been identified.[9] The best-known receptor is the transient receptor potential vanilloid 1 (TRPV1) receptor. TRPV1 is a ligand-gated ion channel. Upon opening, cations, in particular Ca^{2+}, flow into the cell and depolarize it. The TRPV1 receptor is expressed in nociceptors but not in other peripheral neurons. It is opened by temperatures higher than 43 °C which are felt as painful heat by humans, by chemicals which elicit burning pain (such as capsaicin and ethanol applied to a wound), by low pH (<5.9) which occurs in inflamed tissue, and it is activated by metabolites of arachidonic acid produced by lipoxygenases such as 12-hydroperoxyeicosaenoic acid (12-HPETE), and by endocannabinoids such as anandamide and


Fig. 59.3 Schematic drawing of a sensory ending of a nociceptor in the tissue. The membrane at the bottom shows ion channels for transduction (which produce a sensor potential), a voltage-gated Na^+ channel for the generation of action potentials (APs), and voltage-gated K^+ and Ca^{2+} channels which control excitability. ASIC, acid sensing ion channel; PTX, purinergic ion channel; TRP, transient receptor potential; TTX, tetrodotoxin. The other part of the membrane displays receptors for mediators which act on different second-messenger systems. Classical inflammatory mediators are bradykinin, prostaglandin E_2, 5-hydroytryptamine, and histamine.

NADA. Furthermore, TRPV1 is indirectly sensitized, via second messengers, by the inflammatory mediators bradykinin, prostaglandin E$_2$, extracellular ATP, glutamate, proteases, cytokines, and nerve growth factor. It is one transducer of noxious heat, and it is crucial for inflammatory **thermal hyperalgesia**. Thus TRPV1 is considered a key receptor of nociception.

Other TRP channels such as TRPV2, TRPV3, TRPV4, TRPM8, and TRPA1 are also expressed in proportions of primary afferent neurons, and some of them are coexpressed with TRPV1 in one and the same nociceptive neuron, whereas others are expressed in non-nociceptive neurons. For example, TRPM8 is opened by temperatures which are felt as cool—hence TRPM8 is assumed to be the transducer in non-nociceptive cold fibres but in general the role of these other TRP channels is less clear. An open question is whether TRP channels are also involved in the transduction of mechanical stimuli and mechanical hyperalgesia, which is more important than thermal hyperalgesia.[9]

Once the ending is sufficiently depolarized by the influx of cations, voltage-gated Na$^+$ channels are opened and action potentials are triggered (Figure 59.3). Different types of Na$^+$ channels exist. Nociceptive afferent neurons express mainly Na$_v$1.7, Na$_v$1.8, and Na$_v$1.9 whereas large-sized non-nociceptive neurons express mainly Na$_v$1.1, Na$_v$1.6, and Na$_v$1.7, and some Na$_v$1.8. These channels differ in their kinetics and their activation threshold, and their presence determines the threshold for opening. While Na$_v$1.7 and Na$_v$1.8 are directly involved in the generation of the action potential, Na$_v$1.9 influences the threshold for action potentials. These channels can be up- or downregulated by second-messenger pathways involving protein kinase A, protein kinase C, sphingomyelinase, calmodulin, and p38 MAP kinase. The excitability of neurons may also be controlled by K$^+$ channels (e.g. of the KCNQ family) and Ca^{2+} channels. Excitability is increased when voltage-gated K$^+$ channels are closed (this evokes sustained depolarization of neurons) or when Ca^{2+} flows into the neuron through voltage-gated T-type channels.[3]

Sensitization

Sensitization of primary afferent neurons during inflammation is generated by inflammatory mediators. These inflammatory mediators act on specific membrane receptors (see Figure 59.3). In general, ligand binding of these membrane receptors activates second-messenger systems which then affect both transduction molecules and voltage-gated ion channels such that they are more excitable (e.g. by phosphorylation). In the long term, some of them may also regulate the expression of such molecules in the membrane. In addition, sensory nerve endings possess Toll-like receptors that signal molecular patterns of infectious agents, indicating an important role of the nociceptive nerve fibres in the context of innate immunity.

'Classical' inflammatory mediators such as bradykinin and prostaglandins activate and/or sensitize neurons within minutes. For example, prostaglandin E$_2$ acts on G-protein-coupled EP receptors which increase cAMP. This activates protein kinase A, which finally leads to a phosphorylation of TRPV1 receptors and voltage-gated Na$^+$ currents. Upon a single application the effects are quite short (minutes only). By contrast, injection of proinflammatory cytokines such as interleukin (IL)-6 and tumour necrosis factor alpha (TNFα) into the joint leads to a slowly developing but persistent sensitization of nociceptive afferents (i.e. increase of the number of action potentials to a stimulus) lasting at least several hours. In addition, cytokines regulate the expression of receptors (e.g. TNFα upregulates TRPV1 receptors).[5] These cytokine effects can be blocked by anti-cytokine therapy with biological agents, and it is expected that this also inhibits release of proinflammatory substance P and other neuropeptides.

The neuropeptides substance P and CGRP sensitize part of the neurons, whereas opioid peptides and somatostatin inhibit the neurons. The latter two peptides may also be released from sympathetic nerve endings but this may be disturbed due to the loss of sympathetic nerve fibres.

Nerve growth factor (NGF) is an essential neurotrophin for the development of sensory nerve fibres. In the adult, a large proportion of sensory nerve fibres remains dependent on the trophic effect of NGF. These neurons express TrkA receptors (specific receptor for NGF), and NGF is required for their structural and functional integrity. However, substantial amounts of NGF are also produced at inflammatory sites and NGF can act as an inflammatory mediator. It enhances currents through TRPV1 channels and reduces the threshold of thermal excitation. Long-term exposure to NGF increases the expression of TRPV1, bradykinin receptors, P2X receptors, Na$^+$ channels, and the synthesis of putative nociceptive transmitters such as substance P and CGRP. In addition, NGF stimulates inflammatory cells to release inflammatory compounds. Thus NGF is a key molecule for nociceptor biology, and its neutralization proved to be highly analgesic in humans.[3]

There exist nerve repellent factors that are able to repel peripheral nerve fibres from the innervation site within minutes to hours. These repellent factors are important in guiding nerve fibres during embryological development of the central and peripheral nervous system. In inflamed tissue, repellent factors of the semaphorin group were detected such as semaphorin 3C and 3F.[10] Macrophages and fibroblasts express only nerve repellent factors of sympathetic but not of sensory nerve fibres, thus explaining the specific loss of sympathetic nerve fibres while sensory nerve fibres are not affected.[11] This leads to a preponderance of sensory over sympathetic nerve fibres, called sensory hyperinnervation.

Ectopic discharges and/or 'neuropathic' activation

Different mechanisms are thought to produce ectopic discharges: changes in the expression of ionic channels, pathological activation of axons by inflammatory mediators, and pathological activation of injured nerve fibres by the sympathetic nervous system (α-adrenergic effects). After nerve injury the expression of such sodium channels is increased, which alters the membrane properties of the neuron in such a way that rapid firing rates are favoured (bursting ectopic discharges). Changes in the expression of potassium channels of the neurons were also shown. Inflammatory mediators such as prostaglandins, nitric oxide (NO), and cytokines are produced by Schwann cells and by inflammatory cells which invade the injured nerve, and damaged axons become sensitive to these mediators. The sympathetic nervous system does not activate primary afferent nerve fibres in normal tissue. Injured nerve fibres may, however, become sensitive to adrenergic mediators. This cross-talk may occur at different sites. Adrenergic receptors may be expressed at the sensory nerve fibre ending. A direct connection between afferent and efferent fibres (so-called 'ephapses') is considered. Sympathetic endings

are expressed in increased numbers in the dorsal root ganglion after nerve injury. The cell bodies of injured nerve fibres are surrounded by 'baskets' consisting of sympathetic fibres.[1]

Molecular mechanisms of central sensitization

Different neuronal receptor/transmitter systems are involved in the induction and maintenance of central sensitization. Both the release of excitatory/sensitizing mediators from presynaptic neurons and the excitability of postsynaptic neurons are enhanced. In addition, glial cells are involved in the nociceptive processing, at least in neuropathic pain states.

Glutamate is the main transmitter in nociceptors. It activates ionotropic *N*-methyl-D-aspartate (NMDA) and non-NMDA receptors and metabotropic glutamate receptors in spinal cord neurons. The activation of non-NMDA receptors is the basis for synaptic activation of neurons. The opening of NMDA receptors (this occurs upon strong depolarization as during noxious stimulation) allows a strong calcium influx into the neurons which then triggers cellular mechanisms of increased excitability. This is a key mechanism of the induction and maintenance of central sensitization.[5,7]

Upon noxious stimulation and peripheral inflammation, the neuropeptides substance P, neurokinin A, and CGRP are spinally released from sensitized nociceptors. They act on neuropeptide receptors on spinal cord neurons and support the development of central sensitization, probably by a facilitation of glutamatergic synaptic transmission. Spinal sensitization is also supported by spinal prostaglandins. The latter are synthesized by a proportion of nociceptors and numerous cells in the spinal cord. Further involved are spinal neurotrophins such as brain-derived neurotropic factor (BDNF).[5]

More recently, glial cells have come into the focus. Neuropathic pain states involve the release of proinflammatory cytokines from astroglia and microglia, and suppression of the activation of glial cells can prevent and/or reverse neuropathic pain.[12] Cytokines such as IL-1β, IL-6, and TNF play a dominant role in cytokine-induced hypersensitivity, and these cytokines are also induced in the spinal cord during experimental arthritis. The cellular mechanisms are only incompletely understood but the following signalling pathways have been mentioned: NFκB, protein kinase A, protein kinase C, c-Jun N-terminal kinase, JAK/STAT3 signalling pathway, p38 mitogen-activated protein kinase (MAPK), Src-family kinase, arachidonic acid pathways, and others.

For example, the p38 pathway was demonstrated to be an important proinflammatory signalling cascade in spinal neurons and microglia cells in experimental arthritis. Phosphorylated p38 is increased in microglial and neuronal cells during the course of experimental arthritis. The intrathecal administration of a specific p38 inhibitor led to decreased synovial inflammation but also suppressed articular cytokine and protease expression as well as joint destruction.[13] TNF can be a signalling element upstream of p38 by activating p38-phosphorylating kinases or downstream of phosphorylated p38 that induces TNF secretion. Intrathecal, but not subcutaneous, TNF neutralization with etanercept inhibited p38 phosphorylation and peripheral inflammation,[13,14] along with a pronounced antinociceptive effect.[14] The efferent pathways for these effects have not been unequivocally identified. In a state of

spinal hyperexcitability dorsal root reflexes may be generated in the spinal cord (i.e. action potentials are generated in the spinal terminals of afferent fibres which are conducted retrogradely from the spinal cord to the periphery where neuropeptides are released[15]) and/or sympathetic efferent fibres may be activated.[5,14]

Sensitization may be counteracted by transmitters which inhibit neurons. Such transmitters are GABA, opioid peptides, 5-hydroxytryptamine, and noradrenaline, the latter two being involved in descending inhibition. It has been suggested that such inhibitory mechanism may fail under neuropathic conditions.

Pain and sensitization: evolutionary considerations

Why peripheral and central sensitization have been positively selected during evolution is an important question. Sensitization of pain has a protective role because it warns about potential danger, enables us to remove noxious stimuli, and stimulates wound management. Furthermore, avoidance of painful situations in the future would be highly desirable. This is nicely indicated by the fact that peripheral inflammatory stimulation of sensory neurons can induce central IL-1β release in the hippocampus,[16] a cytokine that is instrumental in hippocampal learning phenomena.[17] Sensitization is an amplification factor which should last as long as painful/noxious stimuli are present (or even a little longer, to stimulate wound management). Thus, sensitization is a supportive factor of innate immunity. It has been positively selected as an evolutionarily conserved learning phenomenon, which will not be stopped until inflammation is terminated, i.e. the noxious stimulus is removed.

CHAPTER 60

Pathogenesis of juvenile idiopathic arthritis

David Bending, Kiran Nistala, and Lucy R. Wedderburn

Introduction

Juvenile idiopathic arthritis (JIA) is the most prevalent form of the chronic rheumatological diseases affecting children. The hallmark of the disease is inflamed synovium, which is thickened, hypervascular, and contains a dense inflammatory infiltrate, of which T cells are typically the most abundant cell type. JIA itself is not one condition (see Chapter 114) but represents a spectrum of conditions with differing degrees of overlap and phenotypes.[1] It is thus unsurprising that the pathogenesis of JIA differs according to subtype, but central themes do emerge—in particular a critical role for the immune system in disease pathogenesis. This chapter therefore seeks to underline common pathological mechanisms involved in disease pathogenesis in JIA, but also extends its reach to highlight subset-specific pathologies where these are thought to be of importance to disease understanding.

Principles in understanding pathogenesis of childhood arthritis

An important principle to understand is that the clinical criteria used to classify JIA into its different subsets (see Chapter 114) may blur the identification of common, underlying pathological mechanisms; in particular, the classification based on the number of joints affected could suggest that such subsets have fundamentally differing pathological mechanisms, when in fact they may have many common features but differ merely in severity (e.g. anti-nuclear antibody positive (ANA+) forms of oligoarticular-(o)-JIA and rheumatoid factor negative (RF−) polyarticular (poly)-JIA.[2]).

Most methods to analyse the pathogenesis of JIA, such as immunological and gene expression profiling, have segregated conditions using criteria that are employed for classification of JIA such as the number of joints affected and/or the presence/absence of psoriasis. However alternative analyses, such as the criteria of the age of onset,[3] may better correlate with gene expression profiles in the peripheral blood of patients than the number of joints affected.[4] Where such data exist, these will be referred to, and their relevance to helping our understanding of JIA discussed.

One subgroup, systemic JIA (sJIA), however, does appear to have a distinct pathogenesis in that it resembles an autoinflammatory-like disorder with central roles for the innate immune system.[5] In particular the cytokines IL-1β, IL-6, and IL-18 are implicated in the pathogenesis of sJIA[5] (see 'Systemic juvenile idiopathic arthritis—a special case of innate dysregulation?'). o-JIA and poly-JIA, on the other hand, are thought to be T-cell-mediated autoimmune conditions, with a key part played by the adaptive immune system, and as will be discussed their pathogenesis is linked to the interplay between T effectors (Teff) and T regulatory (Treg) cells.[6] In this chapter, therefore, we analyse central pathological themes involving the adaptive and innate immune systems and, where appropriate, refer to subset-specific mechanisms of disease. Since o-JIA and poly-JIA account for most cases of JIA, we first address the involvement of the adaptive immune system in these forms of JIA.

Adaptive immune system involvement in the pathogenesis of non-systemic juvenile idiopathic arthritis

It is thought that the autoreactive response in children who develop JIA is initiated by the activation of T and/or B cells. For instance, data from many association studies, recently confirmed by genome-wide association studies, have identified that there exist subtype-specific HLA associations (see Chapter 43),[7] which supports the involvement of the adaptive immune system in disease progression. In particular, the strongest associations exist with alleles at the *HLA DRB1* locus, which codes for the β chain of MHC class II molecules, whose central role is the presentation of peptide antigens to CD4+ T cells. As well as distinct subtype-specific genetic associations, several studies have also shown an age-specific risk conferred by particular *HLA* alleles and haplotypes. For example the *HLA DRB1*1103/*1104* allele, which is strongly associated with o-JIA, is also a risk factor for other clinical types on JIA in younger children (onset <6 years) but not older children.[8] In addition to *HLA* genes, single nucleotide polymorphisms (SNPs) in genes involved in T-cell activation, such as the tyrosine phosphatase *PTPN22*,[9] or T-cell regulation (i.e. the α chain of the IL-2 receptor (CD25),[10]

a molecule that is crucially important for Treg), have been reported to be associated, suggesting that T-cell dysregulation is a likely factor in the pathogenesis of JIA. Furthermore, data from mouse models also give insight into this notion: mice with a genetically altered threshold for T-cell activation due to a mutation in the *ZAP70* gene (important for transducing TCR signals) go on to develop arthritis spontaneously[11]; and additionally, T-cell self-reactivity can create a cytokine milieu that can drive the spontaneous development of pathogenic T cells, which can mediate autoimmune arthritis.[12]

What triggers this self-reaction is not clear; however, research from mouse models has suggested that gut-residing bacteria may have a role to play in the generation of Th17 cells that target the joint,[13] and, intriguingly, that self-antigen recognition may not always be necessary for the development of arthritis—local joint injury in mice, such as microbleeding, can lead to an IL-6- and IL-17A-dependent arthritis in the absence of tissue antigen recognition in a genetically prone mouse strain.[14]

B cells are thought to play less prominent roles in the progression of JIA than T cells, but recent data have suggested that their involvement may be underappreciated since an early B cell signature can identify early-onset arthritis independent of the number of joints affected.[3] Autoimmune B cells, or mature plasma cells, are the source of the ANA autoantibody, a risk factor for the complication of uveitis in JIA, although the direct pathogenic role of ANA antibodies remains unproven. One potential function of B cells in contributing to pathogenesis[15] is not their capability to produce autoreactive antibody but to act as antigen-presenting cells (APC) and prime Th1 cell development. It is this Teff development, and immune regulation[6] that appear to be highly influential factors in dictating the outcome of disease progression in non-systemic forms of JIA.

T-cell roles in the pathogenesis of juvenile idiopathic arthritis

As already stated, T cells are thought to play essential roles in non-systemic forms of JIA. In the following section, the relative contribution of Teffs, which are thought to mediate damage, and their interplay with Treg, which act to restrain inflammation, is discussed. The issues of Teff resistance to regulation and Treg function and stability at sites of inflammation will be discussed to generate a conceptual framework in order to help understand disease progression in the joint.

Effector T cells

In the majority of cases of JIA, CD3+ T cells constitute the major population in synovial fluid mononuclear cell (SFMC) compartments. These are almost exclusively of the CD45RO+, highly activated 'memory' population.[16] Of the CD4+ Th cells, both Th1 and Th17 populations have been observed and both are enriched compared to the peripheral blood compartment, with a relative abundance of interferon (IFN)γ+ Th1 cells.[16,17] Despite the high prevalence of IFNγ+ T cells, blockade of IFNγ has not proven beneficial in mouse models or clinical trials in adult inflammatory arthritis. However, it is known that both Th1 and Th17 cells can also make TNFα, and blockade of this cytokine, using biologics, has shown excellent therapeutic benefit.[18]

IL-17A, the signature cytokine of Th17 cells, which are enriched in the joints of o-JIA patients,[17] is increased in synovial fluid[19] and in-vitro modelling has shown that it can drive the production of

IL-6, IL-8, and matrix metalloproteinases (MMPs) from synovial fluid fibroblasts,[19] demonstrating that IL-17A can induce many of the immunopathological features of arthritis.

Both Th1 and Th17 cells may become enriched in the joints by a variety of mechanisms. Preferential recruitment of Th1 cells may be an important factor, in part via recruitment mediated by the receptors CCR5 and CXCR3,[16] as, interestingly, individuals expressing a mutant form of CCR5 (CCR5d32) show relative protection from JIA development.[20] Th17 recruitment may occur in response to tissue injury, such as microbleeding,[14] leading to the upregulation of CCL20 and recruitment of CCR6-expressing Th17 cells.[17] In comparison between mild o-JIA (known as persistent o-JIA), and the more severe extended form, the enrichment of Th17 cells is significantly higher in extended o-JIA.[17] Th1 cells may also be enriched due to Th17 conversion to Th1 in the joint,[21] which may be driven by the abundance of IL-12 and absence of TGFα in the synovial fluid environment.[21] This 'functional plasticity' may mask the apparent importance of Th17 cells in disease progression. Supporting this claim is that, in the remitting form of o-JIA (known as persistent o-JIA), a higher turnover of Teffs in the synovial fluid compared to peripheral blood compartment is observed,[22] suggesting constant recruitment and turnover at the inflammatory sites. Many 'snapshot in time' analyses, therefore, are unlikely to reveal the highly dynamic nature of T-cell behaviour in the joints.

For CD8+ T cells, these cells may have an increased importance in the o-JIA subset, since the CD4:CD8 ratio has predictive power in determining the likelihood that children may go on to develop more severe disease.[23] It has been hypothesized that levels of a CD8+ T cell chemo-attractant, CCL5 (RANTES), may be important in recruiting CD8+ T cells to the joints in children who go on to develop extended o-JIA.[23] CCL5 is known to be high in synovial fluid, and is produced by the synovial CD8+ T cells in high amounts compared to peripheral blood CD8 T cells, creating a positive feedback loop.[24]

As well as the production of cytokines and chemokines, activated T cells in the synovium alter the balance of bone deposition and breakdown in neighbouring bone, through the high production of osteoclast-activating factors such as RANKL (a member of the TNF family),[25] and osteopontin,[26] which contribute to local osteoporosis typically seen around actively inflamed joints.

Teff pathology, however, does not go unchecked, and as well as an enrichment of effector cells, FOXP3-expressing Tregs are also enriched in the joints of patients.[17,27,28] In fact, the ratios of Teffs to Tregs may be an important feature in dictating the outcome of the disease process.[17] The next section, therefore, discusses the crucial role that Tregs play in the control of disease pathogenesis.

Regulatory T cells

Since Tregs are also enriched at the sites of inflammation when compared to peripheral blood,[27] it seems plausible that active attempts are made by the immune system to regulate the inflammatory response. In keeping with the importance of regulation in affecting disease outcome, associations with the *IL10* gene itself[29] and IL-10-regulated genes have been made.[4] Both the nature and number of Tregs appear important: in the o-JIA form of disease, preferential recognition of the self-antigens hsp60 and dnaJ by Tregs correlates with the milder form of disease,[30] and an enhanced frequency of Tregs is observed in the synovial compartment of patients with remitting o-JIA compared to those with the more severe extended

o-JIA.[17,27] The set-point for regulation may be an opportunity for therapeutic intervention, since patients treated with autologous transplantation displayed increased proportions of Tregs after the procedure.[31]

The increased proportion of Tregs at the sites of inflammation may at first seem paradoxical. This has led to the question of whether Tregs are suboptimal or subfunctional in patients with JIA; on the other hand, Teffs themselves may become less susceptible to regulation due to the inflammatory milieu in the joint. It is the nature of the Treg–Teff interaction that will determine the outcome of disease progression, and it is likely that both extrinsic factors (environment, i.e. cytokine milieu) as well as intrinsic factors (e.g. genetic factors—see Chapter 43) have roles to play.

Teff resistance vs Treg stability and functionality

The programme of synovial fluid Tregs is thought to be as stable as that of peripheral blood Tregs, since epigenetic analysis of the Treg-specific demethylated region in these cells has shown that both types display demethylation at this locus—a hallmark that is associated with stable FOXP3 expression.[32] In addition, work in mice using genetic fate-tracking technology has documented that Tregs maintain stability in inflammatory environments,[33] although such work has not been rigorously assessed in humans (in part because FOXP3, the accepted marker of Tregs, can be promiscuously upregulated in Teffs following their activation).

Although there is still some debate as to whether Treg stability may be an issue in inflammatory environments, the in-vitro functionality of Tregs isolated from the site of inflammation has been assessed. Using Treg suppression assays, the suppressive nature of synovial fluid Tregs has been compared to Tregs isolated from the blood of patients. When these in-vitro assays have been conducted (and similar findings have been demonstrated in animal models of type 1 diabetes[34]), synovial fluid Tregs have been equally suppressive[32] as peripheral blood Tregs (possibly more so[28]); however, neither set of Tregs have been effective in suppressing the proliferation of Teffs that were isolated from synovial fluid.[32] This suggests that the defect might not lie in the biology of Tregs but in the biology that controls the resistance of Teffs to suppression.

Very recently, some insight into the biology of what may drive the resistance of Teffs to regulation has been gained. Studies of Teffs isolated from synovial fluid have shown that activation of the PKB/AKT pathway in Teffs, in part due to inflammatory signals like IL-6 and TNFα, confers resistance of Teffs to TGFα-mediated inhibition of proliferation.[32] Although questions remain as to whether this represents a disease-specific phenomenon, or whether Teffs acquire resistance to regulation as part of their differentiation during chronic immune responses, there is no doubt that this is an intriguing area of research with the potential to open up new therapeutic strategies. It is highly likely, therefore, that the tuning of the biology of Teffs at the sites of inflammation will now become an area of intense investigation.

B cells

Although autoantibodies are common in many types of JIA (although in sJIA there is notable absence of specific autoantibody production), in particular ANA, the presence of mature germinal centres in the inflamed synovia in JIA is rare compared to rheumatoid arthritis patients.[35] Although the pathogenic role of the ANA antibody is unclear, it remains a valuable clinical tool in indicating

risk for autoimmune uveitis.[36] For example in one study of 426 cases of recently diagnosed JIA,[36] uveitis was detected in 24.5% of cases; ANA was present in 66% of patients with uveitis compared to 37% of patients without uveitis (p<0.001). The ANA has also been proposed as a useful biomarker for a homogeneous phenotype of childhood arthritis, namely young-onset disease with risk of uveitis.[2]

One interesting publication has reported that early-onset disease (irrespective of the number of joints affected) had a distinct gene expression signature indicative of immature B cells in the blood of patients.[3] This gene expression profile may be linked to the enrichment of transitional B cells seen in the blood of JIA patients when compared to age-matched controls.[35]

B cells can also function as APC, and it has been reported that activated B cells within the joint, displaying high levels of costimulatory molecules CD80/CD86, may be important in the priming of Th1 responses.[35] Interestingly, an expansion of B cells within the joint has been linked with increased risk of disease extension in oligoarticular forms of JIA.[23]

Innate immune system in the pathogenesis of juvenile idiopathic arthritis

Successful treatments with biologics have implicated innate cytokines in the pathogenesis of JIA—particularly in sJIA, where innate cell dysregulation is thought to be a key factor in disease progression (see 'Systemic JIA—a special case of innate dysregulation?'). It should also be appreciated that the innate immune system is likely to be party to all the immunological events in JIA (Figure 60.1)—e.g. antigen presentation to autoreactive T cells, monocyte infiltration in response to T-cell infiltration, the induction of matrix remodelling and joint erosion, activation of endothelia, and the induction of angiogenesis.

In fact, the activation of cells of the innate immune system and stroma likely contributes many aspects that lead to the clinical symptoms of JIA. Cytokine production and chemokine production drive inflammation and cell recruitment; cytokines may act to induce the production of tissue remodelling enzymes like MMP-1 and MMP-3, leading to tissue destruction; vascular endothelial growth factor (VEGF) production by monocytes and macrophages will drive angiogenesis; and inflammatory mediators will activate endothelia leading to the further recruitment of immune cells, contributing to joint swelling and pain. Targeting innate immune pathways has proven successful, and therefore the contribution of this arm of the immune response to disease pathogenesis will be discussed. Given its unique innate immune system signatures, a separate section is devoted to sJIA.

Monocytes

Whilst proportions are similar between synovial fluid and peripheral blood compartments, these cells are much more highly activated in SF.[23] They can secrete a vast array of cytokines, such as IL-6, IL-1β, and TNFα,[37] and chemokines, such as CCL5, CCL20, IL-8, MCP-1, and CXCL10. Joint hypoxia has been shown to induce CCL20 production from monocytes,[38] which may contribute to the recruitment of CCR6+ Th17 cells.

In o-JIA, a distinct IFNγ signature is present in the monocyte population,[23] which is more severe in those children who go on to develop extended disease. IFNγ can also drive production of
Fig. 60.1 Immune cell involvement in the joints of children with JIA. Cells from all arms of the immune system are involved in the pathogenesis of JIA. B, B cell; DC, dendritic cell; M, monocyte; MMP, matrix metalloproteinase; N, neutrophil; NO, nitric oxide; VEGF, vascular endothelial growth factor.

reactive oxygen species, such as nitric oxide (NO)—and in the joint this is likely to be immune-cell derived since NO production correlates with lymphomononuclear cell frequency.[39] Reactive oxygen species will have direct effects on the stroma and synovium, which in response may produce cytokines and MMP, thus setting in motion an amplification loop of inflammation and tissue destruction. In addition, innate or stromal cytokine production may create a cytokine environment that renders Teffs resistant to regulation,[32] potentiating inflammation.

Neutrophils

Highly elevated levels of myeloid reactive protein (MRP)8/14, secreted by activated monoctyes and neutrophils, are present in sJIA patients,[40] and very elevated MRP levels in synovial fluid are also typical of o-JIA and poly-JIA, where they correlate with disease activity. Such augmented levels of proteins can induce IL-17 production from CD8+ T cells,[41] illustrating how disrupted innate immunity can lead to dysregulated adaptive immunity. MRP8/14 is also elevated in serum of all subtypes of JIA compared to controls, although at lower levels than in the synovium, and serum levels of this protein complex, measured prior to withdrawal of treatment in children who achieve apparent remission, can be used to predict those who are at high risk of flare after drug withdrawal.[42]

Examination of the gene expression patterns of neutrophils between patient and control blood found over 700 genes to be differentially expressed, with gene families linked to IL-8 and IFNγ being prominent amongst them.[43] Interestingly, these gene levels did not revert back to baseline levels after clinical remission, suggesting that remission in patients reflected a state of immunological rebalancing, and not a return to normality.

Systemic juvenile idiopathic arthritis—a special case of innate dysregulation?

Systemic-onset JIA presents with overproduction of IL-1, IL-6, and IL-18. Given the absence of autoantibody and (as yet) no current HLA associations, this strongly suggests that sJIA is a disease of innate dysregulation.[44]

Features of this disease are high serum levels of IL-6[45] and augmented IL-1β—activation of patient peripheral mononuclear blood cells (PBMCs) leads to a release of a large amount of this cytokine.[46] Additionally, IL-18 levels are chronically elevated, which is thought to explain the defect in NK cell cytotoxicity[47] found in this subtype of JIA.

Serum levels of MRP8 and MRP14 are very high in sJIA, and the MRP8/14 complex has recently been shown to be a sensitive indicator of disease activity and likelihood of disease relapse.[48] It is thought that MRP8/14 may drive IL-1β levels, since removal of this complex almost completely attenuates the potential of sJIA serum to induce IL-1β[40]; however, the primacy of IL-1β to disease pathogenesis has been questioned since only one-half of patients respond to blockade of the IL-1β pathway,[49] and this is thought to reflect heterogeneity in the pathological mechanisms driving disease in the group currently classified as sJIA. Disrupting IL-6 with a soluble IL-6 receptor (tocilizumab), on the other hand, has proven much more successful,[50] and given that IL-6 expression is likely to be upregulated by (amongst others) IL-1β, it may act as the final common pathway for inflammation.

Macrophage populations have been analysed and both classical highly inflammatory ('M1 type') and alternatively activated ('M2 type'; in some environments more anti-inflammatory) phenotypes are apparent at the single-cell level.[51] Analyses during inactive

Table 60.1 Subset-specific pathologies

Subtype	General	Innate defects	Adaptive defects
sJIA	Predominantly an innate immune disorder	High levels IL-1b, IL-6, and IL-18 Response to IL-1b can segregate into two groups[49] Individuals with fewer joints affected and higher neutrophil count respond better to IL-1b disruption; MAS	Possible alteration of T-cell subsets[58]
o-JIA	T-cell-driven disease; disease severity dictated by Treg–Teff balance	IFNγ signature in monocyte population in individuals who go on to extend[23] Increased CCL5 in extended-to-be group[23]	Severity of disease correlates with Th17:Treg ratio[17] Higher proportion of CD30+ HSP-specific Tregs favours milder disease[53] Genetic associations differ between mild and severe forms (e.g. MHC alleles at HLA-DRB1 locus[7]; IL-10[29]) Teffs in joint are resistant to suppression[32] CD4:CD8 ratio can be predictive of disease extension[23]
RF+ poly-JIA	More analogous to Rheumatoid arthritis		Shares genetic associations at HLA locus with rheumatoid arthritis, *HLA-DRB1*0101* and *0401*[7]; Antibodies detected against cyclic citrullinated peptides—may be pathological under conditions of low-grade joint inflammation
RF−poly-JIA	Gene expression analysis suggests several separate signatures in patients; ANA+ Poly-JIA may represent a more severe form of o-JIA	A monocyte-related gene signature subset[54] An immediate early genes associated subset[54]; Increased pDC subset[54]	Subset has reduced CD8+ T cells and increased pDC[54]; ANA+ poly-JIA does not fit into one of the three subset signatures[54] and may represent a more severe form of ANA+ o-JIA, as these two cluster together upon expression analysis[2]
ERA/psoriatic arthritis	Some features clinically and genetically shared with adult AS	ERA is associated with inflammatory bowel disorder; MMP-3 serum level correlates with disease activity[55] Membrane TLRs are overexpressed in PB- and SF-MCs, resulting in raised IL-6 and IL-8 production upon TLR ligation[56]	*HLA B27* association—misfolding of molecule in the context of microbial antigens can drive IL-23 production and promote Th17 response[57]; other genes coding for proteins crucial to ER function are also associated, such as ERAP

ANA, anti-nuclear antibody; AS, ankylosing spondylitis; DC, dendritic cell; ERA, enthesitis-related arthritis; ERAP, endoplasmic reticulum-associated peptidase; ER, endoplasmic reticulum; HLA, human leukocyte antigen; HSP, heat-shock protein; IL, interleukin; MAS, macrophage activation syndrome MC, mononuclear cells; MHC, major histocompatiblity complex; MMP, matrix metalloproteinases; o-JIA, oligo-articular juvenile idiopathic arthritis; pDC, plasmacytoid DC; RF, rheumatoid factor; SF, synovial fluid; TLR, toll-like receptor.

phases of disease have lead some authors to conclude that this is due to the manifestation of 'compensated inflammation'.[51]

A pathological feature of sJIA is macrophage activation syndrome (MAS). This potentially life-threatening condition arises as a result of activation of T cells and haemophagocytic macrophages. These macrophages express CD163, a scavenger receptor, which recognizes haptoglobin–haemoglobin complexes. Increased uptake of such complexes can leads to production of ferritin by macrophages, thus providing an explanation for the hyperferritinaemia associated with MAS. In keeping with the phenotype, CD25 and soluble CD163 have been identified as potential biomarkers of this condition.[52] The causes of MAS are unknown; however, defects in genes associated with cell-mediated cytotoxicity, such as the perforin gene and genes involved in its secretory pathway (e.g. *MUNC13-4*), have been associated with some studies in JIA, but not in others.

Subset-specific pathologies

The previous sections have aimed to bring together common pathogenic mechanisms, but each subset has its own specific pathologies; for ease of reference, these are listed in Table 60.1.

Conclusion

In essence, the pathogenesis of JIA is the direct result of disrupted immune regulation, with both genetic (Chapter 43) and environmental factors influencing the course of disease. The major immunopathological distinction in JIA is between the sJIA form, which is thought to represent a disorder of dysregulated innate immunity, and the o-JIA and poly-JIA forms, where the balance between Teffs and Tregs is crucial to disease outcome. It is likely that future research will seek to better understand mechanisms of immune regulation at the sites of inflammation, and how and why these mechanisms may fail to bring about immune homeostasis in the joints of children with JIA. This new information will help identify novel pathways for therapeutic intervention, as well as identify subset-specific biomarkers of disease.

CHAPTER 61

Haematology

Patrick Kesteven

Introduction

A wide variety of haematological abnormalities may be found in patients with diverse rheumatic disorders. These are summarized in Box 61.1.

Anaemia

Some degree of anaemia is found frequently in any active rheumatoid condition. In the majority of cases this will be the anaemia of chronic disease (ACD), which may mask the many other, rarer, anaemias associated with these conditions. Diagnosing these requires a thorough understanding of ACD as well as maintaining a healthy level of suspicion should the patient's full blood count parameters not reflect the underlying clinical picture.

Anaemia of chronic disease

This is the commonest anaemia associated with rheumatoid conditions. ACD may occur in response to any activity in the immune system (infective, autoimmune, or malignant). Several mechanisms have been postulated for ACD, acting individually or in combination. Several cytokines, including interleukin(IL)-1, IL-6 and tumour necrosis factor (TNF), have been shown to affect erythropoiesis by inhibition of iron release from gut endothelium, hepatocytes, and macrophages (via induction of hepcidin)[1]; inhibition of marrow stromal growth; and reduced erythropoietin (EPO) production. Although patients with ACD have elevated levels of plasma EPO, levels are not as high as in iron deficiency anaemia with the same haemoglobin level. Furthermore, some improvement in ACD has been noted following administration of EPO. Improved haemoglobin levels in ACD have also been induced by TNFα blockade[2] and by IL-6 receptor blockade with tocilizumab.[3]

When interpreting haematological parameters it is simplest to consider ACD as due to a block in the transfer of iron from reticuloendothelial stores to red cell precursors. This process can be seen in bone marrow biopsies stained for iron. The depth of the anaemia will depend in part on the degree of immune activation—in shorthand, how high the erythrocyte sedimentation rate (ESR) is—and also on the duration of the disease process. In isolated form it is unusual for the haemoglobin to fall below 8 g/dL, while white cell and platelet counts usually remain in the normal range. The mean corpuscular volume (MCV) is usually low–normal, but if the process continues for months, red cells become microcytic. The blood

---

Box 61.1 Haematological abnormalities in rheumatic disorders

Red cells

- Anaemia of chronic disease
- Iron deficiency
- Vitamin B_{12} and folate deficiency
- Sideroblastic anaemia
- Pure red cell aplasia, especially systemic lupus
- Haemolytic anaemia: immune (especially SLE)/non-immune
- Erythrocytosis

White cells

- Neutrophilia and monocytosis
- Neutropenia (e.g. Felty's syndrome)
- Lymphopenia
- Eosinophilia (polyarteritis nodosa)

Platelets

- Thrombocytosis
- Thrombocytopenia: immune/non-immune
- Platelet dysfunction
- Thrombotic thrombocytopenic purpura

Coagulation

- Lupus anticoagulant
- Acquired coagulation factor deficiencies (immune related)
- Disseminated intravascular coagulation

Others

- Pancytopenia (SLE)
- Myelofibrosis
- Drug-related changes (e.g. aplastic anaemia and pure red cell aplasia)
- Amyloidosis

SLE, systemic lupus erythematosus.

film is unremarkable other than rouleaux formation reflecting the raised ESR, and the reticulocyte count will never be raised.

Iron stores are normal, or increased, due to reduced usage in red cell production and may be measured by serum ferritin or by examining bone marrow aspirate stained for iron (Perl stain). In addition to normal or increased reticuloendothelial stores, the bone marrow will demonstrate absence of stainable iron in the developing red cells (siderotic granulation).

Interpretation of serum iron results may be difficult. The serum iron concentration is low, and similar to levels seen in iron deficiency. But unlike the latter, the serum total iron-binding capacity (sTIBC—mostly made up of transferrin) is also reduced, such that the percentage saturation (serum iron/sTIBC × 1000) remains approximately normal. In iron deficiency, by contrast, the sTIBC is greatly increased so that the percentage saturation tends to be very low (see Table 61.1).

Treatment is only occasionally indicated, and only in the short term, for blood transfusion to prepare a patient for surgery. Suppression of the increased immune activity will result in a climb in haemoglobin levels. The importance in making this diagnosis is the exclusion of other causes of anaemia which may require more active investigation or intervention.

Iron deficiency

Iron deficiency may be difficult to diagnose in patients when ACD is also present. Iron deficiency is an extremely common cause of anaemia in all patients, but in particular, anti-inflammatory medications may cause upper gastrointestinal bleeding. This is an important diagnosis to make as, until proven otherwise, all iron deficiency is due to blood loss which must be stopped; and treatment of the iron deficiency is simple and clinically effective.

As seen in the previous section, laboratory results must be interpreted with care (see Table 61.1). The MCV will tend to be lower than in the ACD, and in severe cases a reactive thrombocytosis (if active bleeding is present) or mild neutropenia may coexist. If it proves impossible to distinguish iron deficiency from ACD on laboratory results, a trial of oral iron supplements may be warranted or, in very complex cases, a bone marrow aspirate stained for iron will establish the diagnosis.

Treatment of the iron deficiency is merely by supplements of iron—either orally, or for those intolerant, intravenously. Because oral iron supplements may themselves cause gastric upset treatment should be started at a very low dose and built up to full dose over a few weeks, as tolerated.

Haemolytic anaemia: immune

Any patient with circulating immune complexes may be found to have a positive Coomb's test. This test merely demonstrates the

Table 61.1 Serum iron and iron-binding capacity in iron deficiency and anaemia of chronic disease

Condition	Serum iron	Total iron-binding capacity	% saturation
Iron deficiency	Low	High (liver produces more transferrin)	Very low
Anaemia of chronic disease	Low (iron retained intracellularly)	Low (transferrin production is reduced)	Normal

presence of immunoglobulins on the red cell surface and may be non-specific.

In autoimmune haemolytic anaemia, found in 10% of patients with systemic lupus erythematosus (SLE),[4] it is necessary to demonstrate both a positive Coomb's test and evidence of reduced red cell survival: raised reticulocyte count (reflecting increased red cell production) and hyperbilirubinaemia (reflecting increased red cell destruction). True haemolysis requires the presence of autoantibodies directed against specific red blood cell antigens in the presence of complement component C3.4. Serum haptoglobins are low or absent in the presence of true haemolysis. However, levels will also be reduced in cases with liver dysfunction.

Haematinic deficiency

Deficiency of folic acid or, less frequently, vitamin B_{12}, may occur in any chronically ill patient and could be masked by ACD. The MCV will tend to be higher than expected and both deficiencies can be diagnosed simply by blood tests.

Other causes of anaemia

Causes of anaemia in rheumatoid conditions may be multiple and it is therefore important that minor or rare aetiologies, masked by either ACD or iron deficiency, are not missed. These include sideroblastic anaemia, amyloidosis, drug-induced aplastic anaemia, pure red cell aplasia, and marrow fibrosis. However, a complete list of rare causes of anaemia is extremely long. Diagnosis of these conditions will rely on maintaining a high level of suspicion should the blood results not reflect the clinical state. Warning signs will show if the haemoglobin, MCV, and reticulocyte count are monitored. All can be diagnosed by bone marrow biopsy.

Case history

A 27 year old SLE patient, well maintained on long-term immunosuppressant therapy presented with a gradually worsening pancytopenia. The bone marrow was hypercellular of normal cells, suggesting relapse of her SLE. Despite increased immunosuppression her blood picture worsened, so a second bone marrow biopsy was performed. This showed widespread leishmaniasis. She had been on a 2 week holiday in Africa 6 months earlier.

White cells

Leucocytosis

Any inflammatory process, such as in connective tissue disease (CTD), may be associated with a neutrophilia. Neutrophil counts are rarely greater than 20×10^9/L and these cells are morphologically normal on blood smears or may be mildly left-shifted. Glucocorticoids may have a similar effect. Apart from being markers of underlying disease activity this is of no clinical significance, but needs to be differentiated from an acute infection. Monocytosis may also be noted with any autoimmune disorder.

Neutropenia

Neutropenia may result from drug effects or be a feature of Felty's syndrome—the association of low white cell count (and occasionally reduced platelet count) and splenomegaly in patients with rheumatoid arthritis (RA). The mechanisms involved in Felty's syndrome

are multifactorial and not merely due to a dilutional effect from the enlarged spleen. This is usually only trivial, but may, rarely, be very large. Increased sequestration of neutrophils within the spleen certainly occurs, but reduced marrow production due to immune-complex-mediated and humoral inhibition of granulopoiesis is also involved. Antibodies to mature neutrophils have been reported in SLE, as have functional defects in polymorph and lymphocyte function.

Lymphopenia

Mild lymphopenia occurs in both SLE and RA, and may be a measure of disease activity. If an isolated finding it is of no clinical significance.

Eosinophilia

Eosinophilia may be seen in SLE, RA, polyarteritis nodosa, and Churg–Strauss syndrome. The pathogenesis is unknown, but presumably involves release of cytokines by T lymphocytes.

Platelets

Thrombocytosis

A moderately raised platelet count (up to 1000×10^9/L)—known as a reactive thrombocytosis—is a frequent finding in cases of chronic inflammation or blood loss. These two, of course, will need to be distinguished on clinical grounds and examination of haemoglobin, reticulocyte count, and iron status. The blood cell morphology on a smear will be normal, as will the platelet size (mean platelet volume).

However, it is important to distinguish a reactive thrombocytosis from a primary thrombocythaemia which is one of the myeloproliferative disorders. In the latter there may be abnormalities in the red cell and white cell line; abnormal platelet morphology; or splenomegaly. The JAK2 (Janus kinase 2—available as a blood test) mutation is positive in approximately 50% of cases of primary thrombocythaemia.[5] A bone marrow biopsy may be required to establish the diagnosis.

Thrombocytopenia: immune/non-immune

A mild reduction in platelet count ($100–150 \times 10^9$/L) may be found in any widespread inflammation, due to non-specific activation of coagulation. In RA this may be aggravated by an element of hypersplenism as part of Felty's syndrome.

Platelet counts below 100×10^9/L require investigation as they may represent an immune thrombocytopenia (ITP). This is a common manifestation of SLE and also occurs in mixed CTD, scleroderma, RA, and dermatomyositis. The pathogenesis involves binding of immune complexes to the platelet surface. These are recognized by the reticuloendothelial system and such platelets are sequestered and destroyed, usually in the spleen. ITP needs to be distinguished from failure of platelet production due to a bone marrow disorder. In ITP the bone marrow will be normal or may, in chronic cases, show an increase in megakaryocyte number and activity.

First-line treatment of ITP is suppression of immune activity (steroids or other immune-suppressing drugs) or rituximab (a monoclonal antibody directed against CD20 found primarily on B lymphocytes). Intravenous infusion of immunoglobulin concentrates is usually beneficial in acute cases. The mechanism of action of this treatment is uncertain but may involve swamping of immunoglobulin Fc-binding sites. Other therapies include infusion of anti-D (rhesus), and splenectomy. Trials of thrombopoietin analogues have shown benefit in some cases.[6]

Thrombotic thrombocytopenic purpura

Thrombocytopenia may occasionally be due to thrombotic thrombocytopenic purpura (TTP), a condition associated with any autoimmune condition. Antibodies directed against a vascular endothelial protein (ADAMTS-13) impair cleavage of von Willebrand factor (vWF). When ADAMTS-13 levels are reduced, large vWF multimers proliferate and aggregate platelets. TTP is characterized by the combination of thrombocytopenia and microvascular haemolysis.[7]

Coagulation

A wide range of minor coagulation changes may occur in patients with rheumatic conditions. This can be due to liver and renal disease or to drug effects. Plasma fibrinogen is a very sensitive marker of underlying inflammation and will be raised in parallel with the C-reactive protein (CRP).

Low-grade Disseminated intravascular coagulation (DIC) may be found in patients with high levels of circulating immune complexes and resulting endothelial cell activation. In such cases the plasma fibrinogen level may not be as high as expected (from the CRP) or may be mildly subnormal. D-dimers, a product of both coagulation cascade and fibrinolytic activity, will be raised.

Intra-articular activation of coagulation systems may be found in all cases of arthritis, but especially those due to immune activity. This may result in intra-articular deposition of fibrin and a washover effect into the systemic circulation.

Lupus anticoagulant

The lupus anticoagulant (LA) occurs as a complication in about 10% of patients with SLE and is (paradoxically) associated with a thrombotic tendency, thrombocytopenia, recurrent miscarriages, and pulmonary hypertension. This is an in-vitro phenomenon due to antibodies directed against the phospholipid substrate on which coagulation occurs (the thromboplastin in coagulation assays). Although it is named as the 'lupus' anticoagulant after the first group of patients in whom it was identified, LA may occur in a very wide range of clinical conditions and even in normal individuals, and may be transient. It is, however, important to identify, firstly to differentiate from other causes of prolonged clotting assays (which may be associated with a haemorrhagic tendency); and secondly, as an important part of the anti-phospholipid syndrome.

The laboratory diagnosis of LA involves finding a prolonged clotting test—almost invariably the activated partial thromboplastin time (APTT)—which can be corrected by 'swamping' the sample with excess phospholipid substrate, to dilute the antibodies. Commercial thromboplastins are available which are relatively insensitive to the anti-phospholipid antibodies and are useful as screening tests for LA.

During heparin infusions levels of anticoagulation are usually monitored by the ratio of the patient's APTT to the 'normal' APTT. In patients with LA it is important to note that this ratio will not be effective and that the patient's pre-heparin APTT may need to be used as the ratio's denominator.

LA needs to be differentiated from clotting factor inhibitors encountered in patients with CTD (especially SLE) including antibodies to vWF and to factors VIII, VII, and fibrinogen.

CHAPTER 62

Biochemical investigation of rheumatic diseases

Berenice Lopez and Patrick J. Twomey

Introduction: clinical quality of results

Biochemical tests are generally ordered to support a diagnosis, or to detect a complication of a disease or a side effect of therapy. Irrespective of the intended use, it is important for clinicians to have an awareness of the quality of the result i.e. the extent to which they can be relied upon for the clinical purpose in hand. Despite the reporting of absolute numbers, every single quantitative result produced by laboratories has an associated uncertainty. This is largely a consequence of biological variation within and between individuals and the limitations of the measurement technology. In addition, the quality of a test result is affected by the sensitivity of laboratory internal quality control and external quality assurance procedures to detect clinically important errors. Without this understanding, a clinician's ability to determine whether a specific pathological process is occurring in a patient or interpret the implications of a difference between sequential results, particularly when monitoring chronic disease, can be compromised and patients may be misdiagnosed, overinvestigated, or even inappropriately treated.

Although there are currently no clearly defined best practice standards for how to incorporate uncertainty into the reporting of laboratory results, in the future more information about the confidence interval for a result and guidance on the significance of a change between serial results may be provided by laboratories. In the interim, adequate completion of request forms with a statement clarifying the pertinent clinical question as well as direct communication with clinical laboratory consultants can help, particularly in acute or difficult clinical scenarios.

Renal function

Patients with rheumatoid disorders are a high-risk group for kidney disease.[1] This may arise as a part of the pathology of a systemic disease particularly in conditions such as connective tissue diseases and vasculitides. However, renal impairment may also be a consequence of drug treatment, sepsis, and/or coincidental renal pathology as may be seen in rheumatic conditions such as osteoarthritis (OA), which affects large numbers of elderly patients with significant comorbidity.

Patients may present with acute kidney injury (AKI), a nephrological emergency which may lead to endstage renal failure and is associated with high mortality. AKI is most frequently caused by ischaemia, sepsis, and/or nephrotoxic drugs but may also be a consequence of rhabdomyolysis, contrast agents, or systemic diseases such as scleroderma crisis which occurs in 5–10% of patients with systemic sclerosis.[2] However, a more common presentation is slowly progressive chronic kidney disease. A classic example is secondary amyloidosis in rheumatoid arthritis (RA) and other inflammatory rheumatic diseases, although the incidence of endstage renal failure is decreasing with improvements in medical care.[3] Notwithstanding, data indicates a high prevalence of chronic kidney disease in rheumatology outpatient clinics.[4] Renal function should therefore be regularly evaluated in patients with rheumatic diseases to enable the early detection of kidney disease and institution of treatment to prevent or slow down progression to endstage renal failure.

Biochemical assessment of renal function

Glomerular filtration rate (GFR), the sum of the filtration rates in all functioning nephrons, numerically represents residual renal function and is currently widely viewed as the best overall index of kidney health.[5] Serum creatinine and its derivative eGFR are the most readily available surrogate markers of GFR and are used to assess degree of renal impairment and monitor its course. Additional screening for kidney damage is often performed by assessment of glomerular integrity including proteinuria, albuminuria, or haematuria and sometimes by diagnostic imaging for evidence of structural disease including renal scarring.

More subtle renal damage reflecting tubular injury—e.g. mild urinary sediment abnormalities, tubulopathy and acid–base disorders—are, however, frequently unrecognized but may also predict GFR and progression towards renal failure. Detection is important but often delayed until a decrease in renal excretory function as measured by serum creatinine or GFR occurs.

Glomerular filtration

GFR varies according to renal mass and correspondingly to body mass. It is conventionally corrected for body surface area (BSA), which in the average human being is 1.73 m^2, to account for this. When the GFR is corrected for BSA, a reference interval can be derived.[6–8] GFR is difficult to measure directly and as gold standard

methods are expensive, time-consuming, technically demanding, and not readily available, other markers are usually used. Serum creatinine, the most widely used marker, may, however, not accurately reflect kidney function as its level also depends on muscle mass and is subject to a number of other non-GFR related influences.[9] In addition, serum creatinine is not linearly related to GFR as a consequence of functional renal reserve, enhanced tubular secretion as levels increase, and other factors.[20–22] A large number of equations have been developed to estimate GFR using age, gender, ethnic origin, and weight as surrogates for muscle mass, in order to improve accuracy. The four-variable Modification of Diet in Kidney Disease study equation is currently in widespread use in the United Kingdom to estimate GFR in adults ≥18 years.[10] It uses serum creatinine, age, ethnic origin, and gender, has been validated in patients with chronic kidney disease, and is reasonably accurate at GFR levels less than 60 mL min^{-1}. However, bias and imprecision may limit its use at higher GFRs.[11] An awareness of other limitations is important. First, equations do not account for all the non-GFR related factors affecting serum creatinine levels such as the effect of drugs,[12,13] diurnal variation,[14] cooked meat consumption,[15] and analytical influences such as time to centrifugation[16,17] and creatinine method.[18] As regards the latter, efforts have been recently made to standardize creatinine measurements across the United Kingdom to ensure that the MDRD formula is appropriately corrected for different local creatinine assays. Second, the coefficients in the equation represent average effects observed in the population used to derive the equation and may not be applicable to other groups, particularly those where creatinine production is atypical or where the volume of distribution of creatinine may be altered. These include muscle wasting states, malnourished or oedematous patients, individuals at the extremes of body size, or pregnant women. Thirdly, a steady state is required and equations should not be used to assess kidney function in acutely unwell patients with AKI or changing renal function.[19]

In most clinical settings, it is sufficient to know whether GFR, and thus disease severity, is changing or stable. A change in serum creatinine of up to ±15% may simply reflect biological and analytical variability.[23] Recent National Institute for Health and Clinical Excellence (NICE) guidelines state that a GFR loss over 1 year of 5 mL min^{-1} or 10 mL min^{-1} L over 5 years may indicate significant progression and should trigger nephrology advice or referral.[10]

Glomerular integrity

Some protein, including small amounts of albumin, low-molecular-weight immunoglobulins, and secreted tubular proteins such as Tamm–Horsfall protein, is normally excreted in the urine. However, urinary protein excretion in the normal adult should be less than 150 mg/day. Higher rates of protein persisting beyond a single measurement may indicate impaired glomerular membrane integrity and kidney damage and must be evaluated.

Glomerular proteinuria is a cardinal sign of kidney disease and carries powerful prognostic information, identifying a subpopulation of chronic kidney disease (CKD) patients at greatly increased risk of kidney disease progression,[24,25] cardiovascular disease,[26,27] and death.[28,29] Although the most common cause of progressive kidney disease with proteinuria in the United Kingdom is diabetes mellitus, in patients with chronic inflammatory diseases, glomerular proteinuria may herald the development of secondary amyloidosis or nephropathy from other causes and this should be regularly screened for. Other types of proteinuria include overflow, typically the mechanism by which Bence Jones protein is first detected in urine and tubular proteinuria.

Assessment of protein:creatinine (PCR) or albumin: creatinine ratio (ACR) in a spot urine sample is more reproducible and useful than 24 hour collections. Samples should not be collected during acute illness or menstruation. Early morning urine samples correlate best with 24 hour urinary protein and albumin excretion, but random samples are acceptable although subsequent specimens should ideally be collected at about the same time.

Urinary albumin measurement provides a quantitative, relatively standardized measurement of excretion of the single most important protein in most nephropathies but samples with higher urinary albumin concentrations can be technically demanding because commercial urinary albumin assays have limited analytical ranges and manual or automatic dilutions may be required. In addition, there is a risk of antigen excess (prozone) phenomenon with some immunoassay approaches.[29a] Urinary protein measurement on the other hand is relatively non-specific, imprecise at low concentrations, and cannot be standardized, but most of the evidence for intervention thresholds in non-diabetic CKD is based on 24 hour urine protein excretion. In general, as ACR has a far greater sensitivity for the detection of low levels of proteinuria, it should be the test of choice for the initial detection of proteinuria but the PCR may be best used to monitor established proteinuria.

Reagent strips predominantly detect albumin not total protein, are not reliable quantitatively, and should not be used for the detection or monitoring of proteinuria. They may, however, provide a more reliable assessment of haematuria than laboratory testing. Haematuria, together with proteinuria, usually localizes the cause of the proteinuria to a glomerular pathology.

Tubular injury—tubular function and integrity

Tubular function

Renal tubules make up 95% of the renal mass, do the bulk of the metabolic work, and modify the ultrafiltrate in the urine. Considering the spectrum of tubular functions, these disorders result in varied, non-specific manifestations and a high index of suspicion is required. Renal tubular disorders may affect multiple or specific tubular functions and should be considered in adults with potassium and acid–base disturbances, hypophosphataemia, hypomagnesaemia, polyuria, osteomalacia or osteoporosis as well as renal calculi, and nephrocalcinosis.

Tubular integrity

Tubular proteinuria may be due to the increased excretion of several endogenous, freely filtered, low-molecular-weight proteins, including β_2-microglobulin and retinol binding protein, or due to failure of reabsorption in proximal tubular disease. Tubular proteinuria may also reflect epithelial cell injury and may be a source of biomarkers for the early detection and risk stratification of AKI. A multimarker panel including urinary neutrophil gelatinase associated lipocalin (NAGL) and kidney injury molecule-1 (KIM-1) may be useful in this context,[30,31] but a large number of other proteins are being assessed.

Liver function testing

Abnormalities of liver function tests (LFTs) and liver function are not uncommon in patients with rheumatic diseases. Systemic

inflammation can cause benign fluctuations in serum aminotransferase (alanine aminotransferase (ALT) or aspartate aminotransferase (AST)) and alkaline phosphatase (ALP) levels, but a hepatitic or cholestatic picture may mark the presence of primary, rheumatic disease-associated liver disease or coincidental pathology or infection. Elevations of serum aminotransferases may be seen in conditions such as viral hepatitis or autoimmune hepatitis. Disproportionate elevations of ALP may be seen in infiltrative including granulomatous diseases or early in the course of cholestatic disorders such as primary biliary cirrhosis, although bilirubin often becomes elevated in most patients as the disease progresses and is a poor prognostic sign. Of note, ALP elevations may reflect osteoblastic activity and ALP isoenzyme analysis should be performed where the source of ALP is in doubt, although a normal gamma-glutamyl transferase (GGT) level in this context usually excludes a hepatic source. Hypoalbuminaemia can be an ominous sign in patients with liver involvement, heralding the presence of severe liver damage, but various other conditions may be responsible including systemic inflammation and malnutrition.

The medical management of rheumatic diseases involves medications which are often hepatotoxic and routine monitoring of LFTs is recommended. Hepatotoxicity may also present as either a hepatocellular or cholestatic injury although some patients may present acutely with jaundice with a proportion rapidly developing hepatic failure. Irrespective of cause, chronic liver injury can lead to fibrosis and cirrhosis with the attendant complications of portal hypertension, impaired hepatic function, and hepatocellular carcinoma. A key question is whether monitoring LFTs is sufficient to detect the development of fibrosis—the rheumatology literature would agree.

Elevations of serum aminotransferases have been found to be predictive of abnormal or worsening histological grade on liver biopsy,[32] and for most disease-modifying drugs anti-rheumatic drugs (DMARDs) the current British Society for Rheumatology guidelines recommend withholding treatment when serum aminotransferases—either ALT or AST—exceed twice the upper reference limit (URL).[33] There are a number of problems with this approach, however. First, using multiples of the URL to define action thresholds is problematic because there is no consensus reference interval for aminotransferases and large differences in the URL can exist between laboratories, due mostly to variable reference intervals rather than method-specific biases.[34] The variability may be due to a the application of historical intervals constructed before anti-HCV testing and restrictive behavioural criteria for donor selection were implemented or because reference intervals have been constructed with varying regard for factors known to significantly modulate aminotransferases including gender, age, glucose, cholesterol, triglycerides, and body mass index (BMI).[35,36] In addition, serum aminotransferases have a skewed distribution with a tail to the right, so it is more difficult to be precise about the URL. Recent studies have provided a strong argument for the implementation of lower and more sensitive outcome-based reference intervals for ALT, but this remains controversial.[35,37] Nonetheless, agreeing and adopting common URLs for aminotransferases is highly desirable.

Second, many patients may have aminotransferase elevations from causes other than drugs. Biological variation of ALT, for example, can be significant within any one individual because it is subject to factors such as time of day and exercise,[38] coffee intake,[39] and dietary intake of sugars such as fructose and calories.[40] In addition,

raised ALT may be due to random analytical error. Thus elevations may be a transient or spurious abnormality.[41] Self-resolving liver enzyme abnormalities cannot, however, be distinguished from drug-induced liver injury (DILI) although observation of trends may be helpful. Both AST and to a lesser degree ALT are found in the cytosol of cells other than liver and elevations may also reflect leakage of these enzymes into the bloodstream due to myofibrillar damage as seen in myositis and other muscle diseases.[42] Raised aminotransferases may also be due to liver disease other than DILI.

Thirdly, there is evidence from the hepatology literature that LFTs are insufficiently sensitive or specific for the detection of liver fibrosis and cirrhosis,[43–46] and the potential for serious liver damage may still need to be explored when aminotransferase elevations are less than twice the URL, particularly in patients with other risk factors for liver disease.

Thus it is advisable that before initiation of therapy, a careful history for risk factors is taken with a particular emphasis on alcohol intake, risk factors for blood-borne viruses (e.g. blood transfusions, tattoos, intravenous drug abuse) or non-alcoholic fatty liver disease (NAFLD), e.g. diabetes mellitus and obesity, and any family history of liver disease. Patients should also be assessed for signs of liver disease (spider naevi, hepatomegaly, splenomegaly, jaundice). Those considered to be at risk and/or who have physical signs or abnormalities in baseline LFTs, full blood count (FBC), and prothrombin time (PT) including low platelets, low albumin, raised liver enzymes, raised bilirubin, or prolonged PT should undergo further liver evaluation. A liver screen including serum autoimmune as well as an immunoglobulin profile, hepatitis B and C serology, serum ferritin, serum α_1-antitrypsin, copper, and caeruloplasmin (if age <50 years), plasma glucose and lipid profile, and an ultrasound evaluation of the liver and spleen should be considered. A coeliac disease screen may also be helpful as this may be present in up to 9% of patients with unexplained elevated liver enzymes.[47–49] Most patients with baseline abnormalities in LFTs and a negative liver screen will, however, have either alcohol-related or fat-related liver disease. On this note, a positive diagnosis of NAFLD can be only be currently made on the basis of a negative liver screen, fatty liver on ultrasound, alcohol intake within recommended limits, and the presence of metabolic risk factors.[49] A liver biopsy or other marker or measure of liver fibrosis should be performed in those where the diagnosis is uncertain or the risk of advanced fibrosis and cirrhosis is high. With respect to clinical and routine laboratory variables, older age (>45 years), presence of diabetes, increasing BMI, low platelet counts, low albumin levels, and an AST/ALT ratio of greater than 1, are all predictive of advanced liver disease in NAFLD.[50]

Risk factors should also be assessed in patients who develop raised aminotransferases while on treatment with a DMARD. An enquiry into alcohol intake and exposure to risk of blood-borne viruses by intravenous drug abuse, blood transfusions, or multiple sex partners is pertinent. Opportunistic infections may also have to be ruled out in rheumatic patients.

Assessment of the severity and progression of DILI may be facilitated in the near future by the use of non-invasive quantitative testing for hepatic fibrosis. Although liver biopsy remains the gold standard for the staging of fibrosis, this is a flawed reference standard because of the potential for sampling error as well as inter- and intraobserver variability. It is also costly, invasive, and associated with a mortality risk of 0.01–0.1%. Non-invasive approaches offer a number of

advantages including reduced risk of adverse effects as compared with liver biopsy, reduced risk of sampling error, objectivity in interpretation of results, appropriateness for repeated measurements, increased availability, and lower cost. A novel ultrasound technique that measures hepatic elasticity (Fibroscan) has been found to reliably identify advanced fibrosis but its clinical role is still being determined.[51] A range of surrogate serological markers have also been evaluated including indirect markers of liver fibrosis such as platelet counts and AST/ALT ratio as well as more direct measures of liver fibrosis such as procollagen type III N-terminal peptide (P3NP), hyaluronic acid, and type IV collagen. These measure matrix turnover rather than fibrosis per se and are not liver specific, thus levels may be high in acute inflammation in the liver or at other sites such as synovial membrane, limiting their utility.[52–54] A growing number of panels have also been developed using various combinations of these markers. The performance of serological markers and transient elastography and their diagnostic cut-offs vary among different liver diseases, however,[55] and as yet even the more successful markers and panels have only been validated in specific patient groups with utility restricted to the identification of the near-absence or the presence of advanced fibrosis and cirrhosis. The current armoury of non-invasive tests cannot be used to identify intermediate stages or to monitor the progression of fibrosis in an individual patient and liver biopsy continues to be required, at least for the time being.

Calcium and bone biochemistry

Calcium and phosphate homeostasis are coordinated by systemic and local factors that regulate intestinal absorption, influx and efflux from bone, and kidney excretion and reabsorption of these ions. Parathyroid hormone (PTH), secreted by the parathyroid gland in response to hypocalcaemia, maintains normocalcaemia by increasing tubular calcium reabsorption, stimulating the conversion of calcidiol (25-hydroxyvitamin D) to calcitriol (1,25-dihydroxyvitamin D) thereby increasing intestinal calcium and phosphate absorption and, with calcitriol, stimulating osteoclastogenesis, increasing calcium and phosphate efflux from bone. Normal phosphate balance is maintained through phosphaturic effects. In addition to PTH and calcitriol, phosphate homeostasis is also regulated by dietary phosphate intake.[56] Two new proteins, klotho and fibroblast growth factor 23 (FGF23) are also emerging as important players in phosphate and calcium metabolism.[57,58] FGF23, a secreted phosphatonin, induces renal phosphate wasting and inhibits synthesis of calcitriol acting through specific FGF receptors with the important cofactor klotho protein. Klotho also directly modulates renal phosphate excretion and calcium reabsorption through effects on transporters.[59] Both overexpression and deficiency of FGF23 cause several clinical diseases including inherited and acquired forms of hypophosphataemic rickets and hyperphosphataemic familial tumoral calcinosis (HFTC).

Biochemical tests in calcium and bone pathology

At physiological pH, 15% of plasma calcium is bound to organic and inorganic anions, 40% is bound to albumin, and 45% is free or ionized calcium. It is the ionized calcium that is physiologically active and under tight homeostatic control, so this should ideally be measured, but difficulties in accurate analysis, lack of standardization, and strict sampling requirements mean that total calcium is more conveniently measured. Better correlation between total calcium and ionized calcium may be achieved when total calcium is adjusted for the plasma albumin because changes in serum albumin concentration can affect total calcium without affecting ionized calcium. The correction equation applied should be specific for the individual laboratory's albumin method and the local population.[60] It is worth noting, however, that use of correction equations, particularly when albumin is in the normal range or higher, remains controversial.[60a,60b] Acid–base disturbances,[61] hyperparathyroidism,[62] and hyperphosphataemia may also affect ionized calcium without affecting total calcium and in these instances direct measurement of ionized calcium may be useful. The underlying pathology of any calcium abnormality can usually be elucidated by the simultaneous measurement of calcium, renal function, and PTH.

Serum phosphate can also provide an initial indication of the pathology of any calcium abnormality, with calcium and phosphate concentrations usually changing in the same direction unless PTH is inappropriately in excess or deficient or renal failure is present. Isolated hypophosphataemia may be seen in primary or secondary hyperparathyroidism, inherited or acquired hypophosphataemic rickets is typically seen in children, or oncogenic osteomalacia in adults. Prolonged phosphate deficiency is associated with bone demineralization, resulting in rickets and osteomalacia. Hyperphosphataemia is a common and serious complication of chronic renal failure and contributes to secondary hyperparathyroidism. On occasion, hypo- or hyperphosphataemia may be spurious, resulting from analytical interference by a paraprotein.[63]

PTH is a relatively unstable peptide hormone which is broken down in blood after venepuncture but is stable for 48 hours in EDTA.[64] PTH circulates in different molecular forms, including the intact molecule (PTH 1–84) and various truncated forms (e.g. PTH 7–84), which may be differentially recognized by the various antibodies used in PTH immunoassays so that PTH results from different laboratories may not be comparable even though quoted reference intervals may be the same.[65] The biological variability of PTH is high and concentrations must change by more than 50% before they can be assumed to be real.[66]

Calcidiol is the major circulating form of vitamin D, with a half-life of 2–3 weeks. It is the best indicator of nutritional vitamin D status but method-related differences means that the comparability and accuracy of different assays may be a concern.[67] This may improve as uniform standards are widely implemented. Of note, calcidiol varies in a sinusoidal manner with large seasonal differences relative to mean concentration so that a single vitamin D measurement may not capture overall vitamin D status.[68] Measurement of calcitriol is not useful for monitoring vitamin D status because its circulating half-life is only 4 hours; levels are 1000 times lower than calcidiol and do not reflect nutritional vitamin D reserves. Measurement may, however, be useful in acquired and inherited disorders of vitamin D and phosphate including hereditary phosphate wasting disorders, oncogenic osteomalacia, and chronic granulomatous disorders such as sarcoidosis.

FGF23 and Klotho assays are currently not harmonized and do not appear ready for routine clinical use.[69]

Biochemical markers of bone turnover

Bone is constantly being remodelled in adults and bone formation is tightly coupled to bone resorption so that bone mass is preserved. Metabolic bone diseases occur when bone formation

and bone resorption are uncoupled. This group of disorders traditionally includes osteomalacia, osteoporosis, and Paget's disease of bone. However, rheumatic diseases, particularly those associated with widespread systemic inflammation, may produce generalized effects on bone remodelling that may affect the entire skeleton.

Changes in the rate of bone turnover are an important determinant of bone disease. Several assays are currently available that measure bone turnover markers (BTM), which are collagen breakdown products and other molecules released from osteoclasts and osteoblasts during the process of bone resorption and formation. Urinary and serum N-terminal telopeptide of collage type 1 (NTX) and C-terminal telopeptide of type 1 collagen (CTX) are the most clinically useful markers of bone resorption, while serum bone specific ALP and procollagen type 1 N-terminal propeptide (PINP) are the most clinically useful markers of bone formation.[70] Their main application is to provide guidance as to whether a patient has a high or low bone turnover, and the impact of therapy.

BTMs are not, currently, widely used in clinical practice because of biological and analytical variability.[71] Bone turnover and BTMs follow a circadian rhythm and are altered by food intake, thus urine should be collected as a second morning fasting sample and blood collected in the morning after an overnight fast. Patients should have all their measurements performed by the same laboratory.

Autoimmune serology

Philip Hamann and Neil McHugh

Introduction

The term 'antibody' was first published in 1891 by Paul Ehrlich in an article on experimental studies of immunity. However, the concept of toxic autoantibodies was initially dismissed by Ehrlich's doctrine of the '*horror autotoxicus*', or the implausibility of pathogenic autoimmunity. Driven largely by the desire to produce new vaccines to infective diseases, further investigations into autoimmunity were largely ignored; it was not until many decades later that the very concept of autoimmunity began to gain acceptance.

With Erik Waaler's, and subsequently Harry Rose's, discovery in the 1940s of rheumatoid factor (RF) from the agglutination of indicator sheep erythrocytes in serum of rheumatoid arthritis (RA) patients tested for syphilis, autoimmune serology found its first diagnostic use in helping to characterize RA. From this discovery, the pathophysiology of RA, and many other autoimmune conditions began to be understood.

Over the past 60 years, autoimmune serology has become central in the characterization of many rheumatic conditions. Indeed, in many cases the presence of an autoantibody may form part of the diagnostic criteria. Interpretation of serological results can be complex, due to varied terms and experimental methods. However, with a thorough understanding of the techniques and terms, as well as the clinico-pathological significance of autoantibodies, autoimmune serology can be extremely helpful in diagnosis and prognosis of many autoimmune conditions.

Serological methods for autoantibody detection

Indirect immunofluorescence

Indirect immunofluorescence (IMF) is a widely used and highly useful technique for screening for the presence of autoantibodies and in some cases for identification of the autoantibody specificity. The type of substrate used for IMF will depend on the autoantibody profile sought. HEp-2 epithelial cells are most commonly used for screening for the presence of an anti-nuclear antibody (ANA), as the individual organelles can be easily visualized and cell-cycle-specific autoantigens detected more readily as the cells are rapidly dividing. Other tissue substrates (e.g. murine liver, kidney, stomach, monkey oesophagus) are sometimes used for screening, but are less sensitive and may miss certain autoantibodies (e.g. anti-centromere

(ACA)) However, tissue substrates may detect other specificities sometimes seen in organ-specific autoimmune disease (e.g. anti-mitochondrial antibody in primary biliary cirrhosis, anti-endomysial antibodies in coeliac disease). Human neutrophils fixed in ethanol are used for screening for the presence of anti-neutrophil cytoplasmic antibodies (ANCA), with the immunofluorescence pattern providing some information on likely specificity. *Crithidia luciliae*, a haemoflagellate, possesses a giant mitochondrion containing a mass of double-stranded DNA (dsDNA), termed a kinetoplast, and is a useful substrate for confirming the presence of anti-dsDNA antibodies. Examples of typical ANA patterns seen on IMF are shown in Figure 63.1. In most cases additional techniques are needed to confirm autoantibody identity. Also, the IMF test is not a perfect screen and may be reported low titre or negative for some specificities (e.g. anti-Ro (-SSA)). Addressable laser bead assays are a more recent advance that provide a platform for simultaneous testing for multiple autoantibody specificities by flow cytometry. Selected antigens are attached to microspheres labelled with different ratios of fluorochromes for each antigen, creating a spectral array that can be quantitated for the reaction with the corresponding autoantibody. It remains uncertain whether the quantitative data obtained by multiplex bead assays yield similar data to other methods. In addition, bead assays rely on the relevant autoantigen being included in the system and therefore may miss the full repertoire of autoreactivity. Other IMF and non-IMF autoantigen microarray systems are under ongoing development.

Immunodiffusion

Gel diffusion techniques (e.g. Ouchterlony, counterimmune electrophoresis) are methods for detecting autoantibodies to autoantigens that can be purified from extracts (e.g. calf or rabbit thymus, human spleen)—hence the term extractable nuclear antigen (ENA). Traditionally autoantibodies to autoantigens such as Ro (-SSA) La (-SSB), U1-RNP, Sm, Jo-1, topoisomease-1 (-Scl-70), and PM-Scl have been identified by this method. However these techniques may be time consuming and relatively insensitive, and are being superseded by solid phase assays.

Enzyme-linked immunosorbent assay techniques

Enzyme-linked immunosorbent assay (ELISA) techniques are popular as they are more automated, less costly, and allow more widespread screening; recombinant proteins for a wide range of
Fig. 63.1 Typical immunofluorescence patterns: (A) anticentromere staining during metaphase in HEp2 cells. (B) dsDNA in the kinetoplast of *Crithidia luciliae*. (C) nucleolar staining in HEp2 cells. (D) Perinuclear ANCA staining in human neutrophils.

autoantigen specificities have become available. ELISA methods may provide more false-positive results usually by non-specific binding of immunoglobulin, but work well for certain autoantibody systems. ELISA may be the sole method for detecting some autoantibody specificities such as anti-cardiolipin (aCL) and anti-β_2-glycoprotein I (anti-β2GPI), anti-citrullinated protein antigens (ACPA), or for confirming autoantibody specificity (e.g. type of ANCA). Also, as ELISA provides semiquantitative results there is the potential for more detailed investigation of how autoantibody levels relate to disease activity—e.g. ANCA levels and vasculitis, anti-dsDNA binding, and systemic lupus erythematosus (SLE).

Immunoblotting

Immunoblotting methods may provide advantages in determining the finer specificity of autoantigen recognition (e.g. the profile of polypeptide determinants within a complex autoantigen that an autoantibody recognizes). Dot-blots or line-blots are derivative methods that contain custom selected profiles of either purified or recombinant autoantigen; they are semiquantitative and gaining increased use.

Immunoprecipitation

Immunoprecipitation (IP) of either protein or RNA from cell lines followed by gel separation is the gold standard for detecting a large range of autoantibody specificities that are difficult to detect by other

means (Figure 63.2). The technique is not widely available, due to constraints from handling radioactivity and the expertise and labour intensity involved. However, certain nucleolar autoantibodies can still only be reliably detected by IP. Also IP may display additional autoantigen targets for which the specificity remains unknown.

Other methods

Agglutination techniques may still be used for detecting RF. The Rose–Waaler test using sheep cells is more specific than the RF latex test using beads. Other methods for detecting RF, including laser nephelometry or ELISA, are more commonly used. There may be the potential for false-positive results by ELISA due to the anti-globulin activity of RF. Fluid-phase radioimmunoassays such as the Farr assay for detecting high-affinity antibodies to dsDNA have been replaced by ELISA and/or the *Crithidiae* test (see above).

Autoantibodies

Antibodies to citrullinated protein antigens

ACPA are the most specific biomarkers in widespread use for detecting RA. Citrullination of peptides occurs during cell apoptosis and is mediated by the peptidyl-arginine deiminases (PADs) class of enzymes. Loss of cell wall integrity during apoptosis in an inflamed joint increases permeability to calcium and the resultant escalation in intracellular calcium levels activates PADs. PADs are present
Fig. 63.2 Examples of some autoantibodies detected by the technique of immunoprecipitation. Each lane contains the autoantigen that has been precipitated out from a radiolabelled cell line by serum containing the autoantibody, then separated out on a SDS-PAGE gel and identified following autoradiography and according to its profile and molecular weight. NS, normal serum.

in high concentrations in neutrophils and monocytes, and their activation results in substitution of positively charged arginines by neutrally charged citrullines (citrullination) in autologous peptides. This increased citrullination of peptides in an inflamed joint may lead to the development of ACPA.[1] However the association of cigarette smoking with ACPA, particularly in shared epitope positive individuals, may indicate citrullination of peptides in the lung as the initiating event in ACPA formation (see Chapter 109).

Rheumatoid factor

RF are autoantibodies with specificity against the C-terminal domain of the constant region of the heavy chain in human IgG. Chronic inflammation and oxidative stress play a key role in altering the structure of IgG, which makes the constant region of the IgG more available and may enhance the development of RF.[2] Immune complexes of RF and autologous IgG and subsequent activation of complement and the inflammatory cascade leads to localized tissue damage. IgG RF also have the potential to activate cells via Fc-γ receptor binding.[3] Between 1% and 4% of healthy persons in a white population of European origin will have RF, and titre increases with age. RF can also form an important part of host defence against bacterial and viral pathogens.[2]

Anti-nuclear antibodies and extractable nuclear antibodies

ANA is a general term encompassing the group of antibodies to intranuclear antigens, that is sometimes generalized to include

anti-cytoplasmic antibodies that may be detected using the same technique (also some autoantigens are located in both the cell nucleus and the cytoplasm). Although many ANAs are disease specific, positive results can be found in healthy individuals and results need interpretation within the clinical context. Approximately 3–5% of randomly selected healthy individuals in a white population of European origin will have a positive ANA, and the prevalence of healthy individuals with a positive ANA rises with increasing age.

ANA staining pattern on IMF can be grouped broadly into three subclasses: nucleoplasmic, nucleolar, and cytoplasmic.[4] Nucleoplasmic staining antibodies are further subclassified according to the pattern seen on IMF, into homogenous (which includes specificities for dsDNA, histone, chromatin, topoisomerase 1(-Scl70); speckled (Sm, nRNP, Ro (-SSA), La (-SSB), PCA, Ku, RNA polymerase II (RNAP II)); peripheral (Lamin A/B/C, nuclear pores); and centromere (CENP A/B/C). ACA is specific for systemic sclerosis (SSc) and requires no further quantification; however, all other nucleoplasmic antibodies require identification with further techniques.

Nucleolar staining antibodies are most commonly found in SSc and consist of antibodies to fibrillarin (U3-RNP), RNAP I/III, hUBF (-NOR-90), Pm-Scl, and Th(1–7).

Lastly, cytoplasmic staining antibodies seen on IMF comprise most of the myositis-related autoantibodies (aminoacyl tRNA synthetases, anti-SRP), as well as anti-mitochondrial antibodies, anti-ribosomal, anti-Golgi apparatus (Golgin), and anti-Ro (-SS-A).

Anti-neutrophil cytoplasm autoantibodies

ANCA are antibodies directed against the lysosomal compartment of neutrophils and monocytes. The two main subtypes of ANCA, anti-myeloperoxidase (anti-MPO) and anti-proteinase 3 antibodies (anti-PR3) yield a typical staining pattern on IMF that can be used as a screen, but ELISA is necessary for confirmation of specificity. A cytoplasmic ANCA (C-ANCA) pattern on IMF is associated with anti-PR3 antibodies, whereas perinuclear (P-ANCA) staining represents the presence of anti-MPO antibodies.

MPO and PR3 antigens are normally only present on intracellular granules. However, in primed neutrophils, these antigens migrate to the surface and are available for binding by ANCA. This leads to production of reactive oxygen species and release of proteolytic enzymes that cause vascular damage and localized inflammation.[5,6]

Anti-phospholipid antibodies

Anti-phospholipid antibodies refer to a heterogeneous group of antibodies variously directed against phospholipids and phospholipid binding proteins. Currently, aCL and anti-β2GPI are antibodies used in the diagnosis of anti-phospholipid syndrome (APS), although numerous other subsets of anti-phospholipid antibodies have been identified.

The presence of a lupus anticoagulant (LA) is demonstrated in vitro by an increase in clotting time in phospholipid-driven clotting studies (such as APTT, dRVVT, KCT). The lack of reversibility of increased clotting time when control plasma is added indicates the presence of an inhibitor of the reagent used to drive the reaction in vitro, rather than a lack of clotting factor from the original sample.[7] The term 'lupus anticoagulant' is a misnomer as the antibodies that cause a positive LA result may be found in conditions other than lupus and are prothrombotic (see Chapter 61).

Cardiolipin was initially identified as the antigen for aCL antibodies, but in the 1990s β2GPI, a cardiolipin binding protein, was identified as a major antigenic target of aCL antibodies. β2GPI is a phospholipid binding protein which has natural anticoagulant properties. Antibodies to β2GPI interfere with its anticoagulant properties, and alter the homeostatic mechanisms leading to a pro-thrombotic state.

Rheumatic conditions associated with specific antibodies

Rheumatoid arthritis

Approximately 55–70% of patients with RA are ACPA positive, whereas RF is present in less than 50% of patients with early RA, rising to 60–90% in more advanced disease.[8] ACPA is the most specific test for RA and has a sensitivity of around 67% and specificity of 95% compared with 69% and 85% respectively for RF.[9] ACPA are linked with smoking and are the strongest single predictor of radiographic progression in early RA. ACPA and RF titres are not useful biomarkers to assess response to treatment, and absolute antibody titres do not correlate with disease severity. Approximately 50%[10] of RA patients are dually positive for ACPA and RF and, in a healthy individual, dual positivity has a near 100% positive predictive value for the subsequent development of RA.[11] Although very specific for RA, ACPA may be found in low prevalence in other autoimmune conditions and some infections. RF is commonly found in many other autoimmune and infectious conditions and is a relatively non-specific marker for RA.

Systemic lupus erythematosus

ANA is a useful screening test for systemic lupus erythematosus (SLE) with a sensitivity of 90–95%. It's specificity is limited, however, with a positive predictive value of only 11–13%.[4] Anti-dsDNA titres correlate well with disease activity in SLE and a strongly positive, or rising, anti-dsDNA level often precedes onset of a flare (often lupus nephritis). Anti-Sm antibodies are virtually pathognomonic of SLE; they are present in 5–30% of patients with the condition and are associated with lupus nephritis, although antibody titre does not appear to correlate with disease activity.[12] Anti-U1RNP may coexist with anti-Sm, as they both target ribonuclear proteins on the spliceosome complex, but anti-U1RNP is less specific for SLE (found in 20–40% of cases[4]) and is a marker for mixed connective tissue disease (MCTD) when present in high titres.[12] Anti-ribosomal P antibodies are also highly specific to SLE and, in some studies but not others, linked with neuropsychiatric manifestations of the disease.

Anti-phospholipid syndrome

Due to the relative frequency of thromboses and miscarriage in the general population, the detection of anti-phospholipid antibodies plays a pivotal role in the diagnosis of APS. The presence of anti-phospholipid antibodies is associated with an increased risk of thrombosis.[13] The risk of thrombosis or fetal loss is greatest with high levels of IgG aCL together with the presence of a LA. As anti-β2GPI and aCL can be found often transiently in many other autoimmune conditions, acute infections as well as malignancies,[7] it is essential to confirm positivity with repeat sampling at least 12 weeks later.

Sjögren's syndrome

Sjögren's syndrome (SS) is typified by the autoantibodies anti-Ro (-SSA) and anti-La (-SSB) that play a key role in the classification of the disease. Anti-Ro positivity is present in 50–70% and dual positivity for anti-Ro and anti-La is found in approximately 30–60% of cases of primary SS (pSS). Single anti-La positivity is rarely found. Seropositivity in pSS is associated with an earlier age of disease onset as well as more frequent parotitis, and extraglandular complications. Sialogram abnormalities are more frequently found in patients with anti-Ro positivity and lip infiltration is more common in anti-La positive pSS.[14] Seropositivity and titres for anti-Ro and anti-La remain relatively constant throughout the course of the disease, and do not change in response to treatment.

ANCA-associated vasculitis

ANCA-associated vasculitis (AAV) includes three disease entities: granulomatosis with polyangiitis (GPA, formerly known as Wegener's granulomatosis), microscopic polyangiitis (MPA), and Churg–Strauss syndrome (CSS). Typically, GPA is associated with anti-PR3 antibodies and MPA and CSS are both associated with the presence of anti-MPO antibody. The full role of ANCA in AAVs is yet to be elucidated, but the efficacy of B-cell depletion therapies highlights their likely importance.

Inflammatory myositis and dermatomyositis

Autoantibodies in myositis are grouped into myositis-specific antibodies (MSA) and myositis-associated antibodies (MAA). MSAs include the anti-tRNA synthetases (e.g. anti-Jo-1), anti-SRP, and anti-Mi2, as well as more recently discovered antibodies.[15] The MSAs correlate very closely to disease phenotype and can be useful in directing screening for future complications of the disease.[16] The MAAs include anti-PMScl, anti-Ku, and anti-U1RNP and are found in myositis, but have a significant overlap with other connective tissue disorders, especially SSc. The largest group of MSAs consist of the anti-tRNA synthetases, which are associated with a symptom complex that has become known as the anti-synthetase syndrome. Features include inflammatory muscle disease, Raynaud's phenomenon, interstitial lung disease, characteristic cutaneous manifestations, and arthritis. Both dermatomyositis and myositis are associated with an increased incidence of malignancy,[17] especially in patients with antibodies to transcription intermediate factor-1 gamma (anti-TIF-1γ). Anti-SRP antibodies are associated with immune-mediated necrotizing myositis (IMNM), and antibodies to HMG CoA reductase with IMNM associated with the use of statins.

Systemic sclerosis

Over 90% of patients with SSc are ANA positive and in most cases a disease-specific autoantibody can be detected that is associated with certain clinical features The serotype can be useful in predicting the disease outcome as it does not alter significantly during the disease course.[18]

ACA and anti-topoisomerase-1 (-Scl-70) are the most commonly found antibodies in SSc (30–35% and 20–25% of cases respectively, and they hardly ever coexist). Anti-topoisomerase-1 (-Scl-70) can be found in both diffuse and limited cutaneous SSc and is more closely associated with pulmonary fibrosis, which contributes to a

high mortality. Conversely, ACA are associated with a limited SSc (lSSc) phenotype with distal skin thickening, peripheral vascular damage, calcinosis, and isolated pulmonary hypertension (but not pulmonary fibrosis). ACA is generally associated with a better disease prognosis and a more indolent disease course. In patients with isolated Raynaud's, ACA can be predictive of future development of lSSc.[18]

RNAP-III antibodies are associated with diffuse SSc (dSSc) and internal organ involvement, with a renal preponderance. Historically, anti-RNAP III antibodies were associated with the worst prognosis due to their association with renal crises, but the development of angiotensin converting enzyme (ACE) inhibitors and improved medical management of renal disease has reduced mortality from this complication.

The remaining anti-nucleolar antibodies, are less commonly seen, but all have distinct disease phenotypes (see Table 63.1).

Mixed connective tissue disease

MCTD has overlapping clinical features of SLE, SSc, RA, and inflammatory myositis. It is characterized by the presence of anti-U1RNP, which is required to make a diagnosis of MCTD, as well as (less commonly) anti-U1RNA antibodies. A strongly positive speckled staining pattern is usually seen by IMF.[19] Anti-U1RNP can be detected before clinical disease onset, but symptoms usually develop within 1 year of antibody induction.[19] In some studies, anti-phospholipid and anti-endothelial antibodies have been detected with anti-U1RNP and appear to be predictive of pulmonary hypertension. The exact mechanism remains unknown, but could involve the activation of endothelial adhesion factors in the pulmonary vasculature along with the upregulation of cytokines, particularly interleukin (IL)-1 and IL-6.[20]

See Table 63.1 for a summary of antibodies and their associations with rheumatoid diseases.

Table 63.1 Antibodies associated with rheumatic disease

Antibody	Primary disease associations	Clinical association
ACPA	RA	Erosive joint disease
RF	RA	Erosive joint disease
Anti-nuclear antibodies (ANA)		
Anti-dsDNA	SLE	Lupus nephritis
Anti-Sm	SLE	Vasculitis, CNS lupus
Anti-ribosomal P	SLE	Neuropsychiatric manifestations
Anti-histone	Drug induced SLE when found in isolation	Use of: hydralazine, procainamide, isoniazid, methyldopa, chlorpromazine, quinidine, minocycline
Anti-chromatin	SLE, Drug induced lupus	Renal involvement
Anti-lamin A/B/C	SLE, APLS, and autoimmune hepatitis	
Anti-PCNA	SLE	
Anti-CENP A/B/C (Anti-centromere)	SSc	Limited cutaneous SSc, pulmonary hypertension (but not pulmonary fibrosis), female gender
Anti-topoisomerase 1 (Anti-Scl70)	SSc	Pulmonary fibrosis
Anti-U1-RNP	SSc, IM, MCTD	High levels with MCTD
Anti-Ku	SSc, IM and SLE	
Anti-fibrillarin (Anti-U3-RNP)	SSc	Pulmonary hypertension
Anti-PM-Scl	SSc/IM overlap	Myositis overlap
Anti-RNAP I & III	SSc	Renal involvement
Anti-Th (1–7)	SSc	Limited SSc and gastrointestinal complications
Anti-hUBF (Anti-NOR-90)	Non-specific marker of systemic autoimmune conditions including, SSc, SLE, RA, Sjögren's syndrome and malignancies	
Anti-Ro60 & 52 (SSA)	Sjogrens, SLE, myositis, and SSc. Single Anti-Ro52 positivity without Anti-La associated with IM	Sicca symptoms Anti-Ro52 with cardiac conduction abnormalities in neonatal lupus
Anti-La (SSB)	Sjogrens, SLE, IM, and SSc	Sicca symptoms Cardiac conduction abnormalities in neonatal lupus
Anti-aminoacyl tRNA synthetases[a]	IM	Anti-synthetase syndrome

(Continued)

Table 63.1 (*Continued*)

Antibody	Primary disease associations	Clinical association
Anti-SRP	IM	Necrotizing myopathy
Anti-p155/140 (Anti-TIF-1γ)	JDM, DM	JDM: DM and ulceration Adults: DM and malignancy
Anti-HMG CoA reductase	IM	Statin induced necrotizing myopathy
Anti-Mi2	DM	
Anti-nuclear pore	PBC	
Anti-mitochondrial	PBC	
Anti-Golgi apparatus	Non-specific autoimmune conditions	
Anti-neutrophil cytoplasm autoantibodies (ANCA)		
Anti-MPO	MPA, CSS, GPA (in order of association) also drug-induced lupus	Small to medium vessel vasculitis
Anti-PR3	GPA, MPA, CSS (in order of association)	Small to medium vessel vasculitis and granulomata
Anti-phospholipid antibodies (APA)		
aCL	APLS	Thromboembolic disease, pregnancy loss
aβ2GPI	APLS	Thromboembolic disease, pregnancy loss

aCL, anti-cardiolipin; ANA, anti-nuclear antibody; ANCA, anti-neutrophil cytoplasm autoantibody; anti-CENP, anti-centromeric peptide; APS, anti-phospholipid syndrome; aβ2GPI, anti-B2 glycoprotein I; CSS, Churg–Strauss syndrome; DM, dermatomyositis; dsDNA, double-stranded DNA; GPA, granulomatosis with polyangiitis (Wegener's disease); IM, inflammatory myositis; JDM, juvenile dermatomyositis; MCTD, mixed connective tissue disease; MPA, microscopic polyangiitis; PBC, primary biliary cirrhosis; RA, rheumatoid arthritis; RF, rheumatoid factor; SLE, systemic lupus erythmatosus; SSc, systemic sclerosis.

aIncluding: Jo-1 (anti-histidyl), PL-12 (alanyl), PL-7 (threonyl), EJ (glycyl), OJ (isoleucyl), KS (asparginyl), Ha (tyrosyl), Zo (phenylalanyl).

CHAPTER 64

Complement

Matthew C. Pickering and Jyoti Bakshi

Complement biology

Complement was first identified as a heat-sensitive component in blood that enhanced ('complemented') the ability of antibodies to destroy bacteria. The biological functions of complement are: (1) host defence and the inflammatory response, (2) the physiological removal of immune complexes and dying cells ('waste disposal'), and (3) an accessory role in the induction of immune responses ('natural adjuvant'). Complement can be activated through three pathways (classical, lectin, and alternative pathways, Figure 64.1). All generate complexes that can cleave intact C3 to its active form,

C3b. C3b can be rapidly amplified through a feedback cycle termed the C3b amplification loop, resulting in opsonization of the activating surface. C3b can trigger the activation of complement C5 and the terminal pathway. This results in (1) the generation of the membrane attack complex (MAC), which can damage or lyse the activating surface, and (2) the production of C5a, a cleavage fragment of C5 that is a potent anaphylatoxin. Finally, C3b itself or further proteolytic fragments (sequentially termed iC3b and C3d) can interact with cellular receptors (termed complement receptors, Figure 64.1).

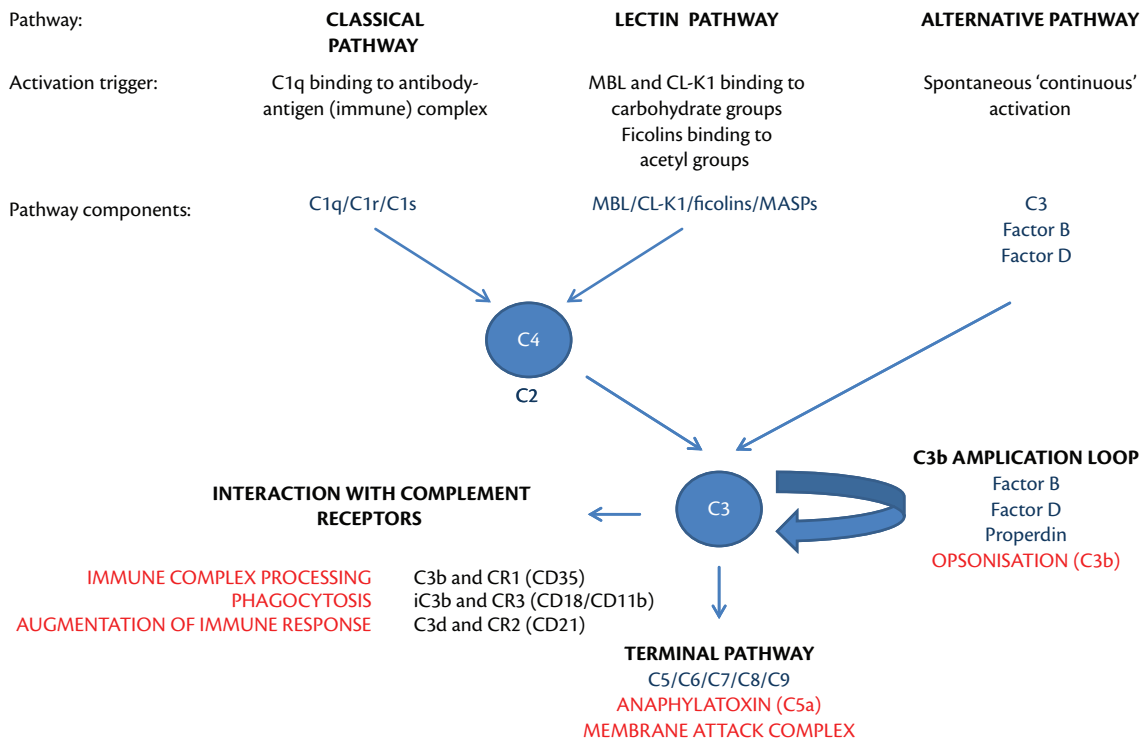
The triggers of the three pathways are distinct. The classical pathway is triggered by an interaction between C1q and antibody bound


Fig. 64.1 Schematic depiction of the complement system. Complement is activated through three pathways that converge on C3. Each pathway has distinct activating signals. The detailed biochemistry of the activation pathways is not clinically relevant but it is important to note that C4 is one of the activation proteins of the classical pathway. Therefore, in immune complex disease where there is increased classical pathway activation, C4 levels are typically reduced with or without a reduction in C3 levels. Only rarely is isolated reduction in C3 seen and this usually indicates abnormal activation of the alternative pathway. Key complement functions are depicted in red. C4 and C3 are schematically emphasised as these are the most frequently measured activation proteins. The other activation proteins are depicted in blue within their respective pathways. MBL, mannose-binding lectin; MASP, MBL-associated serine protease.

to antigen (immune complex). The lectin pathway is triggered by pattern recognition molecules that recognize carbohydrate or acetyl residues on surfaces. These include mannose-binding lectin (MBL), CL-K1 (CDC (cell division cycle)-like kinase 1) and ficolins.[1] (Degn et al.[1] is a key reference, providing a comprehensive review of complement biology and disease-associated complement mutations). The alternative pathway does not require a specific trigger. It is in a continuous state of activation, constantly generating C3b.

Complement activation is controlled by regulatory proteins that act at multiple steps in the activation pathways. Clinically, key regulators are C1 inhibitor (C1INH), CD59, factor H, and factor I. C1INH prevents classical pathway activation and is defective in hereditary angioedema (HAE). CD59 inhibits the MAC and is deficient on erythrocytes in paroxysmal nocturnal haemoglobinuria (PNH). Factor H and factor I regulate the alternative pathway and deficiencies are associated with C3 glomerulopathy and atypical haemolytic uraemic syndrome (aHUS).

Complement deficiency states

Complement deficiency states can be divided into those due to impaired activation and those due to excessive activation (Table 64.1).

Activation protein deficiencies

Increased susceptibility to childhood pyogenic bacterial infection is frequently seen for many of the homozygous deficiencies, whereas heterozygous deficiency is usually asymptomatic (Table 64.1). Infections become less frequent or even absent during adulthood when the protective antibody repertoire has expanded.[2] Alternative and terminal pathway deficiencies are particularly associated with neisserial infection.[3]

The most important non-infective phenotype is the association between classical pathway deficiency and systemic lupus erythematosus (SLE). Over 95% of homozygous C1q-deficient individuals develop SLE.[4] The reasons for this association are complex and include abnormal immune complex processing and impaired tolerance to autoantigens through defective clearance of apoptotic cells (see Chapter 115). The association between C2 deficiency and SLE is much less strong and is approximately 10%.[4]

Homozygous deficiencies are rare with the exception of C2, MBL and, in Japanese populations, C9 deficiency. C2 deficiency occurs in 1:20 000 individuals and is usually asymptomatic. MBL deficiency occurs in 5–10% of individuals but increased infection risk is only seen if there are immunosuppressive comorbidities.[1,5]

Regulatory protein deficiencies

In PNH an acquired somatic mutation in the *PIGA* gene results in a clone of CD59-deficient erythrocytes that are susceptible to intravascular complement-mediated lysis. This results in a complement-dependent intravascular haemolytic anaemia.

aHUS is characterized by renal failure due to thrombotic microangiopathy. This condition, which is distinct from HUS associated with shigatoxin-producing strains of *E. coli*, is associated with mutations in the alternative pathway. These mutations result in impaired regulation of complement along the renal endothelium. This results in a complement-dependent thrombotic microangiopathy.

C3 glomerulopathy is characterized by isolated accumulation of C3 within glomeruli. This condition is associated with impaired regulation of the alternative pathway in plasma. This results in the accumulation of C3 along the glomerular basement membrane with consequent glomerulonephritis. Examples include dense deposit disease and complement factor H-related protein 5 nephropathy.[6–8]

HAE is associated with heterozygous C1INH deficiency. It is an autosomal dominant condition which may be due to absent (type I) or dysfunctional (type II) C1INH. Rarely, SLE and lymphoproliferative disorders may be associated with C1INH deficiency due to anti-C1INH autoantibodies.[9]

Important features that suggest HAE are: (1) recurrent angioedema, lasting more than 24 hours, non-pruritic and not responsive to anti-histamines, (2) absence of urticaria, (3) unexplained abdominal pain, especially if recurrent and 'colicky' in nature, (4) a family history of any of these features, and (5) low C4 level.[10]

C1INH is a protease inhibitor with multiple biological actions. It is a complement inhibitor (inhibiting the classical and lectin pathways) from which it derives its name. In C1INH deficiency uncontrolled classical pathway activation results in a low C4 level.

To appreciate the pathophysiology of HAE it is critical to understand that C1INH has multiple actions outside of its role as an inhibitor of the complement C1 complex.[11] It inhibits proteases of the contact system (kallikrein and factor XIIa), the coagulation system (thrombin), and the fibrinolytic system (plasmin and tissue plasminogen activator). The pathogenesis of the angioedema in C1INH deficiency relates to its role as an inhibitor of factor XIIa and kallikrein of the contact system. Failure of C1INH to inhibit these enzymes results in uncontrolled bradykinin generation and angioedema.

Mutations in the contact system that result in HAE in the presence of normal C1INH (type III HAE) have been reported.[12–14] Type III hereditary angioedema predominantly affects females and is associated with high oestrogen levels.

The commonest cause of acquired angioedema is angiotensin converting enzyme (ACE) inhibitors which impair the breakdown of bradykinin through the inhibition of kininase II.[15]

Complement investigations

The standard and specialized complement assays typically used in clinical practice are listed in Table 64.2. Most commonly antigenic levels of circulating C3 and C4 are measured in rheumatology clinics as part of the laboratory assessment of SLE activity. Low levels indicate enhanced classical pathway activation and active disease.

One drawback in simply measuring antigenic levels of C3 and C4 is that this does not provide information about the metabolic turnover rate of these proteins. For example, if a 50% increase in C3 consumption is accompanied by a 50% increase in C3 synthesis the antigenic level remains constant. Consequently, there have been many studies that have analysed activated complement components in SLE. These assays are challenging, since activated components are highly sensitive to sample handling. However, erythrocyte-bound C3d and C4d are stable and measurement of these SLE biomarkers may be feasible in clinical practice.[16]

A particular difficulty can arise with interpretation of C4 levels in SLE. The C4 gene locus is extremely complex, with frequent variation in both the number and size of C4 genes. In one study the number of C4 genes in healthy individuals varied between two and

Table 64.1 Complement deficiency and disease

Complement deficiency	Phenotype	Comments
Activation proteins		
Classical pathway deficiency: C1q, C1r, C1s, C2, C4	SLE Recurrent encapsulated bacterial infections	All extremely rare except C2 deficiency where estimated prevalence is 1:20 000 Association with SLE weakest for C2 deficiency
Alternative pathway deficiency: factor B, factor D	Recurrent meningococcal infections Recurrent encapsulated bacterial infections	All extremely rare (factor B deficiency only reported in a single incompletely characterized case)
Lectin pathway deficiency: MBL, ficolins, MASP-1, MASP-2 and MASP-3, CL-K1	Increased infection among immunocompromised individuals (MBL deficiency) H-ficolin deficiency associated with necrotizing enterocolitis Mutations in the genes encoding CL-K1 (*COLEC11*) and MASP-3 and MASP-1 (*MASP1*) associated with an autosomal recessive developmental syndrome termed '3MC syndrome'[a]	All extremely rare except MBL deficiency where estimated prevalence is 5-10% in white populations
Terminal pathway C5, C6, C7, C8 and C9	Recurrent meningococcal infections	All rare except C9 deficiency in Japanese where estimated prevalence is 1:1000
C3	Recurrent encapsulated bacterial infections Membranoproliferative glomerulonephritis (rare) SLE-like illness (rare)	Extremely rare
Regulatory proteins		
C1INH Negative regulator of: ◆ classical and lectin pathways ◆ contact system ◆ coagulation system ◆ fibrinolytic system	Hereditary angioedema	Estimated prevalence 1:50 000 Angioedema results from uncontrolled production of bradykinin due to dysregulation of the contact system, i.e. does not arise from uncontrolled complement activation Associated with low C4 due to uncontrolled classical pathway activation
Factor H, factor I, and CD46 Negative regulators of the alternative pathway and C3b amplification loop	aHUS C3 glomerulopathy	All rare aHUS manifests in heterozygous deficiency states Complete factor H deficiency associated with both aHUS and C3 glomerulopathy
Factor H-related protein 5 Putative modulator of C3 processing within the kidney—biological function incompletely understood	C3 glomerulopathy ('CFHR5 nephropathy')	Rare Predominantly individuals with Cypriot ancestry
CD59 Negative regulator of terminal pathway activation	Paroxysmal nocturnal haemoglobinuria	Rare Acquired somatic mutation Renders CD59-deficient erythrocytes susceptible to complement-mediated intravascular haemolysis
Properdin Positive regulator of C3 activation	Recurrent meningococcal infections	Rare X-linked deficiency

aHUS, atypical haemolytic uraemic syndrome; C1INH, C1 inhibitor; CD46, also known as membrane cofactor protein; CL-K1, also known as collectin-11; HUS, haemolytic uraemic syndrome; MBL, mannose-associated lectin; MASP-2, MBL-associated serine protease; SLE, systemic lupus erythematosus.
[a] 3MC syndrome is a term used to describe clinically identical syndromes that were independently described: the Mingarelli, Malpuech, Michels, and Carnevale syndromes.

five and there was a positive correlation between C4 levels and gene number.[17] C4 null alleles are frequent in SLE patients.[18] Therefore where a low C4 level is detected in healthy individuals or where a C4 level in an SLE patient remains low despite absence of active disease, the cause may be C4 genetic variation not classical pathway activation. The number and size of C4 genes can be measured in specialized complement laboratories, although this is rarely indicated.

C1INH assessment includes both antigenic and functional assays to detect type I and II deficiency.

Screening for activation protein deficiency starts with functional assays that test the integrity of the three activation pathways. These are available in most laboratories, typically as CH100 and AP100, (Table 64.2) with lectin pathway assessed using an ELISA-based assay. If these assays yield abnormal results, referral

Table 64.2 Complement investigations

Standard assays	Comments
Serum C4	Reduced levels usually indicate classical pathway activation or presence of C4 null alleles
	If C4 low with normal C3 this indicates predominant classical pathway activation and typical causes include:
	◆ Active SLE
	◆ HUVS
	◆ C1 inhibitor deficiency
	◆ Mixed essential cryoglobulinaemia
	◆ Rheumatoid vasculitis
	◆ Chronic infections associated with immune complex formation, e.g. subacute bacterial endocarditis
Serum C3	Reduced levels indicate complement activation
	Commonly reduced in active SLE, usually in combination with reduced C4 level, indicating classical pathway activation
	Low C3 with normal C4 indicates predominant alternative pathway activation. This is rare and causes include:
	◆ Poststreptococcal glomerulonephritis
	◆ C3 glomerulopathy, e.g. dense deposit disease
CH100	Functional test in which classical pathway activation is triggered in vitro and terminal pathway activation assessed by measurement of the membrane attack complex either directly (using anti-C5b-9 antibodies) or indirectly (using red cell lysis)
	Normal CH100 requires intact classical pathway, functional C3 and intact terminal pathway
	Important test to screen for complement deficiency
AP100	Functional test in which alternative pathway activation is triggered in vitro and terminal pathway activation assessed by measurement of the membrane attack complex either directly (using anti-C5b-9 antibodies) or indirectly (using red cell lysis)
	Normal AP100 requires intact alternative pathway, functional C3 and intact terminal pathway
	Important test to screen for complement deficiency
C1 inhibitor (C1INH) assays	Standard assays test both antigenic and functional activity of C1INH
	Essential test to detect type I and type II hereditary angioedema
Specialized assays	
Anti-C1q antibodies	Associated with SLE nephritis but not routinely measured in clinical practice
	Indicated in suspected HUVS
C3 nephritic factor	Represents an autoantibody that enhances the C3 convertase of the alternative pathway
	Associated with enhanced alternative pathway activation
	Indicated in C3 glomerulopathy
Anti-factor H autoantibodies	Associated with enhanced alternative pathway activation
	Indicated in atypical HUS and C3 glomerulopathy
Mutation screening for structural and sequence variation in complement genes encoding alternative pathway proteins and regulators	Indicated in patients with atypical HUS prior to renal transplantation

HUS, haemolytic uraemic syndrome; HUVS, hypocomplementaemic urticarial vasculitis; SLE, systemic lupus erythematosus.

to specialized complement laboratories is required to define the specific defect.

Specialized assays include anti-C1q autoantibodies which are strongly associated with the development of glomerulonephritis in SLE (reviewed by Pickering and Botto[19]). In addition they are a defining serological feature of hypocomplementaemic urticarial vasculitis syndrome (HUVS).[19] These antibodies rise prior to lupus nephritis flares,[20] and serial measurements may be helpful in this setting.

In C3 glomerulopathy and aHUS complement genetic screening, in addition to specialized serological assays such as C3 nephritic factor and anti-factor H autoantibodies, may be indicated and are best guided by specialist expertise.

Hypocomplementemic urticarial vasculitis syndrome

HUVS is a rare multisystem disorder first recognized in the early 1970s.[21–23]

Classification criteria and clinical features

Originally patients were identified on the basis of the presence of unexplained urticarial rash with biopsy evidence of leucocytoclastic vasculitis together with evidence of hypocomplementaemia (low C1q, C2, and C4) and anti-C1q antibodies.[22] (Wisnieski et al.[22] is a key reference, outlining the clinical spectrum of HUVS.)

Using these criteria the most frequent clinical manifestations were angioedema, ocular inflammation, mesangial or membranoproliferative glomerulonephritis, and chronic obstructive pulmonary disease (COPD).[22] Typically the urticarial lesions persist for more than 24 hours (distinguishing them from non-vasculitic urticaria). It is important to consider the presence of cardiac valvular abnormalities in these patients, a complication that may accompany Jaccoud's arthropathy.[24,25]

Pathogenesis

Anti-C1q autoantibodies bind to the collagen-like region of C1q. They have been demonstrated in murine models to enhance complement activation triggered by C1q-containing immune complexes in the kidney.[26] Conceptually they can be thought of as acquired factors that augment classical pathway activation by tissue-bound C1q-containing immune complexes.[27] Of course this mechanism would be predicted to apply to immune complex-triggered complement activation at any site and not just within the glomerulus. Whether a similar mechanism could operate at other tissue sites is not known.

Hypocomplementaemia is a defining part of the syndrome. Typically the classical pathway proteins (C1q, C2, and C4) together with C3 are reduced.[23] In common practice C4 and C3 are the most useful tests as, unlike C1q and C2 assays, these are widely available in clinical practice. Levels of alternative and terminal pathway proteins are not affected.

Histologically the cutaneous lesions in HUVS are leucocytoclastic vasculitis. One report has described pulmonary capillaritis and severe panacinar emphysema in an affected individual with progressive COPD.[28] In one report of valvulopathy histological analysis demonstrated acute necrotizing endocarditis and fibrin deposition on the surface of valve leaflets.[24]

Diagnosis

The diagnosis is established by (1) the presence of urticarial vasculitis with biopsy evidence of leucocytoclastic vasculitis, (2) evidence of hypocomplementaemia (low C4 with or without low C3), (3) the presence of anti-C1q autoantibodies, and (4) exclusion of SLE.

Case series have used other criteria such as: the presence of typical urticarial skin lesions and hypocomplementaemia together with two of the following: dermal venulitis, arthritis, glomerulonephritis, episcleritis or uveitis, recurrent abdominal pain, and anti-C1q antibodies.[21] In these studies individuals with positive anti-nuclear and/or anti-dsDNA antibodies were excluded.

Differential diagnosis

SLE and mixed essential cryoglobulinaemia are the important differential diagnoses to consider in patients with hypocomplementaemia and cutaneous vasculitis.

Treatment

HUVS is a rare condition and there are no published controlled trials investigating therapy. Consequently, therapeutic considerations derive from case series. Corticosteroid therapy is effective and usually combined with steroid-sparing agents such as methotrexate, azathioprine, and mycophenolate mofetil. Dapsone[29] and hydroxychloroquine[30] have been used in the treatment of the cutaneous lesions but may be more effective in combination with glucocorticoids or other immunosuppressive therapy.

It is imperative that patients with HUVS are strongly discouraged from smoking as this condition is associated with significant lung involvement which is accelerated by smoking.[21]

Therapeutic manipulation of the complement system

C1 inhibitor

C1INH deficiency can be treated by (1) increasing production of C1INH by the unaffected allele since the condition is due to heterozygous deficiency, (2) preventing C1INH breakdown, and (3) C1INH replacement.[31] The last strategy is most commonly used and there are now three C1INH preparations available for clinical use. Two are derived from plasma, Berinert P[32] and Cinryze,[33] and the third is a recombinant C1INH molecule, named Rhucin.[34] All are administered intravenously so there are inherent practical difficulties with this approach.

Increased production of C1INH through the use of attenuated androgen therapy has been used but side effects are poorly tolerated. Prevention of C1INH consumption with tranexamic acid has also been used but again is limited by side-effect profile.[10]

C1INH is rapidly effective in acute attacks of oedema. In one study of laryngeal oedema, the most feared complication, administration of C1INH reduced the median duration of the attack from 100 ± 26 hours to 15 ± 9 hours.[35] C1INH should be given rapidly at the first sign of an attack and prophylaxis considered if attacks are frequent or patients are undergoing procedures that may trigger an attack, e.g. dental procedures. A detailed consensus document outlining approaches to home therapy has recently been published.[36]

With the knowledge that the pathogenesis of the angioedema results from dysregulated bradykinin production, two other therapeutic approaches have been developed: bradykinin B2 receptor blockade (icatibant, a 10-amino-acid peptide) and inhibition of kallikrein (ecallantide, a 60-amino-acid protein). Both are effective in acute attacks,[37,38] can be administered subcutaneously, and, unlike C1INH preparations, are effective in type III angioedema.

Eculizumab (monoclonal anti-complement C5 antibody)

Eculizumab is a monoclonal antibody that blocks complement C5 activation.[39] It prevents the production of the anaphylatoxin C5a and the generation of the MAC. It is licensed for the treatment of transfusion-dependent haemolytic anaemia in PNH.[40] In this condition MAC-mediated lysis of the abnormal CD59-deficient erythrocytes is prevented and transfusion requirements reduce or cease. It is administered intravenously and has the important side effect of increased susceptibility to neisserial infection. This is a predictable side effect since it is well known that terminal pathway deficiencies are associated with increased susceptibility to neisserial infection and eculizumab induces an acquired C5 (and therefore terminal pathway) deficiency state. Patients receiving this agent are therefore immunized against neisserial strains and, if needed, treated with prophylactic antibiotic therapy.

Recently eculizumab has been shown to be effective in treating patients with aHUS,[41,42] and is now licensed for this indication both in the United States and in Europe. Its efficacy reflects the observation that C5 activation along the renal endothelium is critical for the thrombotic microangiopathy to develop.[43]

Limb anatomy and medical imaging

Mike Benjamin, Dennis McGonagle, Maribel I. Miguel, David A. Bong, and Ingrid Möller

Introduction

In ultrasonography (US) there is clearly a need for identifying and naming specific anatomical structures so that the topography of a limb can be successfully navigated. However, this is comprehensively covered by modern atlases.[1,2] What is more often ignored in writings aimed principally at clinicians is a discussion of basic limb anatomical principles. This is now highly relevant with the widespread availability of high-resolution US, which can routinely distinguish between structures 0.1–0.2 mm apart; the highest-resolution machines can resolve down to 0.04 mm. The resultant superb image definition, along with the ability to examine tissues dynamically and evaluate their vasculature, gives the clinical imager access to the body that was previously limited to anatomists.

Our purpose is to present a more generalized framework for understanding basic principles of limb anatomy and function. The aim is help the clinician to master the anatomic component of image acquisition and interpretation in a way analogous to that of a mathematician applying a series of general formulae to solve a specific problem. This can help the sonographer with this challenging anatomic aspect of image acquisition and interpretation, going beyond the two-dimensional world of the 'semiotic slice' into real three-dimensional anatomy.

Basic design of the limbs

Upper limb

The upper limb is ultimately geared towards enabling the hand to move with ease and precision anywhere in three-dimensional space. This principal is underpinned by the distribution of different types of synovial joints in the limb—e.g. a shoulder ball and socket joint, elbow hinge and pivot joints, and finger hinge joints. It also means that the heaviest part of the limb must be proximal and the lightest distal, so that the limb tapers towards its free end. All this is necessary to economize the effort needed to move the hand and fingers. Consequently, the biggest muscles are proximal

(e.g. pectoralis major, latissimus dorsi, deltoid) but the most numerous and longest tendons are distal (e.g. any of the tendons operating the digits). Many tendons are thus crowded into the wrist region, placing a premium on space in the carpal tunnel, which must also accommodate the median nerve. Anything that reduces space in the tunnel (e.g. synovitis) may compress the nerve and result in neuropathy. Because the hand must be the smallest and lightest of the three segments of the upper limb, it follows that its intrinsic muscles are also the smallest. They promote precise movements of the fingers, whereas the larger forearm muscles facilitate a more powerful, gripping action of the hand. From the imaging perspective, these principles require techniques to be valid in the detection of subtle changes in very small and densely packed structures. This is exemplified by the sonographer's ability to detect changes in the median nerve in the case of carpal tunnel syndrome and its potential aetiology with the evaluation of surrounding structures (Figure 65.1).[3,4]

Lower limb

The lower limb is both an organ of propulsion and a column that supports the body weight. Thus, it must have stronger and more numerous ligaments and more powerful muscles that are securely attached to the axial skeleton, and is longer and heavier than the upper limb. Following the general principle of limb structure, the greater bulk of muscle tissue is proximal and tendons are more evident distally. Unlike the upper limb, the lower limb rotates during embryonic development. This is why muscles extending the knee joint lie on the front of the thigh, whereas those that extend the elbow are on the back of the arm. It also accounts for why the dermatomes of the lower limb follow a spiral course and why the femoral/popliteal artery twists around the femur.

The foot is not a 'lower limb hand'

Upon learning, or relearning, the muscles of the leg, a clinician examining the region may focus on the fact that some muscles are dorsiflexors, plantarflexors, invertors, or evertors. However, such movements occur when the foot is *off* the ground and much of the

(a)

(b)
Fig. 65.1 Transverse high-resolution ultrasound (a) and anatomic (b) images of the proximal end of the carpal tunnel distinguishing the numerous structures traversing the wrist at this level. The tunnel is bordered by the scaphoid (1) and capitate (2) bones and the overlying flexor retinaculum (3). Within the tunnel, the median nerve.(4) with its fascicular pattern is located superficially and is surrounded by a bright hyperechogenic perineurium (5). The majority of the tunnel is occupied by the tendons (6) of the extrinsic hand muscles with their characteristic fibrillar pattern. It is also possible to differentiate blood vessels (7) and superficial fascia with intervening fat (8) above carpal tunnel.

time this is not the case. Thus, it is not often realized that a primary role of all of the muscles of the leg (and not just soleus) is postural control. Consider flexor hallucis longus (FHL). It is relatively easy for the skilled medical imager to identify its tendon and muscle belly. Yet a proper appreciation of its function is less common. Most anatomy texts will correctly say that it flexes the terminal phalanx of the big toe, but this movement is not of great consequence.[5] It is much more important to realize that FHL is a postural muscle. Thus, the distal part of the muscle–tendon unit (its insertion on the terminal phalanx of the big toe) becomes the fixed point, while it is the proximal end (its origin from the fibula) that moves. If the centre of gravity of the body shifts to the front of the ankle joint, FHL contracts and draws the leg backwards over the foot to help restore stability.[5] It also contributes (along with the fibularis muscles) to pulling the leg outwards over the foot when the centre of gravity of the body shifts to the medial side of the ankle.[5] It is in a position to do this because the tendon of FHL enters the foot medially. By comparison, flexor pollicis longus (FPL) is obviously concerned with flexing the thumb and such a movement is of great importance to the overall dexterity of the hand. The problem comes when FHL is simply viewed as the functional counterpart of FPL in the foot.[5]

Basic principles of muscle action and design

Muscles are 'pulling engines'

One of the first things that is often learned about muscles is that 'they pull, but do not push'.[6] If muscles pushed rather than pulled,

their tendons would need to be stiff rods rather than flexible sinews—which would obviously not facilitate joint movement and flexibility.

Prime movers, antagonists, synergists and fixators

Muscles may act as prime movers if they promote a movement, antagonists if they oppose a movement, synergists if they remove some unwanted component of muscle action that might otherwise occur in the prime mover, and fixators if they keep a part of the body (typically a bone) from moving.[7] Consider the apparently simple action of abducting the little finger so that it is drawn away from the hand. The prime mover is abductor digiti minimi (located in the hypothenar eminence). In order to act more efficiently in moving the finger in this way, its proximal attachment to the pisiform must be stabilized—i.e. this bone must be prevented from moving by the contraction of a further muscle that is also attached to it, the flexor carpi ulnaris (FCU), but is located in the forearm. FCU acts as a fixator. However, it is also capable of flexing the wrist joint. Hence, muscles on the extensor aspect of the forearm must contract to keep the wrist in a neutral position. In doing so, they act as synergists. Furthermore, FCU can also act as an ulnar deviator of the wrist, so to prevent this unwanted movement from occurring, flexor carpi radialis is further engaged as a synergist. Thus, it is important to think not only of muscles that execute actions as prime movers, but also of the supporting cast of antagonists, synergists, and fixators. Indeed, some muscles rarely act as prime movers at all—e.g. those of the rotator cuff, where the chief purpose is to act as 'extensible ligaments', maintaining shoulder joint stability and adapting their tension according to the joint position.[8] As pointed out, the muscular work involved in performing what seems at first sight to be the tiniest of action (simply moving the little finger!) is out of all proportion to the purely mechanical requirements of the act. As a corollary to this, it should now be obvious that if a muscle is compromised by injury or disease, then its loss will be felt in several actions other than those which it performs as a prime mover. Hence, one should not think of a given muscle just in relation to one definite action.

Several points emerge from the above that are worthy of mention in relation to the above account of muscle actions.

Movements and not muscles are represented in the cerebral cortex

Although limb muscles are described as 'voluntary skeletal muscles', only the action of a prime mover is under voluntary control. This reflects the fact that it is movements and not muscles that are represented in the cerebral cortex.[9] As an example, sneezing is an involuntary action that is determined by the lower centres rather than the cerebral cortex; it involves the contraction of some voluntary muscles that span between the trunk and the upper limb (notably latissimus dorsi). Thus, in a paralysed individual who has suffered motor cortex damage, it is still possible for a voluntary muscle to contract even though it may be paralysed for a voluntary action.

Muscle fibre contraction is 'all or nothing'

Muscles 'go full steam on half-boilers, and not half-steam on all boilers'.[9] Thus for example, the subtle control of the action of a prime mover by its antagonist does not involve the contraction of all its muscle fibres. Those that do contract, contract fully—and if a more powerful muscle action is required, then more motor units are recruited. This is probably clinically relevant in myositis

where weakness only manifests when fibre loss is considerable. Furthermore, this principle is particularly relevant for large rather than small muscles, as the latter tend to be used for finesse rather than power e.g. the extrinsic eye muscles.

Gravity has a considerable modifying effect on muscle action

If the act of adducting the arm (so that it is brought back to the side of the body) is resisted, then pectoralis major and latissimus dorsi contract powerfully in an effort to perform the action. However, if the movement is not resisted, these adductors remain relaxed and it is deltoid (an abductor and antagonist in this action) that actually contracts eccentrically (i.e. the muscle lengthens during its action). What it is doing is to control the speed and precision with which the arm is moved—it pays out slack in much the same way as one pays out a length of rope wrapped around a windlass that acts as a pulley. This eccentric contraction mechanism of muscle action is very common in all regions of the body and is widely deployed as a way of controlling the action of a prime mover with smoothness, subtlety, and precision.

Larger muscles are not necessarily more powerful than smaller ones

It seems that the best predictor of the ability of a muscle to generate force is its macroscopic architecture—i.e. the number and orientation of its muscle fibres.[10] Ultrasound can distinguish between parallel-fibred muscles such as sartorius, that have long fibres spanning the length of the muscle, and pennate muscles such as deltoid that have shorter fibres arranged at an angle to the long axis of the muscle. Different subtypes of pennate arrangement are recognized (unipennate, bipennate, multipennate, and circumpennate).[7] In essence, parallel-fibred muscles are well suited to promoting delicate actions where there is a wide range of movement of a joint. Pennate muscles are more powerful, but act over a shorter range. Muscles with coarse fascicles (fascicles are bundles of muscle fibres) are typical of muscles which facilitate relatively gross movements of average strength, but it takes a muscle with finer fascicles to produce delicate movements.[8] While the largest muscle in the lower limb is gluteus maximus, the strongest muscles are vastus lateralis, gluteus medius and soleus.[10] Intriguingly, the strongest individual muscle is soleus—situated in the distal half of the limb—where lightness is at a premium for efficiency of movement.[10]

Fibre architecture and biarticular muscles

The soleus is a muscle that only crosses one joint (the ankle) and its architecture differs strikingly from that of the more proximal biarticular muscles (sartorius, gracilis, and semitendinosus) whose tendons form the pes anserinus complex. All of these muscles, act on both the hip and knee joint and thus need the wide range of excursion that a parallel-fibred architecture can promote.[10] Interestingly, biarticular muscles (e.g. the hamstrings) often exhibit conflicting length changes at either end of the muscle (i.e. shortening at one end and lengthening at the other), that effectively cancel each other out and mean that the muscles act with relatively little overall change in length—i.e. a pseudoisometric or 'econcentric' contraction. Since the movements at either end of the hamstrings occur simultaneously, the overall net length changes are far less than if two separate monoarticular muscles were to control the hip and knee movements.[10] The role of biarticular muscles gets even more subtle, as they can transfer moments to distal joints that they do not actually cross, by combining their activation strategies with other

biarticular muscles that cross one of the same joints, but then go on to cross another more distal joint. This means that the hamstrings (that cross the hip and knee joints) have an influence on the ankle joint via the gastrocnemius muscle that crosses the knee and ankle joints. This makes it difficult to say what the role of any individual muscle is during the gait cycle.[10]

Fibre architecture on opposing side of a limb

A comparison of muscle groups that cross a common lower limb joint (e.g. ankle, knee, or hip) shows that differences in physiological cross-sectional area (PCSA, the total area of all cross-sections that are perpendicular to the fibres in a muscle) correlate with differences in the power with which the movement can be executed. Two examples will suffice:

- Plantar flexion, an anti-gravity movement that is a key to forward propulsion in the gait cycle, is a more powerful action than dorsiflexion. Accordingly, the plantar flexors have a greater total PCSA and shorter muscle fibres.[10]

- The quadriceps femoris muscles have a greater PCSA than the hamstrings and this in the line with the common observation that knee extension is more powerful than knee flexion.[10]

The foregoing discussion highlights how complex muscle action is. It also illustrates how distant muscles are involved in the execution of fine movements and helps one to understand the implication of dysregulation of these processes or 'muscle imbalance' in the causation of pain or aching. This is very poorly understood.

Tendons and ligaments

Tendons are characteristic of limb muscles and can be rounded, oval, or flattened and have a distinctive and well-recognized ultrasound pattern. If the muscle with which a tendon is associated is an extensive flattened sheet (e.g. latissimus dorsi or pectoralis major), then its tendon will probably also be highly flattened. Such tendons are called aponeuroses. Ligaments generally link two different bones across a joint, but occasionally they run from one region of a bone to another part of the same bone and can vary greatly in shape and may be rounded or greatly flattened. It is well known that they guide and limit joint movements, but their proprioceptive potential (stemming from their rich afferent nerve supply) should not be forgotten. Indeed, the loss of this, following ligament rupture, may present as great a challenge to a patient's rehabilitation as the failure of mechanical function. Most ligaments attach close to joints. Some are thickenings of the joint capsule (e.g. the medial collateral ligament of the knee joint), but others form distinctive intra- or extracapsular structures (e.g. the cruciate and lateral collateral ligaments respectively).

Tendons obviously serve to transfer muscle pull to bones. However, they have several other functions as well.[5] Some tendons concentrate the pull of different heads/bellies of a muscle on to a single bony point (e.g. the tendon of triceps brachii). Others dissipate muscle action onto several different bones (e.g. flexor digitorum superficialis and profundus). This will serve to reduce the local stress concentration at the meeting of hard and soft tissues. However, it may have other significance as well. Thus, a tendon that splits into two or more segments may be a way of holding bones in position during muscle action. For example, the tendon of tibialis posterior divides into numerous slips as it approaches its insertional area and these slips attach to all of the tarsal bones except

the talus. Such a complex arrangement draws the bones together and helps to maintain the arches of the foot.[5] A tendon that splits into two may allow a single muscle to oppose the action of two muscles on the opposite side of the limb. The tendon of flexor carpi radialis exemplifies this. As the muscle approaches its insertion, it splits into two slips that attach to the bases of the index and middle fingers. This allows the muscle to be an effective antagonist for both extensor carpi radialis longus and brevis. If a muscle has two tendinous insertions, this may allow it to have different point of action in different positions of the joint.[11] Importantly, tendons can economize on muscular effort by their elastic recoil following the release of a stretching force.[12]

Tendons can be very efficient at facilitating the longitudinal excursion that is necessary somewhere in the muscle–tendon unit when a muscle contracts concentrically (i.e. shortens when it contracts). Unlike muscles, their movement can be facilitated by tightly fitted, but lubricated synovial sheaths—muscle bellies must rely on a covering of loose connective tissue to glide over neighbouring structures. The role of such loose connective tissue in inflammation and in skeletal pain has not been defined. The corollary of this, however, is that punctured tendon sheaths offer an easy passage to the spread of infection. Knowing the detail of the topography of these sheaths can thus be highly relevant to a clinician. As an illustration, an infection in the thumb can spread via the tendon sheath of FPL to the palm, but an infection affecting the middle finger stays within the sheath of that digit. It is also useful to know that the typical response of the body to a damaged synovial sheath is to seal up this lubricating space around the tendon. US demonstrates the spectrum of tendon sheath pathology, ranging from effusion or synovial hypertrophy encircling the tendon to dynamic evaluation of tendon motion.

Finally, tendons can alter the direction of muscle pull because they can resist compression in regions where they contain fibrocartilage.[13] Fibrocartilage is avascular and the tendon cells gain their access to tissue fluid by virtue of the water-imbibing properties of aggrecan molecules within the fibrocartilage. The pressure exerted on a tendon as it wraps around a bony pulley (the medial malleolus, for example, in the case of the tibialis posterior tendon) is reduced as the tendon widens locally. A tendon may also be thicker than in adjacent, non-compressed regions, because of the presence of aggrecan and the associated increased water content. Hence in this ankle region, the sonographer may well see a change in shape and/or thickness of tendons and thus should be aware that such features do not necessarily suggest pathology.

The anatomical and biomechanical configuration of tendons where they wrap around the malleoli has been likened to a functional enthesis.[14] This is because mechanically or inflammatory related pathology at such sites is often associated with underlying bone abnormalities. However, unlike a true enthesis, the underlying bone pathology occurs with bone contact alone—i.e. not requiring bone attachment. The role of the underlying bone in the pathophysiology of tendon-related joint pain was not fully appreciated until these abnormalities could be observed on MRI.

The enthesis organ concept

The concept of an enthesis as simply the site of attachment of a tendon, ligament, or joint capsule to a bone has been broadened in recent years to include adjacent structures that are functionally related to the enthesis (primarily because they reduce stress concentration in the area) and which collectively constitute an enthesis organ.[14,15] Ultrasound is useful in evaluating the enthesis organ and its pathologic changes. Many enthesis organs exist in both the upper and lower limbs, but the best example for understanding the fundamentals of the concept is provided by that of the Achilles tendon. The insertion site itself lies at the middle of the posterior surface of the calcaneus. However, the superior tuberosity of that bone creates a raised eminence that presses against the deep surface of the tendon when the foot is dorsiflexed. The larger the tuberosity (its size varies between individuals), the greater the compression. In order for the bone and the deep surface of the tendon at the point of mutual contact to be able to cope with the pressure, both surfaces are fibrocartilaginous.

As the tendon must move relative to the bone (i.e. its 'insertional angle' changes) during dorsiflexion, there is a bursa (retrocalcaneal) at the insertion site that forms a synovio-entheseal complex with the tendon.[16] To minimize pressure changes within the bursa that could occur with foot movements, there is a fat pad (Figure 65.2) that acts like a variable plunger during dorsi- and plantarflexion.[17,18] The fat could also facilitate the spread of synovial fluid, prevent tendon–bone adhesions, and play a key role in proprioception.[19] Thus, retrocalcaneal bursitis should be considered in relation to the whole enthesis organ and it may well be a mistake to regard it as a pathological change in the bursa alone. It is difficult to envisage the bursa being involved without other changes occurring elsewhere in
Fig. 65.2 Longitudinal, high-resolution ultrasound (a) and anatomic (b) images of the Achilles tendon (1) and its insertion onto the calcaneus (2). Deep to the tendon and lying above the tibia (3) is the flexor hallucis longus muscle (4). Its fascia (5) separates it from the extensive Kager's fat pad (6). Note the small distal extension of the fat pad (7) into the space occupied by the retrocalcaneal bursa (which is not visualized).

the enthesis organ, for the walls of the bursa are actually constituted of these other parts.

In the upper limb, a good example of an enthesis organ is provided by the insertion of the central slip of the extensor tendon of the fingers on to the base of the intermediate phalanx.[15] Here, the tendon presses on the head of the proximal phalanx when the finger is flexed and thus has a sesamoid fibrocartilage within it signifying the site of compression. The joint cavity itself is the functional equivalent of the retrocalcaneal bursa and the head of the proximal phalanx is the counterpart of the superior tuberosity.

Historically, clinicians have viewed enthesitis as a focal insertional disorder with inflammation confined to a small territory—something that was clinically supported by the pattern of tenderness at inflamed insertions. However, imaging studies of enthesitis have shown that the inflammatory process extends over a large area to involve the adjacent bone and the adjacent soft tissues and synovial cavity. When the microanatomy of entheses was more thoroughly explored,[14,15] it became evident that fibrocartilages were not just confined to attachment points, but also lined the adjacent surfaces of tendons or ligaments, and that the mechanical stress during movement was distributed over a wide area. Therefore, it is important to appreciate that there is a functional integration between the soft tissues of the enthesis and also between the enthesis and the bone around it.[20] The anatomical complexity of entheses and enthesis organs explains why enthesitis-associated pathology may be associated with diffuse pain, osteitis, or immediately adjacent synovitis. It also explains why the sonographer must look over a wider area than the actual point of insertion to appreciate the cause of enthesitis-associated pain. Given that many insertions are clinically inaccessible, MRI is necessary to recognize such pathology.

Nerves

The motor nerves supplying limb muscles generally enter the muscle belly on its deep surface (thus protecting the nerve from damage) and often do so at the geometric centre of the muscle.[8] The number of nerve fibres increases progressively in a motor nerve if the nerve is traced along its course in the limb. This is because of branching of the original fibres, a process that continues within the muscle itself. One motor nerve supplies a group of muscle fibres (i.e. a motor unit) and these motor units are typically large in muscles producing powerful but coarse actions, and small in muscles promoting delicate precise movements. The peripheral nerves supplying muscles also contain afferent nerve fibres (muscle spindles) that play a key role in proprioception. Not surprisingly, muscle spindles are prominent in postural muscles, e.g. in the muscles of all three compartments of the leg.

In gross anatomical dissections and even in MRI and static US imaging, nerves can look like tendons because the tissue that accounts for most of the bulk of a 'nerve' is connective tissue, rather than nervous tissue itself. This connective tissue enables nerves to resist stretch and to provide a conduit for blood vessels. If nerves could not resist stretch, they would be easily torn in limb movements. The key component that resists stretch in tendons is the type I collagen fibre, and it is the same in a nerve. The perineurial sheath in particular is highly collagenous and is often thick and dense. This sheath (which groups nerve fibres into fascicles) creates a special 'microenvironment' around the nerve fibres that is conducive to the conduction of nerve impulses. To the best of our knowledge it has not been adequately considered that neuropathies may actually be primarily linked to dysregulation of intraneuronal fibrous tissue.

The importance of fascia

'Fascia' is a vague term embracing a variety of connective tissue structures that are found throughout all segments of both limbs. Historically, fascia has often been dismissed as an inconsequential packing, wrapping or binding tissue that occupies spaces not filled by 'more important' structures. Fortunately, there is a strong resurgence of interest in fascia that is doing much to dispel this view.[21]

Many of the fascias that are most significant to clinicians are either made of loose (areolar) or dense fibrous connective tissue. The former are exemplified by the superficial fascia that lies beneath the skin or by the films of areolar tissue within muscles. Loose connective tissue is a conduit for blood vessels. Its cellular composition includes occasional fat cells and the native fibroblasts that differentiated in situ from mesenchymal cells. The remaining cells are an immigrant and transitory population of white blood cells that have migrated through the walls of exchange vessels within the connective tissue.

Beneath the skin, loose connective tissue (constituting the papillary layer of the dermis) is essential for its blood supply and, within muscles and nerves, it brings exchange vessels close to muscle cells and nerve fibres. The loose connective tissue can also act as a mechanosensitive signalling system capable of integrating structures in different regions of the limb analogous to that of the nervous system.[22,23] Of central importance here is the network of communication between the native fibroblasts via gap junctions.[22,23] The fascial planes are readily visible in US owing to their bright signal intensity and are the clue that leads the sonographer to discover the important neurovascular structures (Figure 65.3).

Dense connective tissue fascias include the deep fascia of the limbs and its specializations (e.g. intermuscular septa, retinacula, the palmar and plantar fascia, and digital fibrous tunnels). The deep fascia and the intermuscular septa arising from it play a well-documented role in partitioning groups of muscles into functional compartments. This is best illustrated in the leg, where the dorsiflexors are grouped into an anterior compartment, the plantarflexors fill the superficial and deep posterior compartments, and the evertors occupy the lateral compartment.

The deep fascia of the lower limb has been described[5] as forming an 'ectoskeleton' that supports and confines the deeper soft tissues and serves as an important site of tendon and muscle attachment. It enables the lower limb to act as a column supporting the body weight as well as an appendage promoting movement. This means that certain muscles (e.g. gluteus maximus) must attach to the limb as a whole and not just to one particular region of it.[5] Recent attention has been drawn to the fact that force transmission in muscles is not just to tendons but to fascia as well.[24–27] Consequently, it does not follow that in fusiform muscles with tendons at both ends, the forces transmitted to those tendons are equal.[28]

Some diseases such as polymyalgia rheumatica (PMR) are associated with diffuse pain that is hard to explain in terms of synovial-based disease alone. This is accompanied by inflammatory changes within fascial planes that are visible on MRI.[29] Extrasynovial involvement in PMR is well recognized, but to what degree the primary inflammatory reaction targets the fascia has not been defined. With the exception of a few clinicopathological entities fascia has

(a)

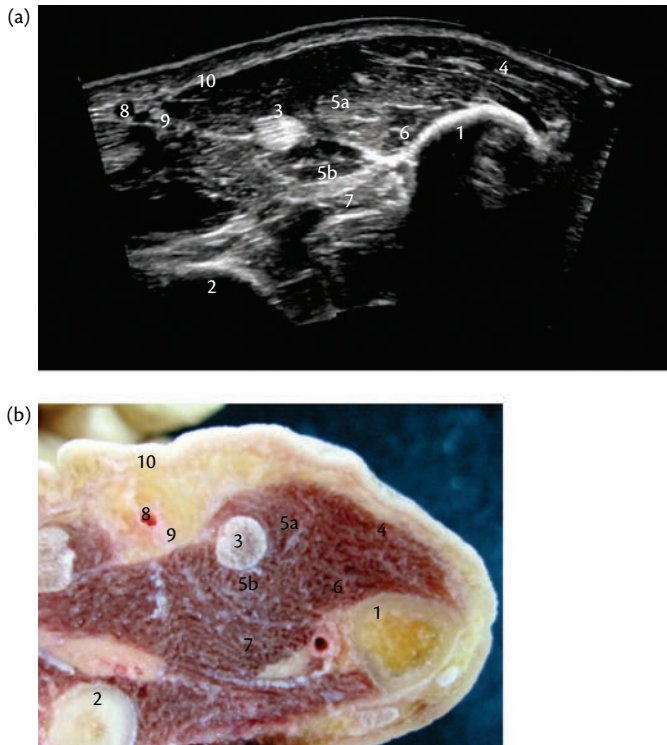
(b)


Fig. 65.3 Transverse high-resolution ultrasound (a) and anatomic (b) images of the intrinsic thenar muscles between the first and second metacarpal bones (1 and 2, respectively) and the tendon of the extrinsic flexor pollicis longus muscle (3). The intrinsic muscles include abductor pollicis brevis (4), the superficial and deep heads of flexor pollicis brevis (5a and 5b), opponens pollicis (6), and adductor pollicis (7). Note the vessels (8) and nerve (9) located in the deep fascia (10).

largely been overlooked in the pathogenesis of the rheumatic diseases and is an area that needs further work. Nevertheless, the deep and superficial fascias, their various specializations, and their pathology can readily be identified by US. As an example, the thickened portion of the fascia of the lateral hip region continues distally to insert into the anterolateral aspect of the tibia at Gerdy's tubercle. The location of the mechanical pathology involving its fibrillar structure or an associated bursa can be easily differentiated by US, whether involvement is at its insertion or as it passes over the lateral condyle of the femur. In a similar fashion, US plays an important role in the static and dynamic evaluation of many other fascial structures including the plantar and palmar fascia, the flexor and extensor retinacula of the wrist and ankle, and the annular pulleys of the flexors of the fingers. The US changes not only directly involve the retinacula themselves (changes in echogenicity, vascularization, and tears) but affect the structures which the retinacula support and restrain. This results in distinct clinical problems such as carpal tunnel and tarsal tunnel syndromes.

Adipose tissue

Since adipose tissue is dominated by fat cells, and these in turn are dominated by large lipid droplets, making the tissue pressure-tolerant. Where adipose tissue is particularly important as a cushion, it is often mixed with fibrous tissue that is anchored to adjacent structures. The integrity of both is important for normal function.[30] The copresence of fat and fibrous tissue ensures that the fat is held in

the position where it is needed and is not squeezed out into neighbouring areas.[31] It is also a conduit for blood vessels, thus allowing the adipose tissue itself to be virtually avascular.[32] Among the best-known sites in the limbs where adipose tissue resists pressure are the palms and soles. Pockets of fat, separated by conspicuous strands of fibrous tissue, are a familiar sight in MRI scans beneath the calcaneus or under the heads of the metatarsal bones. Indeed MRI offers considerable potential for exploring the mechanical properties of fat pads, via the continued development of MR elastography techniques.[33,34]

Heel fat pads are readily imaged by US[35] and are resilient structures that return 70% of the energy used to deform them.[36] These pads are involved both in rheumatoid arthritis and in the spondyloarthropathies. In the palm of the hand, the fat that is conspicuous beneath the palmar aponeurosis has a primary role in protecting the underlying vessels and nerves from pressure when the hand is gripping an object.

Blood vessels

The main arteries in the limbs run on the flexor aspects because here they are less likely to be exposed to tension during limb movements.[8] Although branches enter muscles to supply them, the main trunk of the artery that continues distally avoids the muscles and is thus not compressed by muscle contraction. Nevertheless, it is also a general rule that arteries take the shortest routes in the limbs possible; if this means that they pass through a muscle, there is usually a fibrous arch to protect the vessel from compression (e.g. in adductor magnus where the femoral artery becomes continuous with the popliteal artery). In the major joints of the limbs (e.g. the knee and elbow joints), there are characteristic arterial anastomoses that serve to ensure that one route of passage to more distal parts remains open when others are closed by joint movement that compresses vessels. The most distal parts of the limbs (toes and fingers) share the common feature that they receive a blood supply from a vessel(s) that forms a communicating link(s) between two muscular arteries. This is exemplified by the plantar arches in the foot and the palmar arches in the hand. As Sinclair[37] points out, this not only gives alternative routes of blood supply in the event of a local blockage, but could also provide a mechanism for equalizing pressure in the digital branches springing from arch vessels.

Haemodynamic factors tend to dictate the angle at which arterial branches leave the parent vessel, so that the loss of energy in the circulatory system is minimal and so that there are no undue falls in arterial pressure.[8] Hence branches of equal size (e.g. the common iliac arteries arising from the aorta) tend to make equal angles with the main stem and small side branches often leave the parent vessel at a large angle (e.g. the anterior tibial artery branching off the popliteal artery).

Arteries in the limbs tend to be accompanied by veins and commonly there are two veins (venae comitantes) accompanying one medium-sized artery. This, theoretically at least, allows the pulsatile nature of the arteries to aid in pumping the blood back to the heart in the veins. This is most likely when the veins are held close to the artery by numerous cross-connexions.[8] As is well known, muscles (particularly in the leg) also have a key role in milking the veins in this manner and venous return is greatly enhanced by valves. The presence of valves is thus an indication that the vessel is subject to intermittent compression—they are absent in bone

marrow veins, because these are protected from all external pressure. Not all veins accompany arteries, of course, and superficial vessels of this type are particularly characteristic of the limbs and are exemplified by the great saphenous and cephalic veins. This reflects the pattern of development of the cardiovascular system whereby superficial marginal veins appear first and deeper routes of venous drainage appear later—presumably when it becomes disadvantageous for venous drainage to occur entirely by subcutaneous routes.[8] This opens the possibility for blood to be transferred between superficial and deep venous systems according to functional requirements, e.g. in the leg when prolonged standing and thus postural control exerted by its muscles occludes the deep vascular channels and forces blood into the superficial veins. Of relevance to power Doppler US is the observation that small nutrient arteries on bone can be misinterpreted as inflammation-related signal and the nutrient foramen can be misdiagnosed as an erosion.

Facilitating movement between adjacent structures in the limbs

Two key points need to be appreciated in understanding how movement is promoted between adjacent structures in the limb.

- Where two structures (e.g. muscles) are in contact with each other, loose (areolar) connective tissue is often present to allow movement. This is because its extracellular matrix contains hyaluronan (better known in synovial fluid) secreted by the native fibroblasts. Hence, when a sonographer sees two structures in real time that seem to be in immediate contact with each other, moving relative to each other, the movement is possible because there is actually a sheet of areolar tissue between them. The same explanation also applies to intratendinous movements that can be very obvious in US examinations. One fascicle or group of fascicles moves relative to its neighbours, by sliding in a plane of loose connective tissue. Such partial independence of the subunits of tendon structure reduces the risk of catastrophic failure of the whole tendon. This same tissue is also where infection is evident—and where infection can spread from one region to another.

- Adipose tissue (fat), which is easy to recognize in various forms of imaging, can also suggest that movement occurs at this site, as fat is liquid at body temperature. A key difference between fat and areolar connective tissue is the bulk of the two tissues—fat can fill a significant three-dimensional volume, whereas areolar connective tissue is usually in the form of thin (almost two-dimensional) films or sheets of tissue. Two of the constant regions where fat may be seen by the medical imager, and where the tissue facilitates movement, are in the mid palmar space, adjacent to the deep flexor tendons, and on the deep fascia covering pronator quadratus.[38]

All of these anatomical considerations are relevant in understanding anterior cruciate ligament (ACL) function in the knee where three major fibre bundles with multiple fascicles are present and where synovium and fat are interposed between fascicles. All function together to minimize stress at attachment sites, but clearly this fails as the osteoarthritic knee may be ACL-deficient in almost one-quarter of cases.

Conclusion

This chapter was written with the clinical ultrasonographer in mind and covers various aspects of functional musculoskeletal anatomy in order to promote a better understanding of normal anatomy and disease processes. Where possible, we have highlighted some structures visible on ultrasound that have not been previously considered in relationship to the pathogenesis of musculoskeletal disease.

CHAPTER 66

Radiographic imaging

Emma L. Rowbotham and Andrew J. Grainger

Introduction

It is recognized that advanced imaging modalities, in particular MRI and ultrasound, are increasingly being used in the assessment of rheumatological conditions. This is due to increased sensitivity of cross-sectional imaging, the ability to image soft tissues and cartilage simultaneously, and the ability of these modalities to make earlier diagnosis when structural abnormalities may still be reversible. However, there is still an important role for conventional plain film imaging, both as a useful screening tool for initial diagnosis and as an adjunct to more complex cross-sectional imaging.

Radiographic assessment

A standard approach using the 'ABCDE' mnemonic is widely employed by radiologists to assess radiographs in patients with an arthropathy; this system of assessment may be utilized to evaluate plain radiographs of any joint in a systematic fashion:

A Alignment

B Bone changes including osteopenia and enthesitis

C Cartilage

D Distribution

E Erosions

F Soft tissue swelling

Alignment

Malalignment of the joints is a feature common to many arthropathic conditions and has a variety of causes including ligament degeneration or disruption, tendon rupture or subluxation, cartilage loss, and bone attrition or erosion. Deformities common to osteoarthritis include varus and valgus angulation at the knee joint caused by asymmetric cartilage loss and ligament laxity. Classic hand deformities in rheumatoid arthritis (RA) include swan-neck and boutonnière changes.

Bone changes

Osteopenia is a common and early finding in patients with inflammatory arthropathy, although subtle osteopenic change may be difficult to detect. It is perhaps more readily identified in cases of monoarticular or pauciarticular disease where changes may be compared with other non-affected joints (Figure 66.1).

Fig. 66.1 DP radiograph of the right hand showing the metacarpophalangeal (MCP) joints. The patient has an early septic monoarthritis of the middle finger MCP joint. Note the relative osteopenia of the middle finger MCP joint head compared with the adjacent bones.

Enthesitis is a characteristic finding associated with seronegative arthritis. Plain film imaging may be used to identify enthesophyte formation and erosive change. Enthesophytes are seen as areas of bony proliferation at or immediately adjacent to an enthesis. They may appear either as coarse bony spurs with both cortical and medullary bone present or as more 'whisker-like' structures (Figure 66.2). The entheses of the lower limbs are more frequently involved than those of the upper limbs, with calcaneal enthesitis one of the most frequently affected areas. Large, bulky enthesophytes are associated with reactive arthritis, psoriasis, and diffuse idiopathic skeletal hyperostosis (DISH). Fine, more delicate ossification is usually more typical of ankylosing spondylitis (AS).

Cartilage

Destruction of articular cartilage is identified as joint space loss on conventional radiographs; this feature is common to many joint diseases (Figure 66.3). In osteoarthritis (OA) there is typically non-uniform joint space loss, in contrast to inflammatory arthritis where the loss of joint space is more classically uniform across a joint. Once joint space loss is evident there has been irreversible damage caused to the joint in question. Preservation of the joint space is also an important feature to recognize on imaging and is characteristic of gout as well as amyloid arthropathy (Figure 66.4).
Fig. 66.2 (a, b) Lateral radiographs of the mid- and hindfeet in a patient with reactive arthritis. There is enthesophyte formation seen associated with the intertarsal joints (black arrowheads) and at the plantar fascia origins (white arrow). Note also periosteal new bone associated with the dorsal tibia (white arrowheads) and the erosive change at the Achilles enthesis on the right (black arrow). (c) DP views of the same patient's feet. There is erosive change at the MTP joints and interphalangeal joints with further bone hypertrophy representing enthesophyte formation (seen particularly at the second distal interphalangeal joint).

Distribution

Arthropathy may be monoarticular, oligoarticular, or polyarticular in nature; this distinction alone may help to narrow the differential diagnosis. Infection, pigmented villonodular synovitis (PVNS), crystal deposition, and synovial chondromatosis are more likely to be mono- or oligoarticular in distribution, whereas RA is more likely to be polyarticular.

Typically RA, scleroderma and systemic lupus erythematosus (SLE) all show symmetrical joint involvement. In contrast, the seronegative arthritides will often show a more asymmetric pattern of disease. Sacroiliac joint disease is also seen to be either symmetric in nature (usually suggestive of AS) or asymmetric, seen in reactive and psoriatic arthropathy (PsA) and more rarely in RA.

Distribution of joint involvement in the hands and feet may also be useful, with RA tending to show a proximal distribution (Figure 66.5) whereas PsA usually demonstrates a distal distribution with sparing of the wrists and metacarpophalangeal (MCP) joints. OA typically involves the distal interphalangeal (DIP) and proximal interphalangeal (PIP) joints with characteristic trapezo-centric thumb base involvement, while the other wrist joints are preserved (Figure 66.6).

Erosions

Bone erosions are a hallmark of inflammatory arthritis and are a sign of significant joint damage. Proliferative erosions are associated with new bone formation and are classically a feature of
Fig. 66.3 AP view of the left hip in this patient with psoriatic arthritis shows a uniform (symmetrical) joint space loss—a characteristic feature of an inflammatory arthropathy. There is also fluffy new bone and enthesophyte formation along with erosion seen at muscle attachments of the ischium (arrowheads).

Fig. 66.4 DP radiograph of the left great toe in a patient with gout. There is extensive erosive change to the first toe. Some erosions have the typical overhanging sclerotic margins associated with gout (arrowhead) while others show a typical juxta-articular location some distance from the joint (arrows). Note the marked relatively dense soft tissue swelling. Despite the extensive disease there is preservation of joint space at both the interphalangeal and metatarsophalangeal joints.

entheseal disease; non-proliferative erosions are a feature of seropositive (rheumatoid) arthritis. Erosions are also described in terms of their position relative to the joint and may be central, marginal, or juxta-articular. Marginal erosions occur at the edge of the joint line and involve the exposed bone between the edge of the articular cartilage and the joint capsule (Figure 66.7). They are a typical feature of RA. Central erosions occur, as their name suggests, into bone normally covered by the articular cartilage. Juxta-articular erosions occur further away from the joint and are typically seen in gout (Figure 66.4). Cortical breaks are only seen when erosions lie in a plane perpendicular to the X-ray beam. En-face erosions will be seen as focal lucencies within the bone without associated cortical breach and may be indistinguishable from cysts. The detection of early erosive disease has become increasingly important and it is recognized that ultrasonography and MRI are more sensitive than conventional radiographs for erosive change, largely as a result of their multiplanar capabilities.

Soft tissue swelling

Soft tissue swelling is often the first detectable radiographic change in arthritis. There is inevitably a wide variation in what might be considered to be within the normal range; however, comparison with a previous radiograph or, in the case of an oligoarthritis, the contralateral side or other joints, may be helpful in confidently describing soft tissue swelling (Figure 66.8). Careful evaluation of

the fat planes normally identified adjacent to the joints may help in determining the degree of any pathological soft tissue swelling.

Fusiform swelling of a joint is usually indicative of a joint effusion or inflammatory pannus and is commonly seen in RA and septic arthritis. Diffuse swelling of a digit, often termed 'sausage finger', suggests inflammatory change outside the joint space and is more typically seen in cases of inflammatory arthritis. Typically, tophaceous deposits associated with gout tend to be eccentric to the joint and have an irregular appearance (Figure 66.4).

Calcification may also be seen within the soft tissues.

Osteoarthritis

OA shows characteristic radiographic findings including non-uniform joint space loss, osteophyte formation, subchondral sclerosis, and subchondral cyst formation (Figure 66.9). However, it is well recognized that the degree of radiographic abnormality in this condition does not correlate well with the severity of symptoms experienced by the patient. Two views in orthogonal planes of the

Fig. 66.5 DP radiograph of the right hand of a patient with chronic rheumatoid arthritis showing typical changes of deformity, joint space loss, and erosion. Note the proximal disease distribution involving the wrist (all joints) and metacarpal and proximal interphalangeal joints, with relative sparing of the distal interphalangeal joints.

Fig. 66.6 DP radiograph of the right hand of a patient with osteoarthritis showing typical disease distribution. The disease distribution predominantly involves distal and proximal interphalangeal joints with less marked metacarpophalangeal joint involvement. Note that in the wrist the majority of joints are preserved with the exception of the thumb base carpometacarpal and scaphoid–trapezoid–trapezial (STT) joints.

affected joint should be obtained, with additional weightbearing views as necessary. Primary OA most commonly affects the hands, hips, knees, and spine.

Hand and wrist

In the hands the diagnosis of OA may be substantiated by the typical findings of sclerosis, loss of joint space, and marginal osteophyte formation. Typically in the hands and wrists the most common sites to be affected are the first carpometacarpal joint and the scaphoid trapezium trapezoid complex (STT) (trapezocentric disease) along with the interphalangeal joints, with a predilection for the DIP joints (Figure 66.6). Involvement of the PIP joints without DIP involvement is unusual. While all the classic features of OA may be seen at the interphalangeal joints, subchondral cyst formation is particularly prominent. In contrast to many other joints affected by OA the interphalangeal joints also tend to show a more uniform joint space loss. A characteristic 'sawtooth' appearance is used to describe the articular surfaces secondary to areas of eburnation and subchondral collapse (Figure 66.10).

In idiopathic, primary OA wrist involvement is usually confined to the thumb base. Involvement elsewhere suggests the changes

have a secondary cause, most typically trauma. Previous scaphoid fracture predisposes to radiocarpal OA, generally between the distal pole of the scaphoid and the radial styloid; this condition is termed scaphoid non-union advanced collapse (SNAC). Radiocarpal and subsequently midcarpal disease as a consequence of scapholunate dissociation is termed scapholunate advanced collapse (SLAC). Although non-traumatic SLAC wrist has been recognized,[1] the absence of a relevant history of trauma and involvement of the radiocarpal or midcarpal joints would suggest an alternative diagnosis such as pyrophosphate arthropathy.

Osteoarthritis at the ulnocarpal joint secondary to ulnocarpal impaction syndrome is seen in cases of positive ulnar variance due to repetitive loading of the ulnocarpal joint, resultant lunotriquetral disruption, and triangular fibrocartilage complex (TFCC) tears.[2] Radiographic findings will include flattening of the articular surface, subchondral cyst formation, and sclerosis to both the lunate and the distal ulnar (Figure 66.11).

Knee

Knee OA may involve all three joint compartments, but the severity typically varies between compartments, frequently involving the medial tibiofemoral and patellofemoral joints most severely

Fig. 66.7 DP radiograph of the right index and middle metacarpophalangeal (MCP) joint of a patient with rheumatoid arthritis. The middle MCP joint shows typical marginal erosions (arrowheads). Note also the joint space loss compared to the adjacent index MCP joint.

Fig. 66.9 AP radiograph of the right hip showing typical changes of severe osteoarthritis. There is joint space narrowing which is asymmetric, appearing more marked superiorly, along with osteophytosis, subchondral cyst formation, and subchondral sclerosis.
Fig. 66.8 Soft tissue swelling, seen as increased density of the periarticular soft tissues, is seen around the middle finger metacarpophalangeal (MCP) joint in this patient with rheumatoid arthritis. The loss of definition of the surrounding fat planes between the MCP joints can also be appreciated. In this case there is also joint space loss and erosive change.

Fig. 66.10 Osteoarthritis affecting the left middle finger distal interphalangeal joint showing the typical 'sawtooth' pattern of joint involvement as a result of subchondral collapse and attrition.

with a corresponding uneven distribution of joint space loss.[3] More marked joint space loss and bone attrition in the medial compartment compared to the lateral compartment is typical and may result in varus deformity, although isolated or more marked lateral changes may also be seen. Where radiographs show uniform arthropathic change in all knee compartments, consideration should be given to alternative diagnoses such as an inflammatory arthritis. Positioning of the knee joint during radiography is important but at present there is no consensus as to the optimal technique. Radiography of the knee joints should ideally be performed in a weightbearing position if joint space is being assessed (Figure 66.12).[4] A recent large study assessing change in joint space width during treatment with disease-modifying OA drugs has demonstrated that semiflexed views may present advantages over extended views.[5] In this technique the patient stands with the knees in a semiflexed position and in contact with the film cassette, with the feet slightly externally rotated.

Hip

In hip OA cartilage loss typically occurs within the superior weight-bearing portion of the joint. However, early cartilage loss may be difficult to detect as pelvic radiographs are not routinely obtained in a weightbearing position.[6] Less commonly, a medial pattern of joint space loss is seen (Figure 66.13). A particular feature of hip OA which appears to be very sensitive to the diagnosis is the formation of new bone along the medial femoral neck of the femur, termed buttressing (Figure 66.13).[7,8]

Inflammatory osteoarthritis

A subgroup of patients with OA are described as having an inflammatory form of disease. Unlike the more common form of OA, erosions may be seen in this group and therefore the terms 'inflammatory OA' and 'erosive OA' have both been used to describe this condition. Inflammatory OA characteristically affects the small joints of the hands, although more rarely large-joint involvement is also seen and has been shown to have a higher clinical burden and worse outcome than non-erosive OA.[9]

The characteristic radiographic findings in inflammatory OA are the presence of subchondral erosion, cortical destruction, and subsequent reparative change which may include bony ankylosis.[10] The distribution of disease within the hands is the same as for generalized primary OA, although erosive change at the thumb base is rarely seen. The erosions are typically central in location leading to the typical 'seagull wing' appearance,[11] a feature which may help distinguish between inflammatory OA and rheumatoid or PsA (Figure 66.14).

Differentiating erosive OA from inflammatory arthropathy can be challenging; in particular, the distinction between erosive OA and PsA may be difficult as both demonstrate bony proliferation and have a distal distribution. More florid periosteal bone formation

Fig. 66.11 Ulna–lunate impaction syndrome. DP view of the wrist joint in a patient with positive ulnar variance. There is subchondral sclerosis and early cystic change seen within the ulnar aspect of the proximal lunate (black arrow).
Fig. 66.12 Standing views of the right knee: (a) AP view with the knee in extension. There is mild joint space narrowing in both medial and lateral compartments with subchondral sclerosis and irregularity consistent with osteoarthritis. (b) PA view of the same knee with 45° of flexion (Rosenberg view). This partially flexed view shows marked joint space loss in the lateral joint compartment not appreciated on the standard AP view.

Fig. 66.13 AP hip radiograph showing osteoarthritis with a predominatly central (axial) pattern of joint space loss; compare with Figure 66.9 (arrows). Note also buttressing along the medial femoral neck (arrowhead).

may be seen in PsA and central bone erosions are more characteristic of erosive OA. The presence of OA at additional sites within the hand such as the thumb base may help with the diagnosis.

Diffuse idiopathic skeletal hyperostosis

DISH predominantly results in extensive ossification of the paraspinal ligaments and soft tissues including the anterior longitudinal ligament and the annulus fibrosis. However involvement of extravertebral sites such as the pelvis, calcaneus, ulnar olecranon, and patella have all been frequently described.[12] The criteria for diagnosing DISH on imaging as determined by Resnick and Niwayama are[13]:

♦ flowing ossification along the anterior and anterolateral aspects of at least four contiguous vertebrae of the thoracic spine

♦ preserved intervertebral disc height

♦ absence of apophyseal joint or sacroiliac joint changes.

This last feature allows distinction from AS. Ossification and calcification of the posterior longitudinal ligament has been described in the cervical spine and has been associated with cervical myelopathy.[14] The thoracic spine is most commonly affected, shown to be involved in 100% of patients in one study,[15] followed by the lumbar and more rarely the cervical spine (Figure 66.15).

Fig. 66.14 DP radiograph of the ring and middle interphalangeal joints of a patient with erosive osteoarthritis. Note the central erosions in the intermediate phalanx of the index finger. There is also marked joint space loss and associated soft tissue swelling.

Fig. 66.15 Diffuse idiopathic skeletal hyperostosis. This lateral view of the lumbar spine reveals the classic flowing mature ossification of the anterior longitudinal ligament. Note the preservation of disc spaces.

Extra-axial radiographic findings in DISH include entheseal new bone formation—commonly seen at the tibial spines, calcaneus, superior patella, and olecranon[16]—and ossification of the sacrotuberous ligament and the symphysis pubis.

Inflammatory arthritis

Rheumatoid arthritis

Despite its limitations in the detection of synovitis and bone oedema, and relative insensitivity to early bone changes,[17] plain film imaging of RA remains commonplace. The hallmarks of RA on plain film imaging are soft tissue swelling, periarticular osteopenia, joint space loss, erosion, and malalignment. The earliest change seen in RA on plain film imaging is usually periarticular soft tissue swelling due to the presence of a joint effusion and synovitis. Osteopenia also occurs early in the disease process and is seen initially in a periarticular distribution but progresses in chronic disease to become more generalized, secondary to disuse. Proximal disease is the hallmark of RA in the hand and wrist and the commonest sites for early detection of erosive change are the radial aspects of the metacarpal heads and ulnar aspect of the carpal bones and ulnar styloid. The first appreciable sign of erosion is the so called 'dot–dash' type of deossification associated with localized osteopenia (Figure 66.16). En-face erosions may simulate cysts, a common finding with erosions in the carpal bones. For this reason the Norgaard or 'ballcatcher's' view has been recommended for the assessment of early rheumatoid disease. This modified AP oblique view allows improved visualization of the radial aspect of the base of the proximal phalanges, the first and second carpometacarpal joints and the pisotriquetral joint (Figure 66.17).

In chronic disease ligamentous rupture can lead to instability patterns and deformity including ulnar translocation, scapholunate dissociation, and distal radioulnar subluxation.

The acromioclavicular joint is commonly involved in RA; early changes manifest as erosion of the distal clavicle and erosion of the coracoclavicular ligament insertion (Figure 66.18). The sternomanubrial and sternoclavicular joints may also be involved but are much less frequently imaged.

Involvement of the thoracic and lumbar spine is unusual in RA; however, the cervical spine is commonly involved. In particular the

Fig. 66.16 Rheumatoid arthritis (RA). This DP image of the right hand in a patient with RA shows various stages of disease within the metacarpophalangeal (MCP) joints. The little MCP joint is normal with no erosive change and normal joint space. The cortex of the third metacarpal head revels the classic 'dot-dash' pattern associated with early erosive change (black arrows) and there is early joint space loss. The index finger metacarpal head shows frank erosive change on the radial margin and marked joint space loss (white arrows).

atlantoaxial region is one of the most common locations for lesions in RA.[18] Erosions of the odontoid peg may be detected on plain film imaging, although this has been shown to be relatively insensitive compared with both MRI and CT.[19] Atlantoaxial subluxation may be seen resulting in malalignment at the C1–2 level with widening of the atlantoaxial distance (Figure 66.19). Normally this distance should not exceed 2.5–3 mm in adults. Multiplanar reconstructive CT imaging of this region is probably the gold standard for diagnosis[20]; however, lateral plain film radiography of the cervical spine is useful in measuring the degree of subluxation, and flexion and extension views may be employed for dynamic assessment of instability.[21]

Atlantoaxial subluxation in the axial plane may also be seen resulting in the tip of the odontoid peg protruding into the foramen magnum and the anterior arch of the atlas aligning with the body of the dens (Figure 66.19). This may be associated with severe neurological complications and MRI assessment is often required.

Seronegative arthritis

Enthesitis is a characteristic feature of the seronegative arthritides. On plain film imaging the important bone changes which may be appreciated in enthesitis are enthesophyte formation and erosion. Enthesophytes which develop either at or immediately adjacent to the site of an enthesis are seen as areas of bone proliferation.

Ankylosing spondylitis

One of the key imaging features of AS is the distribution of disease with symmetric involvement of the sacroiliac (SI) joints a characteristic feature. Early radiographic findings include loss of cortical definition followed by erosions and joint widening. In the more chronic phase of disease there will be sclerosis and ultimately ankylosis of the SI joints (Figure 66.20).

Within the spine early changes of AS are manifest as small erosions at the anterior corners of the vertebral bodies. These are usually surrounded by reactive sclerosis and have been termed Romanus lesions (Figure 66.21). Squaring of the vertebral body is also common, a feature caused by a combination of corner erosions and periosteal new bone formation along the anterior aspect of the vertebral body. This is followed by syndesmophyte formation in which ossification of the outer fibres of the annulus fibrosus form, eventually bridging continuously. In endstage AS there will be ankylosis of the spine leading to the typical 'bamboo' spine of chronic AS with fusion of vertebral bodies and the facet joints along with prominent spinous enthesophytes. The fused and subsequently osteoporotic spine seen in chronic AS is particularly susceptible to fracture (Figure 66.22).[22]

The hip is the most common appendicular site of AS involvement. If protrusion or other radiographic hip abnormalities are found then the sacroiliac joints should be examined.[6] Other joints such as the glenohumeral, sternomanubrial, and costochondral joints are less commonly involved.

Psoriatic arthritis

Typically PsA is seen to affect the small joints of the hands and feet with a distal distribution. Findings are often asymmetric, in contrast to RA which tends to be more symmetric in distribution. Enthesitis is a common feature and typically affects the calcaneus, ischial tuberosity, femoral troachanter, anterior patella, and the

Fig. 66.17 The Norgaard or ballcatcher's projection is optimal for reviewing the radial aspect of the metacarpal heads for early erosive change. The forearms are placed in supination with 45° of obliquity.

Fig. 66.18 Erosive change is seen affecting the distal end of the clavicles in this patient with long-standing rheumatoid arthritis. There is also erosion and subluxation of the humeral head bilaterally.

olecranon—this is not a feature of RA. Radiographic findings in the hands of patients with PsA are:

◆ **Bone erosion** beginning in a periarticular distribution and progressing to more central areas, and eventually osteolysis leading to the classic 'pencil-in-cup' deformity (Figure 66.23).

◆ **Asymmetrical destruction of the DIP with bony ankylosis**: in contrast, RA preferentially affects the MCP joint and PIP joints.

◆ **Resorption of terminal phalangeal tufts**; occasionally increased density of the terminal phalanges is seen, termed 'ivory phalanx'.

◆ **Periosteal reaction and small enthesophytes** may also be seen within the phalanges.

In the feet interphalangeal and metatarsophalangeal joint erosive change is common and the site of insertion of the Achilles tendon and/or plantar fascia is often affected, with enthesophyte formation and erosive change.

SI joint involvement is often asymmetrical with marginal erosions but fusion is not a feature. Another common site of disease is the spine where there is often bulky asymmetrical non-marginal osteophyte formation. These are commonly seen in the thoracolumbar spine initially and may progress to involve other areas of the spine.

Fig. 66.19 Lateral flexed cervical spine radiograph in a patient with rheumatoid arthritis. There is anterior subluxation of C1 on C2 with widening of the atlantoaxial distance (black arrows). The odontoid peg has migrated in a superior direction, giving rise to basilar invagination (white arrow). Note also that the malalignment is also evident between the spinous processes of C1 and C2.

Reactive arthritis

In the early stage of disease radiographs may be normal. However, in more progressive disease an asymmetrical distribution is seen with predominantly lower limb involvement. Characteristic sites of abnormality include the calcaneus, ankle, knee, and SI joints.

Fig. 66.20 Ankylosing spondylitis (AS) of the sacroiliac joints. AP film of the sacroiliac joints in this patient with long-standing AS shows complete fusion of the superior portion of the joint bilaterally. The lower portions of the joints show irregularity and sclerosis bilaterally but without ankylosis.

Fig. 66.21 Lateral view of the lumbar spine demonstrating early changes of ankylosing spondylitis. There is squaring of the vertebral bodies with associated sclerosis of the corners (Romanus lesions).

Fig. 66.22 Ankylosing spondylitis with Anderson fracture. Extensive ankylosis is seen in both the thoracic and lumbar spine. In addition there is a fracture through the spine at the L2/L3 level. Fractures of this nature usually extend through the fused posterior elements and are unstable.

Radiographic changes are similar to those seen in PsA with soft tissue swelling, joint space narrowing and marginal erosions with enthesophyte formation (Figure 66.2). In addition there may be sesamoid enlargement secondary to periostitis.[23] Periarticular osteopaenia is often seen with acute exacerbations.

Juvenile idiopathic arthritis

The most common radiographic abnormalities in patients with juvenile idiopathic arthritis (JIA) have been shown to be soft tissue swelling around the affected joint, growth disturbances (thought to be due to hyperaemia), joint space narrowing, and erosions.[24] Plain radiographic evidence of erosive change is also a relatively late and irreversible sign and as with adult inflammatory arthritis, MRI is increasingly being employed to assess for early signs of disease.[25] The wrist has been shown to be the most informative joint to detect bone erosions on plain radiography.[26] The knee is the most common site of involvement and there is often epiphyseal enlargement, overgrowth of the patella, and widening of the intercondylar notch. In the hands changes include boutonnière, flexion, and swan-neck deformities of the fingers alongside widened phalanges and
Fig. 66.23 There is a severe mutilating polyarthritis in this patient with psoriatic arthritis with subluxation at the metacarpophalangeal joints and extensive erosive disease. The right index and left little finger proximal interphalangeal joints show developing changes of a pencil-in-cup deformity (white arrows). The thumb metacarpals also show early pencil-in-cup change bilaterally (black arrows).

Fig. 66.24 Chronic changes in an adult resulting from juvenile idiopathic arthritis. Severe arthropathic change is seen at the wrist joints and within the carpi with fusion of several of the carpal bones. The joints of the hands are also abnormal, with cupping deformity of the proximal phalangeal bases and metaphyseal overgrowth.

metacarpals as a result of growth disturbance and periosteal new bone formation (Figure 66.24). Ankylosis of the involved joint is also a feature of the condition in its chronic stage and is common at the wrist joint. Osteoporosis associated with the condition may lead to epiphyseal collapse and deformity as a result of compression fractures secondary to abnormal stress on the bone.

Crystal arthritides

The crystal-induced arthritides are characterized by crystal deposition either in or adjacent to an affected joint. This is a heterogeneous group of diseases resulting in a variety of radiographic findings. Common crystals implicated are monosodium urate (producing gout), calcium pyrophosphate dihydrate, and calcium hydroxyapatite.

Gout

Conventional radiographs typically show changes only in advanced chronic gout.[27] However, this modality is still useful in monitoring articular and soft tissue lesions over time, especially in response to urate-lowering therapy.

Radiological features of gout may take 5–10 years to become evident following the first symptomatic episode. In contrast to other arthropathies, joint space and bone density are typically preserved until late in the disease process in gout and articular cartilage remains intact—this is one of the features that may be helpful to distinguish gout from other arthritides (Figure 66.4). Soft tissue swelling is typically irregular and asymmetric. The tophaceous swellings are relatively radio-opaque compared to the surrounding soft tissues, but do not usually show calcification unless there is concomitant renal disease. Late-stage features are typified by progressive

erosions, classically with overhanging margins, in a juxta-articular distribution with sclerotic margins and intra-articular deposits (Figure 66.4). Although disuse osteopaenia may occur late in the disease, periarticular osteopaenia is not usually a feature of gout.

Gout typically affects the peripheral joints of the appendicular skeleton and rarely involves the axial joints.[28] The first MTP joint is frequently involved but other MTP joints and interphalangeal joints of the feet may also be affected. Joint disease in the hand most commonly involves the interphalangeal joints in an asymmetrical distribution. The wrist may also be involved and extensive osseous erosion in the wrist is not uncommon. In the knee the patellofemoral compartment is most commonly affected where tophaceous masses are commonly located on the medial aspect of the infrapatellar fat pad and anterior joint recess, while erosions are most commonly seen at the lateral rim of the lateral femoral condyle.[29]

Calcium pyrophosphate crystal deposition disease

Both the radiographic findings and distribution of the arthropathy associated with calcium pyrophosphate crystal deposition (CPPD) are relatively distinctive. Although any joint may be involved, the most commonly affected are the knees, wrists, and hips and the distribution is usually bilaterally symmetric. The characteristic finding is the presence of CPPD crystals in or around the joint. Most commonly this is present as chondrocalcinosis, but crystal deposition may also occur in either synovial or capsular tissue. The presence of these findings does not necessarily imply pyrophosphate arthropathy; this term refers to a pattern of joint damage occurring in CPPD which has similarities to OA with joint space narrowing, subchondral sclerosis, and cyst formation either with or without associated chondrocalcinosis. The distribution of these two conditions differs, however; in the hands CPPD favours the radiocarpal joint as opposed to the typical trapeziocentric pattern seen in OA and tends to affect the MCP joints in preference to the interphalangeal joints. Chondrocalcinosis at the wrist is frequently seen in the triangular fibrocartilage and also in the lunate–triquetral ligament.[30] Chronic disease may be associated with scapholunate dissociation and eventually SLAC.[31] (Figure 66.25). A further feature of the disease in the hand is the presence of hook-like osteophytes seen typically on the radial aspect of the first metacarpal head; this pattern is classically seen in patients with either haemochromotosis or pyrophosphate arthropathy.

At the knee, crystal deposition is seen within the menisci and also within the hyaline cartilage; patellofemoral arthropathy predominates over involvement of the tibiofemoral compartments. Calcium deposition in the gastrocnemius tendon origin is also associated with CPPD disease of the knee.[32] Hip involvement is less common but should be considered where there are large subchondral femoral head cysts present particularly in the presence of chondrocalcinosis.

Calcium hydroxyapatite crystal deposition disease

Calcium hydroxyapatite deposition disease results in either periarticular or intra-articular crystal deposition which may cause either acute or chronic joint symptoms. This condition is most commonly recognized at the shoulder with calcification located either within the rotator cuff tendons, the biceps tendon, or the subacromial–subdeltoid bursa (Figure 66.26). The most common site of calcium deposition at the wrist is the flexor carpi ulnaris tendon, although deposits are occasionally also found in the flexor

Fig. 66.25 Calcium pyrophosphate arthropathy at the wrist with scapholunate advanced collapse (SLAC). Synovial calcification with chondrocalcinosis is seen at the ulnocarpal joint (note also calcification between the lunate and triquetrum in the lunate-triquetral ligament). This is associated with radiocarpal arthropathy and scapholunate dissociation.

Fig. 66.26 Hydroxyapatite deposition in supraspinatus tendon. The AP shoulder radiograph shows a large deposit of amorphous calcification in the supraspinatus tendon representing hydroxyapatite deposition (arrow).

carpi radialis, abductor pollicis longus, or extensor pollicis brevis tendons.[33] This calcification is usually readily appreciated on plain film imaging and, in contrast to calcium pyrophosphate, has an amorphous appearance without internal trabeculation. Intra-articular hydroxyapatite deposition has also been described, again commonly affecting the shoulder joint and associated with chronic tears of the rotator cuff—this has been termed the Milwaukee shoulder syndrome. On plain radiographs there is glenohumeral

joint destruction, narrowing, and sclerosis with occasional cyst formation; osteophyte formation is not prominent. The hands and wrists are also commonly involved.

Although the exact aetiology remains unknown there is some suggestion that hydroxyapatite deposition in soft tissues may be related to repetitive low-grade trauma.[34]

Connective tissue disease

Scleroderma, dermatomyositis, and polymyositis, and SLE all have associated arthropathy as a common feature; they share some similar radiographic findings such as osteoporosis and soft tissue wasting.

Scleroderma

Articular manifestations are common in systemic sclerosis, and joint pain is therefore a common presentation of disease.[35]

In the soft tissues flexion contractures have been shown to be the most common radiographic finding, with soft tissue atrophy over the distal phalanges and soft tissue calcification also both extremely prevalent findings. The soft tissue calcification is dystrophic in origin and amorphous in appearance and is most commonly seen in the digits; however, it may be seen in any location including within the joints either in the presence or the absence of joint destruction (Figure 66.27).

The most common site of bony resorption is the tufts of the terminal phalanges of the hands, but this phenomenon may also be seen at the angle of the mandible, the posterior ribs and diffusely around the wrist.[36] Resorption in the toes is far less common than in the fingers and is usually less severe. In chronic disease patients

may develop an erosive arthropathy, which typically affects the DIP and PIP joints with sparing of the wrists.

Dermatomyositis and polymyositis

The most common radiographic change of dermatomyositis is the finding of 'sheet-like' calcification within the subcutaneous soft tissues along muscle or fascial planes. Typically these areas of calcification are diffuse, affecting both the skin and skeletal musculature, with the thigh being the most common site of involvement. Joint disease may also occur clinically but radiographs are usually unremarkable or may demonstrate subtle changes such as periarticular osteopaenia and soft tissue swelling. Other imaging findings such as muscle oedema, fatty infiltration of the muscles, and wasting are more readily appreciated on MRI. Polymyositis has similar radiographic findings but involves only skeletal muscle.

Systemic lupus erythematosus

Articular symptoms are common in SLE and have been reported in 76% of patients with this condition. The hands and wrists are commonly affected, although the feet are also sometimes involved. The most frequent finding is synovitis which will manifest as soft tissue swelling and osteopenia. Classic joint deformities are also seen secondary to ligamentous laxity and include ulnar subluxation of the MCP joints and hyperextension at the thumb interphalangeal joint. The arthropathy associated with SLE is typically non-erosive—a feature which allows distinction between this condition and RA. Osteonecrosis is a well-recognized feature in SLE and may occur in the femoral head, humeral head, knee, and MCP heads. Soft tissue calcification is a less common radiographic feature in some patients and is usually seen in a periarticular distribution.

Fig. 66.27 Scleroderma. There is extensive soft tissue calcification seen within the subcutaneous tissues adjacent to the index, middle, and ring fingers bilaterally and the right thumb. There is also soft tissue loss from the distal ends of the fingers. This combination of findings is typical for scleroderma.

Miscellaneous conditions

SAPHO syndrome

The radiological appearances of the skeletal manifestations of the synovitis, acne, pustulosis, hyperostosis, and osteitis (SAPHO) syndrome are crucial in the diagnostic process.[37] The bone changes associated with this condition are thought to be due to an inflammatory process. Many of the manifestations described are appreciable on plain film imaging and studies have shown that although radiographs performed in the first 3 months of the disease course were normal in 80%, all patients had abnormal radiographs at the end of follow-up.[38] The most common site of bony involvement is the anterior chest wall and in particular the sternoclavicular, costochondral, manubriosternal, and costosternal junctions.[39] The distribution and severity of involvement varies from the adult to the paediatric form of chronic recurrent multifocal osteomyelitis (CRMO).

The radiographic findings have been subdivided into three stages: stage 1 is localized to the costoclavicular junction and is characterized by soft tissue swelling, erosion and new bone formation; stage 2 is generalized involvement of the ipsilateral sternocostoclavicular region with sternoclavicular arthropathy and increased sclerosis of the medial end of the clavicle; and stage 3 is further progression of hyperostosis, osteosclerosis and hypertrophy of the medial ends of the clavicle.[39] The spine is the second most common site of involvement with six main radiological manifestations: vertebral body corner lesions, non-specific spondylodiscitis, and osteodestructive lesions all seen in both adults and children, and osteosclerotic vertebral lesions, paravertebral ossification, and sacro-iliitis seen only in adults.[40]

Neuropathic arthropathy

The radiographic findings associated with a neuropathic joint are similar irrespective of the aetiology. Two distinct patterns of arthropathy are described, namely atrophic and hypertrophic neuropathic osteoarthropathy. Atrophic destruction manifests as osteolysis usually affecting the distal ends of tubular bones, usually in non-weightbearing joints, which may be mistaken for surgical amputation. The more common pattern of involvement is hypertrophic and characteristically the findings at an affected joint have been described as increased bone density, debris production, dislocation, disorganization, and destruction (Figure 66.28). Osteophytes are also formed in neuropathic arthropathy and may differ from those seen in osteoarthritis on the basis of ill-defined and rounded margins. Early changes may, however, be difficult to differentiate from OA, infection, or more rarely tumour. Neuropathic changes are much more commonly seen in the lower limbs than in the upper limbs or spine. Fractures associated with neuropathy are common and may be difficult to diagnose due to surrounding destruction and debris.

Haemochromatosis

Arthropathy associated with haemochromatosis is similar in radiographic presentation to the features of CPPD but there are some distinguishing features; haemochromatosis arthropathy typically involves the second and thirrd MCP joints where hook-like osteophytes are seen to the radial aspect of the metacarpal head and the metacarpal heads become flattened. In more chronic disease there

Fig. 66.28 Charcot foot. There is marked disruption of the midfoot in this patient with diabetes. There is a divergent Lis Franc dislocation and fragmentation of the midfoot bones.

may be large-joint involvement, usually of the knees, hips, and shoulders. In these joints there may be multiple subchondral cysts, subchondral sclerosis, and symmetric joint space loss. Disease progression is usually slow.

CHAPTER 67

Ultrasound

David Kane and Philip Platt

Use of ultrasound in rheumatology

The inclusion for the first time in this textbook of a chapter on ultrasound indicates the recognition of musculoskeletal ultrasound (MSUS) as a routine part of rheumatological practice. The first report on the use of ultrasound in a rheumatology clinic was published over 30 years ago.[1] Ultrasound assessment of small joints, a particular interest for rheumatologists, only became feasible in the 1990s with the advent of high-frequency transducers.[2] Further technical advances and falling equipment costs have allowed rheumatologists to obtain equipment and begin training, and have facilitated the introduction of ultrasound into routine clinical practice. Training in the use of ultrasound is currently a compulsory part of rheumatology training in some European countries, with training courses and programmes established in most European countries. In 2005 up to 93% of rheumatologists in the United Kingdom reported that they used ultrasound in the management of patients, with 33% performing ultrasound themselves.[3]

The principal advantage of ultrasound over MRI, CT, and scintigraphy is its immediate availability in a clinical setting. It is performed after clinical history and examination, allowing the rheumatologist to focus in on the key joint or joints of interest. The diagnosis can therefore be immediately confirmed or refuted and therapy instigated without delay. Ultrasound allows guidance of aspiration and injection, improving the accuracy rates of procedures. Other advantages are that it is non-invasive, non-radioactive, and has very high patient acceptability with no issues regarding claustrophobia or pregnancy. Soft tissue imaging with ultrasound provides higher definition than other imaging modalities, including MRI. Although there are initial equipment costs, the running costs are low and ultrasonography is largely immune to the metal artefacts that can cause difficulties with MRI and CT.

The disadvantages of ultrasound are that it requires the initial purchase of equipment and a significant commitment to training. Adding an ultrasound scan to your patient assessment will lengthen the initial appointment time, but usually reduces the need to review the patient again for the same complaint, thus saving time overall. Ultrasound cannot image into or beyond bone, which MRI and CT imaging can, and ultrasound has a limited resolution for deeper joints, such as the hip, particularly in obese patients. There are also valid concerns about the standardization of examinations by different sonographers and how best to assess and certify competency in trainee ultrasonographers.

Ultrasound by rheumatologists is complementary to that of musculoskeletal radiologists but it does not replace it completely. Patients who undergo an ultrasound examination by a rheumatologist often have different clinical characteristics and diagnostic targets from those assessed by a radiologist. Formal ultrasound by an experienced musculoskeletal radiologist is still invaluable in cases of diagnostic uncertainty and for the selection and interpretation of other imaging modalities such as MR and CT.

Technical aspects of ultrasound

Equipment

There are a number of important considerations when selecting ultrasound equipment.[4] Cost relates directly to image resolution and quality, but the cost of equipment is falling and the quality is improving. It is a good principle to purchase the best machine that you can afford, particularly for your first ultrasound system. The choice of probe size and frequency depends on the size and depth of the structures you wish to image. A higher-frequency probe (10–20 MHz), ideal for small superficial structures, has a smaller footprint with high resolution, but poor tissue penetration. The reverse is true for lower frequency probes (<7.5 MHz). Linear array transducers are the preferred option for most musculoskeletal scanning. Equipment portability is an advantage for multisite use, but incurs more expense to obtain the equivalent image quality of a larger, less mobile system. Colour and power Doppler options are essential for rheumatology practice.

Ultrasound technology

Ultrasonography uses reflected pulses of high-frequency sound to assess soft tissue, cartilage, bone surfaces, and fluid-containing structures. These pulses are emitted and reflections are received by the same ultrasound transducer. The basic principle of ultrasonography is that the denser the material the sound wave is passing through, the more reflective it is, the stronger the reflected signal received by the transducer, and the whiter (or more echoic) it appears on screen. Water is the least reflective body material. Sound waves pass straight through water with minimal reflection and it appears black (or anechoic). Bone is the most reflective body material and appears as a bright white line (hyperechoic).

Greyscale or B-mode ultrasonography displays the different intensities of echoes in black, white, and shades of grey. Where a tissue has organized into areas of different density and structure there may be multiple reflections, such as occurs in a tendon where reflections from the multiple tendon fibres give a characteristic linear appearance.

Doppler

Doppler ultrasound uses the principle that sound waves increase in frequency when they reflect from objects (such as red blood cells) that are moving towards the transducer (displayed as a red signal) and decrease when they are moving away from the transducer (displayed as a blue signal). Power Doppler ultrasound measures the amplitude of the Doppler signal (which is determined by the volume of blood flow) and superimposes it on the greyscale image, thereby depicting increased microvascular blood flow.

Power Doppler is generally used for assessment of small-vessel blood flow that occurs in inflammatory soft tissues, whereas colour Doppler is used for larger-vessel assessment, as in temporal arteritis. A subjective assessment of the degree of vascularity present in soft tissues can be made by scoring on a semiquantitative scale of 0 to 3, where the score is assigned according to the number of vessels or the percentage area of vascularity within the joint tissue (0, no Doppler signal; 1, signal <10% of the field; 2, signal is 10–50% of the field; 3, signal >50% of the field).

Standard views and artefacts

Ultrasound scans are defined by two views and all examinations should include both planes: transverse or short axis (similar to axial views on CT/MRI) and longitudinal or long axis. The correct probe size and frequency should be selected according to the size and depth of the joint to be examined. Most ultrasound systems used in rheumatology practice now have presets for different joints, allowing the appropriate settings of the ultrasound equipment to be adjusted. A more detailed technical description of ultrasound system technology is outside the scope of this chapter but can be found in all major ultrasonography textbooks.[5]

There are a few ultrasound artefacts to be aware of:

- **Anisotropy**. This is the property of certain tissues to change their reflectivity with changes in the angle of incidence of the ultrasound beam. If the beam is not perpendicular to the tissue being scanned, the sound waves are scattered rather than being reflected back to the transducer. This causes the structure to appear darker than it should and can result in the inaccurate diagnosis of, for example, tendinosis or tendon tears.

- **Edge artefact**. Hypoechoic areas occur at the edge of spherical structures such as tendons or fluid collections, giving an edge artefact or refractile shadow.

- **Acoustic shadowing**. This occurs when the ultrasound beam hits a highly reflective surface such as bone, air, or calcified tissue. The region below (behind) it appears anechoic (black) or hypoechoic (grey) as very few sound waves can reach it.

- **Power Doppler artefacts**. Caution has to be exercised when assessing power Doppler signal. It is extremely operator and machine dependent. Doppler signal is very sensitive to the slightest movement of the transducer and too much pressure on the

transducer can occlude small vessels, thus giving a false,negative power Doppler signal.[6]

Variability

A valid concern is the high degree of operator dependence in ultrasonography. In order to minimize variability it is best to use a standard scanning protocol.[7] All images should always be interpreted in light of the clinical history and examination. The OMERACT ultrasound task force has confirmed good levels of inter- and intraobserver variability of ultrasound imaging among expert ultrasonographers and there is good reliability between experts using different types of ultrasound machine.[8]

Ultrasound pathology

Ultrasound has been shown to have many uses in the diagnosis and management of musculoskeletal disorders. MSUS is consistently superior to clinical examination in

- measuring the extent of anatomical damage and inflammation in early arthritis

- assessing inflammatory and non-inflammatory soft tissue diseases

- determining therapy efficacy

- providing guidance for joint and soft tissue injection.[9,10]

Musculoskeletal ultrasound should always complement clinical examination and has the further advantage of improving the operator's knowledge of functional anatomy and pathological processes.[4] The high resolution of today's ultrasound machines means that normal amounts of synovial fluid can often be detected in healthy joints. Standard reference values have been compiled in order to help distinguish between normal and pathological structures.[11] The OMERACT MSUS group published the first definitions of sonographic pathology for rheumatologists in 2005.[12] Specific pathologies are fully described in the relevant disease sections.

Rheumatoid arthritis

The application of ultrasound in the diagnosis of inflammatory arthritis was a key event in positively influencing the uptake of ultrasound performed by rheumatologists. Initial studies in established rheumatoid arthritis (RA) had confirmed the accuracy of ultrasound in detecting joint and soft tissue inflammation.[2] A number of studies then confirmed the increased sensitivity of ultrasound diagnosis of joint inflammation over clinical examination in early RA, facilitating earlier diagnosis and therapeutic intervention.[13–15]

Joint inflammation is detected as joint effusion, an anechoic or hypoechoic appearance, that is compressible and displaceable, or as synovitis (Figure 67.1). Synovitis is diagnosed by the presence of an abnormally thickened hypoechoic tissue around the joint that is partially compressible but not displaceable. Normal synovium is not visualized in healthy joints and the presence of synovitis is closely correlated with the presence of effusion. Ultrasound is more sensitive than clinical examination in the detection of synovitis.[9,16] It has been shown to detect subclinical synovitis, which can predict radiographic progression in both the early and established stages of disease.[17] Tenosynovitis is also detected frequently on ultrasound of RA joints.
Fig. 67.1 Ultrasound in rheumatoid arthritis: (A) Characteristic anechoic well-circumscribed Baker's cyst (**) in effusion of the knee in rheumatoid arthritis (posterior longitudinal view). (B) Mixed echogenicity with anechoic effusion (*) and hypoechoic synovial thickening in metatarsophalangeal (MTP) joint synovitis (dorsal longitudinal view)—the joint is labelled at the junction of the hyperechoic bony cortex of the metatarsal and phalanx. (C) MCP joint synovitis with hypoechoic synovial thickening causing convex displacement (arrowed) of the extensor tendon (dorsal longitudinal view). (D) MCP joint synovitis with power Doppler signal in the hypoechoic synovial thickening (dorsal longitudinal view).

Power Doppler scanning has become an integral part of the sonographic assessment for synovitis and tenosynovitis (Figure 67.2). Doppler is most sensitive in the superficial joints, such as the hands and feet, and is less sensitive in the deeper joints, such as the hip and shoulder. Joint hyperaemia due to vasodilatation is an early feature of articular inflammation. Angiogenesis is a key feature of synovial pannus formation leading to chronic inflammation and joint destruction. Power Doppler can detect minimal increases in perfusion in the synovium and has comparable sensitivity and specificity to MRI[15] with proven correlation to histological vascular density of the inflamed synovial membrane.[18]

The presence of power Doppler signal in RA implies active tissue inflammation. It can be quantified and has shown better inter- and intra-observer reproducibility than greyscale synovitis across several studies. Advances in ultrasound imaging now produce similar sensitivity for joint inflammation with either colour or power Doppler in most modern ultrasound systems. However, Doppler has the potential for a number of well-recognized artefacts leading to false-positive results, and care must be taken in using appropriate machine settings and minimizing movement and systematic artefact.[19]

MSUS is increasingly being used as a clinical tool to monitor disease activity in RA and to assess response to treatment. Power Doppler has been shown to be a valid method for monitoring response to anti-TNFα therapy in RA. It is reproducible and sensitive to change and may have predictive value in relation to radiological outcome.[17] Taylor et al.[20] looked at patients with early RA and measured the degree of synovial thickening in 10 metacarpophalangeal (MCP) joints and a Doppler-based vascularity score. There was a marked improvement following treatment with infliximab compared to controls and the vascularity score was more sensitive than the clinical disease activity score (DAS).

Both greyscale and power Doppler ultrasound have validity in assessing changes in articular inflammation and a number of objective scoring systems have been proposed. As these systems have been reported by experienced ultrasonographers assessing large numbers of joints with ultrasound,[21,22] an ultrasound score for RA remains a research tool at present. A recent study looked at a number of these measurement tools and found that ultrasound evaluation was an outcome measure 'at least as relevant as physical examination'.[23] The OMERACT ultrasound task force is currently developing a Global OMERACT Scoring System (GLOSS) for use in RA in addition to sonographic scoring systems for enthesitis and osteoarthritis.[24]

Radiographic bone erosion is a key pathophysiological feature of RA and is one of the American College of Rheumatology (ACR) diagnostic criteria. Radiographic erosions can be scored to allow monitoring of disease progression and outcome. Several studies
Fig. 67.2 Ultrasound in rheumatoid and seronegative arthritis: (A) Proximal interphalangeal (PIP) joint synovitis in rheumatoid arthritis with hypoechoic synovial thickening and power Doppler signal on the extensor aspect of the joint (dorsal longitudinal view). (B) Flexor tenosynovitis (FT) is seen in the palmar longitudinal view of the PIP joint in panel A with hypoechoic widening of the tendon sheath and power Doppler signal in the tendon and sheath. The presence of tendon inflammation is a common feature in RA and does not differentiate seropositive from seronegative arthritis. (C) Tibialis posterior tenosynovitis in reactive arthritis shows similar hypoechoic widening of the tendon sheath (transverse view over medial ankle). (D) Panel C with power Doppler signal in the tendon sheath and tendon.

have confirmed that MSUS is more sensitive than plain rtadiuography in the detection of bone erosions in patients with RA. Wakefield et al.[14] reported that ultrasound detected 6.5 times more erosions than plain radiography in the MCP joints of patients with early RA and 3.4 times more in established RA. MRI and MSUS correlate well in the detection of bone erosion, though MRI has advantages in less accessible joints, such as the wrist and the third and fourth MCP joints. There is a high level of reliability within and between observers in detecting bone erosion on MSUS.[14,15] The development of an objective ultrasound erosion score to replace radiographic scoring is ongoing.

Spondyloarthropathies

Spondyloarthritis (SpA) is the preferred terminology for a group of diseases characterized by joint synovitis, tendonitis, and enthesitis peripherally in combination with pathognomic axial inflammation particularly at the sacroiliac joints. SpA may occur in association with psoriasis, inflammatory bowel disease, or uveitis, usually in the absence of rheumatoid factor and anti-citrullinated peptide antibodies.

All of the peripheral pathologies in SpA can be readily identified on ultrasound imaging, and initial studies show the potential for ultrasound in imaging sacroiliac joints and psoriasis. The

increased sensitivity of ultrasound in the diagnosis of synovitis is well described in RA. There are no consistent qualitative or quantitative features that discriminate synovitis in RA from SpA.

Greyscale and Doppler MSUS are sensitive techniques in the detection of synovitis of the hand and knee in established psoriatic arthritis (PsA) and in the objective monitoring of response of synovitis to therapy.[25,26] MSUS can also detect subclinical PsA in patients with psoriasis.[27] In early seronegative oligoarthritis, the increased sensitivity of MSUS in the diagnosis of synovitis led to 29/80 patients (36%) clinically classified as oligoarticular being reclassified as polyarthritis based on MSUS. The implication of this study is that MSUS may identify patients with SpA who have higher disease activity and who merit more aggressive early therapy.

Inflammation of the enthesis—the tendon, ligament, or capsule junction with bone—is a common feature of SpA and has stimulated much research and debate on the classification and pathophysiology of SpA. But enthesitis is not exclusive to SpA and can occur in gout or secondary to mechanical stress in many rheumatic diseases. MSUS features of enthesitis include hypoechoic entheseal thickening, fibrillar separation of the enthesis due to oedema, presence of power Doppler signal within the enthesis, associated bursitis, and bony insertion erosive change and enthesophyte formation.[28,29]

Tendonitis has similar ultrasound appearances distal to the insertion with the additional features of tenosynovitis of the tendon sheath and paratenonitis. Using MSUS as the gold standard, clinical examination was initially reported to have a low sensitivity (22.6%) and moderate specificity (79.7%) for the detection of enthesitis of the lower limbs.[29,30] Enthesitis can be observed at any enthesis, but is most frequent in the lower limbs particularly at the plantar fascia and Achilles tendon (Figure 67.3).[31] A recent review noted that there are now more than 20 studies of scoring of enthesitis that confirm ultrasound as the most sensitive diagnostic tool.[32] The Glasgow Ultrasound Enthesitis Scoring System (GUESS) is the most commonly used score, though there is no agreement on a standardized ultrasound enthesitis score that incorporates all the ultrasound features of enthesitis.

Dactylitis of the digits and distal interphalangeal (DIP) joint involvement are characteristic clinical features of PsA. MSUS and MRI studies confirm that flexor tenosynovitis and diffuse soft tissue swelling are the principal component features of dactylitis in early SpA,[33,34] while synovitis is also found in patients with dactylitis and established PsA.[35] DIP joint disease is a feature of a number of arthritides and MSUS can differentiate PsA DIP disease from erosive or nodular osteoarthritis, chronic tophaceous gout, calcification in systemic sclerosis, and simple synovial cysts.[36]

MRI is the gold standard for imaging sacroiliitis in SpA, but MSUS with colour Doppler and microbubble contrast agent enhancement has shown excellent correlation with MRI sacroiliitis (sensitivity 94%, specificity 86%)[37] and can be used to monitor the response to anti-TNF therapy.[38] MSUS may be used to detect structural damage such as bony erosion in patients with PsA.[36] Given that the rate of radiological damage in early PsA is modest, more sensitive techniques such as MSUS and MRI have a potential role in future clinical trials.

Osteoarthritis

Ultrasound has emerged as a very promising imaging modality for osteoarthritis (OA) with the ability to reliably detect changes in articular cartilage, both thickness and quality, the presence of effusions, synovial hypertrophy, other soft tissues, and bone surface.[39] Potential OA changes can be evaluated readily in knee hip and finger joints, although research has centred predominantly on knee OA.

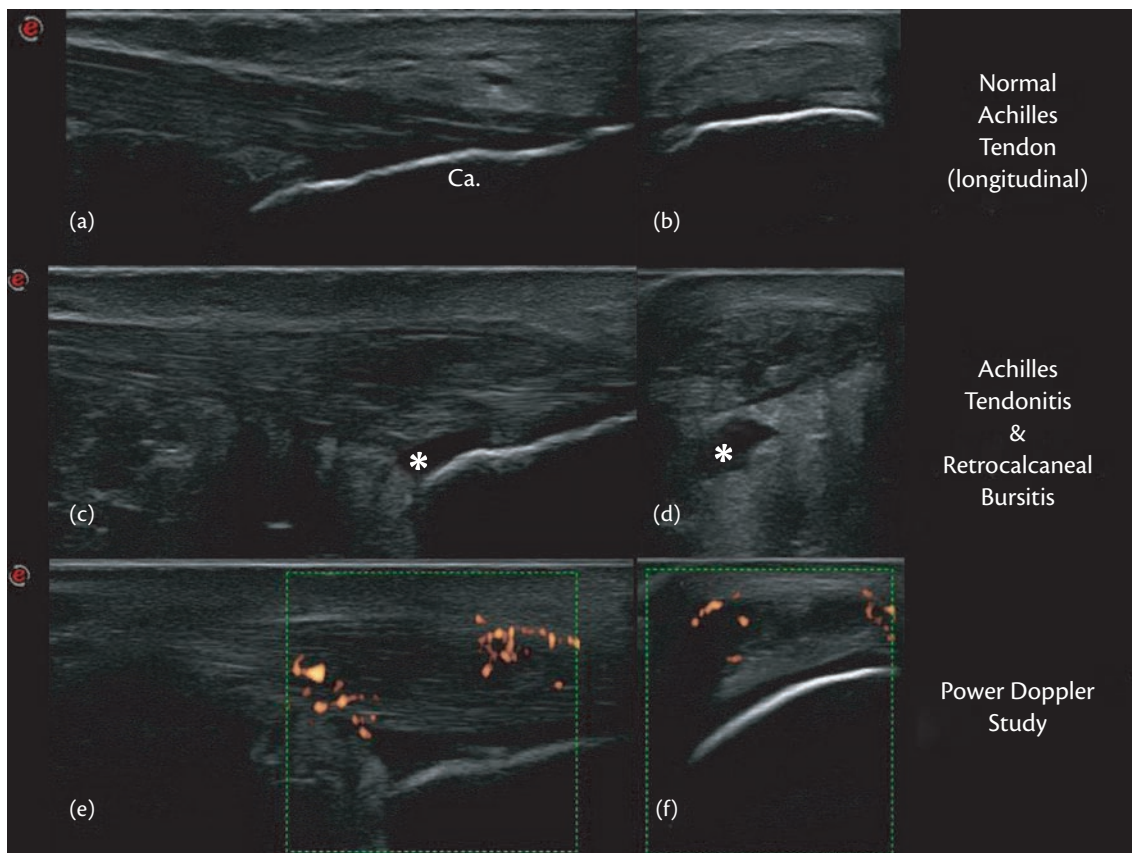
Normal articular cartilage is anechoic, whereas degenerative cartilage has increased echogenicity. Ultrasound can demonstrate loss of normal sharpness of chondral surface and chondrosynovial interface with reduction in thickness of the cartilage. Increased echogenicity of the osteochondral interface and sensitive detection of osteophytic change and identification of erosions have been reported.[39] There are some limitations, including difficulty in delineating progressive changes in articular cartilage due to problems with reproducibility, and also the limitation of acoustic windows into some joints.[39]


Fig. 67.3 Achilles tendonitis in seronegative spondyloarthritis: (A) Normal longitudinal view of Achilles tendon insertion. (B) Normal transverse view of Achilles tendon insertion. (C) Hypoechoic thickened Achilles tendon at calcaneal insertion (Ca.) with mixed echogenic retrocalcaneal bursal effusion and synovitis (longitudinal view). (D) Transverse view of previous panel. (E, F) Increased power Doppler signal in the thickened Achilles tendon. * marks the site of the retrocalcaneal bursitis.

Ultrasound has demonstrated that synovitis is a common feature of OA. In a study of 600 patients with knee pain, D'Agostino et al.[40] demonstrated effusion and/or synovitis in 46% of knees. Ultrasound has been shown to be more sensitive in detecting effusion and Baker's cyst than clinical examination.[41] However, the detection of hip and knee effusion and synovitis does not predict response to intra-articular steroid injection.[41,42]

Non-inflammatory soft tissue disorders

Ultrasonography is the imaging modality of choice for tendons. The resolution for superficial tendons is greater than for MRI and has the advantage that the real-time imaging allows movement of tendons and hence dynamic assessments. The characteristic appearance is due to low echogenic collagen fibrils surrounded by highly echogenic connective tissue matrix. This gives the tendon a bright, striated, appearance on ultrasonography, when imaged with the probe perpendicular to the long axis of the tendon. When the tendon runs obliquely to the ultrasound beam the echogenicity is reduced and is described as anisotropy.

Tendon pathology in the form of tendinopathy, is characterized on ultrasound by swelling of the tendon with inhomogeneous hypoechoic areas in the tendon substance. This is often accompanied by neovascularization demonstrated by power Doppler ultrasound. Tendon rupture is characterized by the absence of echoes between the free edges of the tear if the gap is filled by fluid, or rather more echogenic material if the gap is filled with haematoma or tissue herniating in to fill the 'gap'. There is also a lack of synchronous movements on dynamic scanning. Tears are frequently accompanied by signs of tendinopathy.

Tendons may be enclosed in a synovial sheath, such as around the wrist and ankle, or a much thinner paratenon of loose vascular connective tissue, as in the case of Achilles and rotator cuff tendons. Tenosynovitis is readily demonstrated on greyscale ultrasound as excessive fluid between the tendon and the synovial sheath or paratenon, and where there is a synovial sheath, synovial hypertrophy. Power Doppler frequently demonstrates significantly increased vascularity in tissues surrounding the tendon. In mild cases of tenosynovitis the most obvious abnormality may be loss of the normal smooth sliding action of affected tendons on movement. Localized thickening of the tendon sheath, often with a Doppler signal in the thickened area of tendon sheath, is seen in De Quervain's. Increased fluid around a tendon does not always indicate tenosynovitis. Fluid around the long head of the biceps tendon may indicate a shoulder effusion and increased amounts of fluid are often seen around the tendons which cross the ankle joint.

Enthesopathy, such as patella tendinopathy or lateral epicondylopathy is characterized by expansion of the tendon at the insertion, inhomogeneous hypoechoic areas, and frequently increased vascularity as demonstrated by power Doppler.

Shoulder

The joint where ultrasonography has made the most significant impact is the shoulder. Rotator cuff tears, tendinopathy, and impingement are common indications for ultrasound examination. Ultrasound is as sensitive and specific at demonstrating rotator cuff pathology as MRI scanning.[43] Although it does not offer the sensitivity of MRI arthrography, it is much more cost effective and is non-invasive.

The complete intra-articular course of the long head of the biceps tendon cannot be visualized, but it can be clearly seen in the bicipital grove as homogeneous, linear, and echogenic. Pathology in the form of tenosynovitis, tears, and subluxation can all be identified. Supraspinatus tendinopathy is common and earliest changes are seen in anterior and distal tendon edges.[44] Tendinopathy is seen as hypoechoic swelling. Tears are seen as a focal area of tendon defect, with the margins separated by fluid or herniated deltoid or subdeltoid bursa.[44] Partial tears may only be identified by a change in the contour of the supraspinatus tendon. Isolated severe subscapularis tendinopathy or tear is uncommon, being more likely to occur as part of a massive rotator cuff tear or previous dislocation. Similarly, isolated infraspinatus pathology is unusual.

Ankle

Normal Achilles tendons are highly echogenic, and anisotropy occurs where fibres curve down to insert into the calcaneum. The superficial nature and lack of any overlying bone make the Achilles tendon an ideal subject for MSUS. A number of pathologies can be readily identified including tendinopathy, enthesopathy and enthesitis, tears, inflamed paratenon, and bursas. Tendinopathy of the Achilles tendon (Figure 67.4) normally affects the mid section of the tendon some 4–6 cm from the calcaneum. The tendon becomes swollen with development of hypoechogenic areas and loss of the normal fibrillary pattern. Power Doppler often shows increased vascularity with new vessels penetrating deep into the tendon. In Achilles tendon tears fluid can be seen between the torn margins; if there is intervening haematoma this can be more difficult to distinguish as the appearance is not dissimilar to tendinopathy (Figure 67.5).

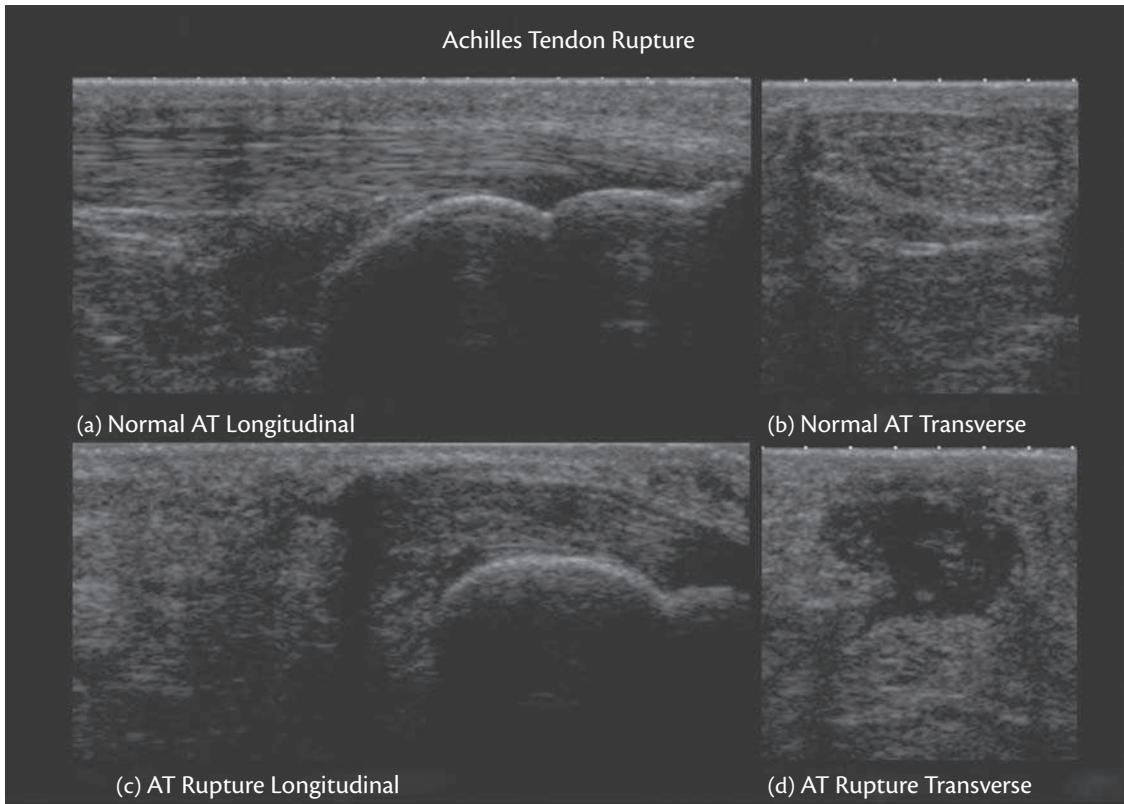
Of the tendons that cross the ankle, the tibialis posterior and the peroneal tendons are most likely to demonstrate pathological changes in the form of tendinopathy, tenosynovitis, or tears. In the case of the tibialis posterior tendinopathic changes are most commonly found close to the medial malleolus and close to its insertion into the navicular bone. Changes of tenosynovitis in the tibial posterior and peroneal tendons are most likely to be found close to the malleoli.
Fig. 67.4 Achilles tendinopathy showing expansion of the mid zone of the tendon, with increased low echogenic areas (longitudinal view).


Fig. 67.5 Complete rupture of the Achilles tendon: (A) Normal longitudinal view of Achilles tendon insertion. (B) Normal transverse view of Achilles tendon insertion. (C) Hypoechoic Achilles tendon with complete loss of fibrillar structure (longitudinal view). (D) Transverse view of previous panel.
Fig. 67.6 Lateral epicondylopathy (tennis elbow), showing radial head, joint margin of elbow joint and lateral epicondyle. Significant power Doppler signal from hard areas close to insertion.

Enthesopathy or insertional tendinopathy

These include common conditions such as lateral epicondylopathy (Figure 67.6), patellar tendinopathy (Figure 67.7), Achilles enthesopathy (Figure 67.8), and lateral hip pain or so-called trochanteric bursitis. Abnormalities demonstrated on MSUS in all these areas follow the same pattern of expansion of the tendon close to insertion, hypoechogenicity, loss of the normal bright fibrillary pattern, and increased vascularity demonstrated on power Doppler. The degree of vascularity of the lesions can be quite striking and is reversible. The role of the vascularity in terms of symptoms and its correlation with degree of symptoms and their disappearance is still controversial. Dense calcification can be seen in all these areas in chronic conditions together with some irregularity of the underlying bone.

Crystal-induced arthritis

As with other causes of erosive disease, ultrasound is a sensitive method of detecting erosive changes in gout.[45] Gout can also produce characteristic ultrasound appearances, the 'double contour' or 'train track' sign in both clinically affected and unaffected joints due to the deposition of monosodium urate crystals on the surface of the hyaline cartilage (Figures 67.9 and 67.10).[45] Tophi have a range of appearances on ultrasound from hypoechogenic areas (soft tophi), to hyperechoic areas (hard tophi), with areas of calcification (Figure 67.11).
Fig. 67.7 Patellar tendinopathy showing expansion of the patella tendon with hypoechoic areas and power Doppler signal (longitudinal view).
Fig. 67.8 Achilles enthesitis with expansion of the enthesis, power Doppler signal (longitudinal view).

In calcium pyrophosphate deposition disease, the crystals are found within the substance of hyaline cartilage and are seen as linear hyperechoic deposits. They may also be detected in fibrocartilage as hyperechoic deposits that persist even when the gain of the ultrasound beam is markedly reduced.

Connective tissue diseases and vasculitis

Systemic lupus erythematosus

The potential for the use of ultrasound in connective tissue diseases has been relatively neglected compared to RA. Erosive changes in Jaccoud's arthropathy have been demonstrated using ultrasound, which were not detected on plain radiography.[46] Synovitis and/or effusions in wrist and hands are found commonly, being reported in one-half the cases in one study,[47] with tenosynovitis in one-quarter and structural damage in 14%. Significant findings have also been reported in larger joints, including synovitis in 40% and effusion in 20% of knees.[48] Vascular changes in systemic lupus erythematosus (SLE) have been more fully evaluated, with carotid plaques reported in 18% of SLE patients with nephritis compared to 2% in controls and increased plaque progression and intimal thickening.[49]

Systemic sclerosis

High-frequency ultrasound is reported to be a reliable and reproducible method of measuring digital dermal thickness in patients with systemic sclerosis.[50] Significant dermal thickening was reported in all groups, oedematous being thicker than fibrotic, which in turn was thicker than atrophic, with significant correlation with modified Rodman score. Patients with early disease (<2 years), are characterized by increased skin thickness and low skin echogenicity reflecting oedema, useful to detect patients with diffuse involvement at a very early stage.[51] Ultrasound elastography being evaluated for use in systemic sclerosis in assessing skin involvement, but appears to be limited to areas of thicker dermis and where bone hyper-reflection is minimal, effectively excluding use in hands.[52]

Fig. 67.10 First MTP joint showing double contour or train track sign due to deposition of urate crystals on the surface of the articular cartilage (dorsal longitudinal view).
Fig. 67.11 Second metacarpophalangeal (MCP) joint showing line of calcification in the midzone of the articular cartilage.

Sjögren's syndrome

In the early stage the salivary glands on ultrasound may be normal or show diffuse enlargement with normal echogenicity.[53] The late features are more diagnostic: a heterogeneous echo pattern with multiple round hypoechoic areas within the parenchyma, sometimes containing frank cystic changes. In long-standing disease, the involved glands appear small and atrophic with a hypoechoic echotexture or may have a reticulated pattern.[54] It has recently been suggested that submandibular gland sonography might be a practical alternative to sialography in the classification of Sjögren's syndrome.[55]

Vasculitis

The combination of greyscale ultrasound and Doppler in the form of duplex ultrasonography has the potential to make a significant contribution to the diagnosis and monitoring of giant cell arteritis. The use of duplex ultrasound was described by Schmidt et al.,[56] who reported a 'halo' appearance on ultrasound due to hypoechoic oedematous swollen temporal arterial wall in active giant cell arteritis. Recent meta-analyses have reported sensitivity of 69% and specificity 82% compared to biopsy[57] and a sensitivity of 68% and a specificity of 91% when compared to ACR criteria.[58] Schmidt et al.[59] reported that extending ultrasound to
Fig. 67.12 (a) Dark ring of oedematous arterial wall around power Doppler signal on a cross-sectional temporal artery scan. (b) Transition between abnormal arteritis area of the temporal artery with narrowed flow as indicated by power Doppler and a normal area.

the proximal upper extremity arteries significantly increased the diagnostic yield in large-vessel giant cell arteritis. In Takayasu's arteritis ultrasound is capable of localizing areas of arteritis in extracranial vessels (Figure 67.12), although the access is limited in some areas.

Polymyalgia rheumatica (PMR) was previously believed to be an extra-articular disease, but shoulder subdeltoid bursitis has been reported in 55 out of 57 patients.[60] Long head of biceps tenosynovitis and synovitis of glenohumeral and hip joints have also been described and confirmed on MRI. A longitudinal study has shown reduced subdeltoid bursitis with steroid treatment although persistence at low levels was seen in some cases.[61]

Peripheral nerve disease

MSUS is ideal for assessing peripheral nerves and allows superior image definition when compared with MRI or CT. Ultrasound is useful for assessing nerve entrapments, the commonest of which is carpal tunnel syndrome (CTS). Ultrasound of the carpal tunnel can reveal causes of extrinsic compression such as anatomical anomalies, tenosynovitis, or a ganglion. Ultrasonography is certainly more acceptable to patients than nerve conduction studies, which are the current gold standard investigation for diagnosing CTS.

Initial studies by Fornage in 1988[62] reported successful imaging of peripheral nerves; major improvement in image quality have been made since then. Studies have been mainly on CTS, and to a lesser extent cubital tunnel syndrome. Peripheral nerves show uniform changes in compression syndromes irrespective of site: fusiform swelling proximal to the compression site caused by intraneural venous congestion and oedema, decrease in diameter of the nerve at the point of compression with hypoechoic loss of fasicular pattern. Doppler studies have shown increased blood flow patterns due to hyperaemia.[63]

In CTS Buchberger et al.[64] described a diagnostic triad of proximal nerve swelling, bowing of the retinaculum, and distal nerve flattening. Maximal cross-sectional area has since been reported to be the most reliable method for diagnosis of nerve compression.[65] In cubital tunnel syndrome focal nerve swelling with loss of fasicular pattern has been reported.[66]

Morton's neuromas, which are benign masses of perineural fibrosis and may be multiple and bilateral, can be demonstrated as round hypoechoic masses in the intermetatarsal spaces. Fluid in the intermetatarsal bursas is often an associated finding.[67]

Muscle pathology

Ultrasound can be used in sports medicine to localize and define the extent of partial or complete muscle rupture. Dynamic testing at the site of muscle symptoms enhances the sensitivity of ultrasound in the detection of tears. It can also demonstrate features of oedema in inflammatory muscle disease although MRI is more sensitive. The potential of ultrasound for evaluation of inflammatory myopathies was described almost two decades ago,[68] with a sensitivity of 82% in detecting histologically proven cases. Different types of myopathies showed typical but not specific ultrasound features; polymyositis showed atrophy and increased echogenicity.[68] The degree of lipomatous change present had larger effect on echogenicity than muscle fibrosis. In a recent review Adler and Garfalo[69] concluded that it is a viable alternative to MRI and that there were promising results from newer ultrasound techniques including power Doppler, extended field of view, contrast enhanced, and sonoelastography.

Interventional musculoskeletal ultrasound

Corticosteroid joint injections are common practice in rheumatology but there are few well-designed randomized studies that demonstrate their efficacy. Traditionally, joint aspiration, intra-articular injection, and soft tissue injection are performed using palpation of bony landmarks as guidance (Figure 67.13). Palpation-guided injections may result in inaccurate needle placement in up to 50% of cases,[70] and this may have an adverse effect on the clinical outcomes.[70,71] Inaccurate placement of corticosteroid can also contribute to local tissue damage, though this can be difficult to quantify.

Injections using direct ultrasound guidance may be preferable in situations where:

- accuracy is imperative such as radioactive synovectomy
- the anatomy is distorted by disease process or obesity
- the target joint is deep, such as the sacroiliac joint or the hip
- there are nearby vital structures such as blood vessels or nerves
- palpation-guided injection has already failed
- there are no bony landmarks to guide injection—bursa or tendon sheath.

This is covered in more detail in Chapter 87 on joint injections.
Fig. 67.13 Subdeltoid bursa injection: (A) Transverse view of subdeltoid bursa. (B) Injection of subdeltoid bursa (transverse view). (C) Longitudinal view of supraspinatus tendon and bursa. (D) Following injection the supraspinatus is obscured by the hyperechoic steroid now in the bursa.

Musculoskeletal ultrasound in primary care and professions allied to medicine

Ultrasonography is becoming increasingly popular in the primary care setting. Many general practitioners (GPs) perform obstetric ultrasound, but as yet there have been no publications regarding the use of MSUS in primary care. As in secondary care, the main barriers to progress are the initial cost of the ultrasound equipment and the time that needs to be devoted to training and competency assessment. Some GPs have been fortunate enough to get mentorship from trained sonographers and have gone on to obtain a postgraduate certificate recognized by the Royal College of Radiologists.

Rheumatology specialist nurses have already been trained to perform clinical assessment of disease activity in RA. It has been suggested that they could be trained in the ultrasound assessment of the wrists and hands.[72] Specialist nurses already perform ultrasound assessments in other specialities such as obstetrics, and some physiotherapists and podiatrists use sonography in their everyday clinical practice.[73,74] A training pathway and course structure is under development with both basic and advanced training courses available for physiotherapists. Whatever discipline is using MSUS, it is essential to have access to suitable training and mentorship. At all times, trainees need to be aware of their limitations and ready to refer difficult patients to a more experienced colleague.

Education and training

The single biggest obstacle to performing ultrasound in rheumatology is the length of time required to develop the necessary practical skills. For the last 10 years, both national (BSR) and international (EULAR) rheumatological societies have organized basic, intermediate, and advanced ultrasound courses and these are a useful learning point for the would-be sonographer. Recommendations for the content and conduct of EULAR MSUS courses have been published,[75] and this is a useful step towards the standardization of training. Short courses can be a stimulus to learning and web-based packages can be a useful adjunct to face-to-face teaching.[76] Neither is a substitute for continuous learning with an experienced mentor.

A recent survey has shown that there has been a considerable uptake of MSUS across Europe.[77] There is, however, huge variation in training and practice between different European countries. MSUS training is already integrated into the training curriculum of rheumatologists in a number of European countries including Germany and Italy. There are varying opinions as to what constitutes adequate training and competency. The ACR recommend that their trainees perform 500 supervised scans to achieve an acceptable standard. The Royal College of Radiologists has published guidelines for non-radiologist-operated ultrasound and suggest weekly mentorship by an experienced sonographer with at least 250 scans performed. There is a need for a single consensus on MSUS

training in rheumatology in order to promote the international development of ultrasound in rheumatology.

Published scans are available[78] with a complete collection of all images of standard scans online (www.doctor33.it/eular/ultrasound/Guidelines.htm). Using this website an untrained novice was able to obtain acceptable musculoskeletal images after 24 non-consecutive hours of mostly self-directed learning on healthy subjects and patients with arthritis.[79] Certification of competency is desirable and European guidelines for certification are under development. A recent report from Northern Ireland described a modular training programme for rheumatologists that used logbook validation and an exit exam to assess basic competency in ultrasound.[80]

Conclusion

MSUS has revolutionized the practice of many rheumatologists in the past decade, but it comes at a price. The initial investment in equipment and training is substantial and it can be difficult to find time in a busy outpatient clinic to perform ultrasonography. However the application of ultrasound has the potential to deliver more accurate and earlier diagnosis in the clinic to the benefit of our patients. Appropriate training is essential and standardization of training and assessment is well under way. Issues of concern regarding validity and reproducibility are being addressed. MSUS is a continuously expanding field and the advent of increasingly powerful machines and 3D ultrasound are likely to further extend its applications in rheumatology.

Magnetic resonance imaging

S. Balamoody, Helena Marzo-Ortega,
and Philip J. O'Connor

Introduction

Magnetic resonance imaging (MRI) has established considerable utility in the assessment of musculoskeletal disorders over the last two decades. This is largely due to the unique capabilities of MRI to allow thorough visualization of soft tissues as well as bone. Providing reproducible three-dimensional (3D) imaging without ionizing radiation, excellent soft tissue contrast and well-defined anatomy makes MRI amenable to clinicians as a 'treatment road map' as well as for diagnosis. Despite its massive contribution towards the understanding of aetiopathogenesis in the commonest musculoskeletal disorders within the research field, the clinical utility of MRI in real practice is limited mainly by high running costs and long imaging times.

MRI has been instrumental in enabling further understanding into the pathogenesis and evolution of arthritis and remains a key diagnostic tool in many musculoskeletal disorders. Important advances include the identification of bone marrow oedema as a prognostic biomarker for erosion progression in rheumatoid arthritis (RA). MRI plays an important diagnostic role in axial spondyloarthritis (SpA), shortening the time to therapeutic intervention. The role of MRI in distinguishing pathologies in early undifferentiated arthritis and in osteoarthritis (OA), as well as its role as an outcome measure, continues to evolve. For now, MRI remains a sensitive imaging tool and provides unparalleled access to joint tissues.

Basic principles of MRI

The nuclear magnetic resonance phenomenon

MRI uses the property of charged nuclei in tissues to behave as a bar magnet. The hydrogen nucleus, often referred to as a 'spin', consists of a single positively charged proton constantly orbiting a single neutron, creating its own electromagnetic field. Placed within a strong external magnetic field, these align in one of two orientations, sometimes described as 'north' or 'south', which have different energy states. A slightly greater number will align in one direction.[1] The particles have energy and as such move within the constraints of their magnetic field. This movement is termed precession and occurs at a set frequency. Adding energy of the same frequency as this precession frequency produces a much greater tissue response,

the so-called 'nuclear magnetic resonance' (NMR) phenomenon. By varying the frequency of precession, an MR scanner can select which protons it adds energy to. Once these protons have been excited, the additional energy must be lost in order to return to their pre-excitation state. The energy is lost by two processes, T1 and T2 relaxation. An MR scanner can preferentially collect T1 and T2 relaxation information from tissues, giving images the differing tissue contrasts accordingly.

Standard image contrast

Contrast refers to the ability to distinguish different signal intensities, manifested as different shades of greyscale within an MR image. This allows differentiation between tissues and tissue qualities. In general, an MR scan will consist of several pulse sequences. These pulse sequences differ in their parameters in order to exploit properties of different tissues. In most cases, a single pulse sequence is inadequate to obtain all the information required and a combination of pulse sequences is required to interrogate the different tissues. T1, T2, and proton density refer to three basic types of contrast used (described as 'weighting'). These can be generated by altering pulse sequence parameters termed TR (repetition time) and TE (echo time). The commonest image sequences applied in the musculoskeletal setting are the T1 and T2 and proton density weighting (T1W, T2W, PDW).

T1 weighting sequences

T1-weighted (T1W) images are sensitive to fat (including fatty bone marrow) which gives a high signal whereas fluid will show as low signal. Highly proteinaceous fluids, certain blood degradation products, and melanin are high signal on T1W. There is good signal-to-noise ratio as T1 relaxation occurs relatively slowly; hence T1W images are considered good for anatomical definition. Cortical bone returns no signal and is shown better on T1W sequences, as a well-defined black stripe outlining bone marrow.

T2W/PDW weighting sequences

T2-weighted (T2W) images are fluid-sensitive and hence demonstrate fluid, oedema, and inflammation as high (or hyperintense) signal. Fat is also demonstrated as high signal on T2W imaging. Fluid-sensitive sequences are often combined with fat suppression techniques to enhance the visualization of fluid/inflammation

within fatty tissues (e.g. bone marrow). T2 relaxation occurs relatively quickly and therefore these images can suffer reduced signal-to-noise ratios compared with T1W images. PDW images can be a good compromise, providing a balance between anatomical definition and pathology detection. When accompanied with fat suppression, proton density images are highly sensitive to pathology such as bone marrow oedema. T2-weighted images are less sensitive but more specific for pathology, hence both sequences are included in some imaging protocols

T2* (T2 star)—imaging of magnetic susceptibility

T2* relaxation is a component of T2 relaxation, occurring even faster than T2 relaxation. Paramagnetic or ferromagnetic structures are demonstrated as black, often with a characteristic 'blooming' artefact—a smudged outer margin. This sequence is useful in the detection of haemosiderin, making it useful for example in the diagnosis of pigmented villonodular synovitis (see 'Pigmented villonodular synovitis').

Fat suppression

Fat suppression is an essential technique for detection of bone marrow pathology, as well as for identifying the presence of fat within lesions. There are several methods of fat suppression, although the main two utilized in musculoskeletal imaging are short-tau inversion recovery (STIR) and (spectral) fat saturation. The STIR method produces global and homogeneous fat suppression and allows for quick imaging acquisition. The main disadvantage of STIR is being not completely lipid specific and hence other non-fat tissues may also have suppressed signal. The fat-saturation method, using a lipid-specific technique, is generally preferred for most musculoskeletal imaging. There are drawbacks to the fat-saturation method including sensitivity to magnetic field inhomogeneities resulting in artefact and substantially lengthened imaging times.[2] Fat saturation is essential with contrast-enhanced imaging to differentiate between high-signal gadolinium and high-signal fat on T1W images.

Further characterization of pathology—intravenous contrast agent

Gadolinium is a paramagnetic heavy metal with a valuable T1-relaxation shortening property. Intravenous (IV) injection of gadolinium accumulates in those tissues with increased vascularity, extracellular fluid volume, and capillary permeability. It is therefore good at demonstrating tumour and inflammatory pathology (Figure 68.1). Nephrogenic systemic fibrosis, a chronic debilitating condition, has been associated with IV gadolinium injection in subjects with chronic renal failure; this finding has led to restricted administration in individuals with pre-existing renal impairment.[3]

Contra-indications to MRI

Conventional MRI is safe for most people, but is contraindicated in people with any of the following: pacemaker, cochlear implants, metallic intraorbital foreign body, aneurysm clips, implanted devices (e.g. nerve stimulator). MRI is considered potentially unsafe in other scenarios and careful consideration is required to assess whether scanning can be permitted. Concerns for patient safety are generally related to the potential for the magnetic field to cause movement of metallic structures and/or the heating effect of the transmitted energy. Patients with internal metallic medical devices not uniformly contraindicated (e.g. shunts, stents) require these to be checked for MRI compatibility.

MRI assessment of arthritis

While much of the work in rheumatic conditions has involved imaging of small joints, MRI remains the preferred modality for imaging of deeper or larger joints such as hip joints and spine to demonstrate inflammatory or degenerative joint involvement or to exclude other pathologic processes such as avascular necrosis.
Fig. 68.1 Imaging of synovitis and the benefit of IV contrast: Sagittal knee images in the same patient of the suprapatellar pouch: (a) PDW fat-saturated (FS) image demonstrates high-signal distension of the suprapatellar pouch in keeping with an effusion. (b) T1W-FS image demonstrates intermediate signal of the synovium and low-signal fluid (thin arrow). (c) T1W post-IV contrast image clearly differentiates high signal of the enhancing synovium from the adjacent low-signal, non-enhancing fluid (thick arrow).

MRI features of acute inflammation

Synovitis

Active acute synovitis is considered a reversible feature of an inflammatory arthritis which may respond to therapy. Synovitis manifests as thickened synovium, sometimes causing distension of a joint or bursa, and demonstrating high signal on T2W/PDW images. Thickening of the synovial membrane may not always be readily identifiable in the presence of excess synovial fluid using fluid-sensitive sequences alone. T1W images are helpful as intermediate-signal synovium can be differentiated from low-signal fluid on careful inspection. Contrast-enhanced images are the gold standard, especially for detection of early changes,[4] but acquisition for routine detection of synovitis is not recommended as unenhanced MRI or ultrasound is generally adequate in most situations.

Pannus refers to focal areas of bulky fibrovascular tissue which occurs in the context of chronic synovitis and subsequent fibrotic change. Pannus therefore demonstrates low-grade inflammation histologically.[5] Pannus may also appear hypointense on MRI, reflecting a higher fibrous and lower cellular/vascular content.[6]

Tenosynovitis/tendonitis

The same signal characteristics seen in synovitis occur in inflammatory involvement of tendons and their tendon sheath. Tenosynovitis manifests as diffuse, smooth, high-signal swelling around the tendon due to thickening of the sheath (often containing excess fluid) surrounding the low-signal tendon. Ganglions of the tendon sheath can have a similar appearance but in general cause a more focal bulge, often to one side of the tendon.

Bone marrow oedema

In neonatal life bones are filled predominantly with 'red marrow' rich in haemopoietic cells. This is gradually replaced through childhood with fat or 'yellow marrow', a process which starts in the appendicular followed by the axial skeleton and from distal to proximal.[7] In adults, imaging of normal bones with fat-suppressed sequences in general displays marrow as homogeneously low signal. Some regions commonly retain red marrow in adulthood, such as the proximal femoral and humeral metaphyses, and consequently manifest as regions of intermediate signal on fat-suppressed (and T1W) imaging.

Consequently, bone marrow pathology is easily visualized as high signal within bone marrow on fat-suppressed fluid-sensitive sequences or contrast-enhanced images. Subchondral bone marrow oedema is typically represented as focal ill-defined high signal extending from the articular surface. Subchondral bone marrow oedema is a non-specific feature, with an extensive differential diagnosis (Box 68.1 and Figure 68.2). In some cases, there are other imaging features present/absent which help to narrow the differential diagnosis and, as always, clinical correlation is required. The histopathology of the bone marrow oedema lesion rarely represents simple interstitial oedema and the term 'bone marrow oedema' is considered an oversimplification. Depending on the aetiopathology, the same imaging appearance can represent variable degrees and combinations of interstitial oedema, increased vascular permeability/congestion, neoangiogenesis, inflammatory cellular infiltrate, necrosis, fibrosis, haemorrhage, and disorganized lipid content. For example, there is histological evidence that the high-signal 'oedema-like' lesions seen in the context of active sacroiliitis in ankylosing spondylitis or in RA peripheral joints do indeed

Box 68.1 Differential diagnosis of bone marrow oedema lesions

- Trauma, e.g. acute fracture, stress injuries
- Infection, e.g. septic arthritis
- Inflammatory arthropathy
- Other arthropathies, e.g. crystal arthropathy, osteoarthritis
- Vascular aetiologies, e.g. avascular necrosis, osteochondral lesions, complex regional pain syndrome
- Red marrow reconversion
- Paget's disease
- Bone marrow oedema syndrome
- Iatrogenic, e.g. radiotherapy
- Neoplasm, e.g. osteoid osteoma, leukaemia
- Reactive to adjacent soft tissue pathology
Fig. 68.2 Examples of bone marrow oedema in different conditions: (a) Diffuse bone marrow oedema in the femoral neck. Linear low signal at the medial cortex (white arrow) indicates the cause—stress fracture. (b) Transient osteoporosis of the hip: note subtle insufficiency fracture at the femoral articular margin. (c) Active rheumatoid arthritis; post-gadolinium image demonstrates bone marrow enhancement due to florid inflammation and synovial proliferation and enhancement at the thumb interphalangeal joint, and less severe changes in the index finger. (d) Calcaneal osteitis and plantar fasciitis in spondyloarthropathy.

---

represent an inflammatory process[8–11] or 'osteitis', a term frequently used to define the MRI appearance of bone marrow oedema. This more specific term technically should be used in reference to post-contrast images to indicate active inflammation. By contrast, in bone marrow oedema lesions of OA, predominant histological abnormalities include marrow necrosis, fibrosis, haemorrhage, and abnormal trabeculae. Bone marrow oedema severity on imaging is considered to have a relation to symptoms and prognosis for certain diseases such as RA[12] and avascular necrosis.[13]

Acute chondrolysis and subchondral destruction

Diffuse acute chondrolysis and subchondral destruction are characteristic features of acute joint infection. Cartilage destruction occurs rapidly, manifesting as intensely high signal on fluid-sensitive sequences. An irregular subchondral bone contour is an indication of a destructive process.

MRI features of joint structural damage

Plain radiography is the simplest and most efficient method of detecting established joint space loss and bone destruction. Although erosions can be visualized by MRI, CT remains the gold standard for cortical bone abnormalities and periarticular ossification, with the added value of being a 3D modality. The main drawback of CT is its significant ionizing radiation burden.

Erosions

Erosions characteristically represent focal bone loss at the joint interface, ranging from a few millemetres to several centimetres in size. Radiographic erosions are the hallmark of structural damage in inflammatory arthropathy. The erosion shape and specific location within the joint can give clues as to the aetiology e.g. psoriatic arthritis vs RA vs gout (Figure 68.3). Erosions seen on radiographs can also be seen on MRI. Because of its tomographic nature, MRI often detects more and smaller erosions than radiographs.

Joint space loss

Joint space loss is originally a radiographic term providing a surrogate estimate of cartilage loss. Loss of tissue in fibrocartilaginous structures such as menisci and labra which have become degenerate / torn can also contribute to reduction in joint space. In the case of meniscal tears in OA, the type of tear can give an indication as to whether this damage is primary or secondary to the process of joint degeneration. Meniscal extrusion outside the joint is often seen in OA, also contributing to joint space loss and abnormal distribution of force within the joint.[14]

Subchondral remodelling and osteophytes

The cumulative response of dynamic changes in subchondral bone architecture to abnormal joint biology and mechanics due to arthritis are also captured on MRI, particularly in slowly progressive diseases such as OA. Osteophytes are a pathognomonic feature of OA, occurring at the bone–cartilage junction. Subchondral sclerosis and attrition can be seen as diffuse low-signal areas on T1W imaging and flattening of the normal surface curvature. These features are less evident in diseases such as RA where bone destruction and inflammation are predominant. Subchondral cysts, a typical feature of OA, are well visualized as focal, well-defined hyperintense areas at the joint margin, often but not always in areas of bone marrow oedema. Subchondral cysts may be mistaken for erosions but can be differentiated from these by the intact overlying cortical bone.

Common arthritic diseases

Rheumatoid arthritis

The greatest advantage of MRI over ultrasound and radiography is its ability to clearly depict all the soft tissue structures involved in RA. In addition, MRI can depict subchondral bone pathology, in particular bone marrow oedema. Histological samples taken from joints undergoing surgery have confirmed that bone marrow oedema in RA has a prominent inflammatory component.[11,15]

Post-IV gadolinium MRI is considered the gold standard for imaging of synovitis. MRI correlation has been shown with other multiplanar modalities such as power Doppler ultrasound and in histopathological studies.[16,17]

MRI is more sensitive than radiography for the detection of erosions; identifying smaller and earlier changes,[18] with high sensitivity and specificity compared to the gold standard, CT.[19] There is, however, a lack of pathological correlation in the literature. Although cohort studies have demonstrated persistence and increased sites of MRI erosions in RA after 1–2 years, not all MRI erosions progress to radiographic erosions.[20] Precisely which factors determine progression remains controversial. Some studies show that a good level of correlation for detecting bone erosions between MRI and CT of metacarpophalangeal (MCP) and wrist joints is seen in RA patients, suggesting that MRI erosions represent a true destructive process.[19,21] Nevertheless plain radiography
Fig. 68.3 Rheumatoid arthritis in the hand of a symptomatic patient: (a) Plain radiograph is unremarkable.(b) T2W fat-saturated image showing bone marrow, ill-defined high signal at the middle metacarpal head, and synovitis. (c) T1W image better demonstrates well-defined low-signal periarticular erosion in the middle metacarpal head and base of middle phalanx.

remains the gold standard for monitoring structural damage in RA, as the true prognostic significance of these MRI-determined erosions remain unclear.[22] Regression of MRI erosions has been observed with combination therapies.[23,24]

MRI and the pathogenesis of rheumatoid arthrititis

MRI-detected erosions in RA can be seen early, within 6 weeks from symptom onset. Synovitis and bone marrow oedema are both considered markers of active inflammatory activity[22] and represent the forerunners of erosion formation in inflammatory arthritis. Progression of joint damage may also occur in part due to biomechanical factors.[25] In some studies bone marrow oedema has been shown to be a better predictor of increased joint destruction than single time-point measures of synovitis,[26–29] as bone marrow oedema probably represents a more direct inflammatory process effecting trabecular bone.

MRI in early diagnosis of rheumatoid arthritis

Early treatment of RA to delay and minimize irreversible joint destruction is now standard. Treat-to-target strategies have been implemented to ablate disease activity from symptom onset.[30] Early diagnosis requires having a low threshold of clinical suspicion supported by biochemical and imaging signs of joint inflammation, before overt erosive change occurs. Ultrasound and MRI are favoured for the purposes of early diagnosis, both modalities being more sensitive and specific than clinical examination and serum inflammatory markers.[31,32] The cost-effectiveness of widespread use of MRI in early diagnosis has yet to be shown. MRI has potential benefit as a prognostic tool, largely by the ability to depict bone marrow oedema which no other modality can detect.[27]

MRI outcomes in clinical trials

One of the main utilities of MRI in RA has been as an outcome measure in the clinical research setting to demonstrate the benefit of biologic therapies. Its success is due to its superior discriminatory ability and greater sensitivity to change in active joint inflammation as compared to conventional radiography, allowing for short observation periods and lower patient numbers when assessing for progression of structural damage.[33] The OMERACT RA-MRI score, involving semiquantitative assessment of synovitis, bone marrow oedema, erosions, and joint space narrowing,[34] is now widely used in clinical trials. MRI also allows for quantification of synovial inflammation by measuring early 'enhancement' or contrast augmentation after intravenous injections of gadolinium (see 'Compositional imaging of cartilage').[35]

Spondyloarthropathy

Traditionally, diagnostic imaging has been confined to the identification of radiographic sacroiliac joint (SIJ) abnormalities or sacroiliitis.[36] Although this approach is still widely applied in clinical practice, it is now well recognized that there may be several years' delay from the onset of clinical symptoms of back pain until the appearance of radiographic sacroiliitis.[36] MRI is highly sensitive to early and active SpA; sacroiliitis can be detected nearly a decade earlier.[37] This is of major relevance since individuals can experience levels of pain and disability at the early stages of disease comparable to those experienced by subjects with established or chronic disease.[38] Furthermore, individual response to biological therapies (the only treatments proven to be efficacious in these diseases) may be greater when initiated early in the disease process.[39,40]

MRI lesions in the sacroiliac joint in spondyloarthritis

A number of MRI lesions representative of active and chronic stages of disease have been described at the SIJ and spine in SpA. In the SIJ, active lesions include synovitis, ligamentous enthesitis, and subchondral bone marrow oedema. SIJ subchondral bone marrow oedema can be reliably detected as high signal in fat-suppressed or STIR sequences (Figure 68.4). These sequences have the same sensitivity as gadolinium-enhanced T1W images for the detection of bone marrow oedema.[41,42] Bone marrow oedema lesions can appear within a few weeks of onset of symptoms of inflammatory back pain.[43] although their natural history remains unclear. At the histopathological level, these 'oedematous' changes correspond to an inflammatory infiltrate with mononuclear cells found in biopsy samples.[8,10] Nevertheless, there is poor correlation between the amount of infiltrate found in the biopsies and MRI appearances of bone marrow oedema with MRI 'missing' more than half the lesions found at histology.

Chronic or structural lesions of the SIJ include fat infiltration, erosions, bone sclerosis, and ankylosis. These lesions are best characterized on T1W sequences. Fat infiltration is due to esterification of fatty acids and appears as bright signal both on T1W and T2W scans (except in fat-suppressed sequences where these lesions appear as low signal). Although thought to represent a postinflammatory process, this change can also be found in healthy individuals, where it is thought to represent normal ageing. Erosions are identified as full-thickness loss of the cortical bone in either side (iliac or sacral) of the SIJ. Erosions are easier to identify when multiple, as they can become confluent giving appearance to the so-called 'pseudowidening' of the sclerosis identified as low subchondral signal on all sequences.

MRI and classification criteria of axial spondyloarthritis

A major breakthrough in the clinical field in SpA occurred with the advent of the new classification criteria developed by the Assessment of SpondyloArthritis International Society (ASAS).[44] The notable change these criteria is the inclusion of MRI alongside radiography as imaging criterion, allowing for the early diagnosis of sacroiliitis in the absence of radiographic abnormalities.[45] In the clinical context it allows for early recognition of AS, as early as 3 months from symptom onset. To aid with implementation of these criteria, definition of a positive MRI of the SIJs in SpA has been proposed by an expert group based solely on the presence of subchondral bone marrow oedema,[46] and its utility is currently being reappraised.[47]

MRI lesions in the spine

The majority of functional burden experienced by patients with SpA is linked to disease affecting the spine rather than the SIJs. Direct association between inflammation in the early stages of disease and structural damage has been shown.[48] The thoracic spine is the most frequently affected area after the SIJ in AS, according to evidence from MRI studies.[49,50] Posterior element, costovertebral, and discovertebral change make up the bulk of spinal disease.

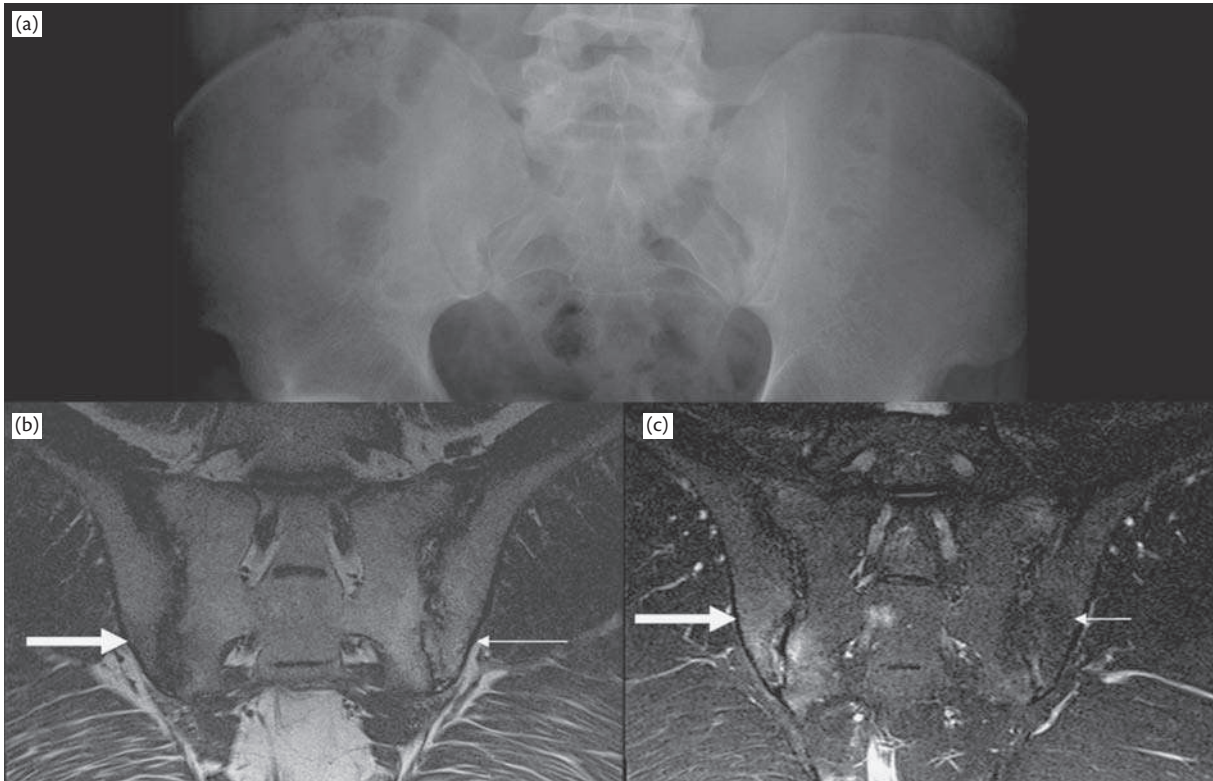
Active lesions are identified by high signal in fat-suppressed sequences with the corresponding low-intensity signal on T1W sequences at entheses, joints, and disc margins. Characteristic lesions include vertebral corner lesions, facet joint, and soft tissue or perifacetal lesions. Corner lesions can occur in the anterior or posterior corners, sometimes covering half and on occasions


Fig. 68.4 Sacroiliitis in SpA: MRI will detect sacroiliitis years before conventional methods[56]: (a) Plain AP radiograph showing sclerosis and irregularity of the left sacroiliac joint (SIJ). (b) and (c) T1W and STIR and coronal oblique images of bilateral SIJs. *Active sacroiliitis*: right inferior SIJ demonstrates bone marrow oedema hyperintense STIR signal with corresponding low signal on T1W image (white thick arrows). *Chronic sacroiliitis*: left inferior SIJ shows joint space loss. Low STIR signal with corresponding high signal on T1W representing increased fat deposition—a postinflammatory feature (white thin arrows).

a whole vertebral body. Several studies have looked at the diagnostic utility of these lesions by assessing different disease groups such as degenerative spinal disease, spinal malignancy, and various other disorders, suggesting that a cut-off of at least three corner lesions is needed to diagnose SpA.[51] Posterior element lesions, although infrequent, appear to be highly specific of AS.[51,52] Costovertebral and costotransverse joints at the thoracic level can often be missed since routine scanning protocols of the spine may not include the lateral segments, hence missing highly specific lesions that may be crucial in the clinical context for diagnosis.[53,54] It is important for sagittal imaging to extend laterally to include the lateral aspect of the pedicles and costovertebral joints, and that these areas are carefully scrutinized. Although limited, there is mounting evidence that MRI-detected inflammatory spinal lesions may predict syndesmophyte formation[55,56] (see Figure 68.5). Spondylodiscitis (Andersson lesion) can masquerade as other causes of discitis.

In chronic disease, the main pathological feature is progressive axial ossification caused by bridging syndesmophytes along ligaments and annulus fibrosus which may eventually lead to the 'bamboo spine'. MRI, although sensitive to the inflammatory elements of SpA, is relatively insensitive to chronic syndesmophyte formation. Plain radiograph remains the gold standard for assessment of chronic SpA, although changes may take years to manifest. Fatty vertebral corner lesions detected on MRI are not a specific feature, but when present in high numbers these lesions are considered diagnostic of postinflammatory axial SpA.[57] Fatty corners are readily identifiable as high signal at vertebral corners on T1W

sequences, and mounting evidence suggests they may be predictive for syndesmophyte formation.[58] It remains to be demonstrated whether therapeutic strategies utilizing biologic therapies early would be able to delay or prevent the process of bone formation and spinal ossification using the new ASAS diagnostic criteria.

Osteoarthritis

MRI can directly assess hyaline cartilage, demonstrating a range of pathology from shallow defects to full-thickness loss; its tomographic nature demonstrates more frequent osteophytes than radiography. In established OA, MRI has also demonstrated frequent subchondral bone marrow lesions (with the appearance of bone marrow oedema) and synovitis. The is now mounting evidence for the use of MRI imaging as a more sensitive tool for detecting early OA.[59]

MRI has few indications in routine clinical management of OA, but can be useful in subjects with true knee joint locking (compared to the more common symptom of gelling), where identification of potentially remediable meniscal tears may be possible.[60,61] Anterior cruciate tears are considered a risk factor for accelerated OA, although recent reviews indicate that this may be due to the presence of meniscal tears.[62] High incidence of cartilage loss has also been noted in subjects post-meniscectomy.[63] Variable degrees of meniscal extrusion may accompany meniscal tears, leading to further abnormal mechanical load on the joint.

MRI predictors of progressive cartilage loss include the presence of meniscal extrusion, meniscal tears, and bone marrow lesions.[64]
Fig. 68.5 (a) Lumbar spine MRI showing active inflammation in SpA at vertebral corners. (b) Sclerosis visible on radiograph in similar locations to change of active inflammation as in (a) (different patient).

Focal cartilage defects also predict subsequent increased rate of cartilage loss. Importantly, MRI has demonstrated certain OA pathological features to be associated with pain, including synovitis and bone marrow lesions.[62]

Undifferentiated arthritis

The role of MRI in early undifferentiated arthritis is yet to be established as there is a generalized lack of data on its potential diagnostic utility. Early MRI studies hinted at different patterns of joint involvement, with intra-articular synovial involvement found to be more common in RA and extrasynovial and capsular involvement found to be more common in seronegative or SpA type presentations.[65] However, these disease phenotypes are not always readily identifiable. Synovitis can have similar appearances in the various inflammatory arthropathies.[5] Features favouring psoriatic arthritis (PsA) rather than RA include the presence of dactylitis, periostiitis, and extracapsular/perientheseal soft tissue oedema. Tenosynovitis is considered to preferentially affect the extensor compartments in RA and the flexor compartments in PsA. Evaluation of disease distribution (proximal or distal) is essential, as with other modalities.

As a rule, MRI features should not be considered in isolation but in conjunction with radiographic findings which may indicate other features less apparent on MRI, e.g. subarticular osteoporosis or entheseal calcification. A recent systematic literature review concludes there is significant evidence for the combination of bone marrow oedema, synovitis, and erosion pattern as a prognostic indicator of future development of RA.[66] Bone marrow oedema has also been shown to be a predictor of future RA when found in metatarsophalangeal and wrist joints in early undifferentiated arthritis.[67] In this study by Duer-Jensen et al., the prediction model was stronger when bone marrow oedema was associated with other factors such as hand joint synovitis, morning stiffness and positive rheumatoid factor. The role of MRI may increase in the clinical setting with the advent of the new American College of Rheumatology (ACR) diagnostic criteria.[68]

Septic arthritis

Infection should always be considered and excluded in the case of an acute or subacute presentation of a monoarthritis. MRI has little ability to differentiate septic arthritis from other causes of acute inflammatory arthritis, so clinical and laboratory tests, including joint aspiration or biopsy, are often required for diagnosis. As with any inflammatory arthritis, bone marrow oedema, erosion, synovial thickening and enhancement, and effusions may be present. No imaging features alone or combined have been proven to differentiate between the septic and non-septic inflamed joint.[69] MRI can help to localize the presence of an effusion in deep joints which can then be targeted for aspiration. MRI is also useful for clarifying disease extent when surgical intervention is required. In the context of septic arthritis, the presence of high T2 oedema signal extending further than the subchondral bone rim, with corresponding T1 low signal, indicates osteomyelitis.

MRI can be particularly useful in certain clinical scenarios such as the diagnosis of spinal infection or in diabetics. A low threshold of suspicion is required for MRI in subjects presenting with insidious back pain and unusually high serum inflammatory markers to exclude a pyogenic discitis. Radiographic findings can be very subtle and, if undiagnosed, consequences can be severe. MRI features include high T2 signal within the intervertebral disc and adjacent oedema of the endplate and adjacent bone. Contiguous discs can be affected and there is often paraspinal soft tissue involvement. Another potential feature of spinal septic arthritis is epidural abscess formation—an indication for surgical intervention. Tuberculous infection of the spine should be considered in cases of subacute

pain, and where suspected, whole spine imaging is indicated due to the high incidence of multifocal disease from subligamentous spread to non-contiguous vertebra and tracking of epidural and paravertebral infection.[70]

Gout

MRI is not often required in the imaging of suspected gout as radiographic findings are usually adequate, with typical features that differentiate from other arthritides. Atypical presentations of gout that may lead to the use of MRI include acute arthritis and chronic tophaceous gout. The disease is characterized by the presence of tophi, a focal accumulation of urate crystals, which often have a peri-articular or intra-articular location, but can also be located in the bone marrow or subcutaneous tissue. Tophi appear as intermediate signal on T1W imaging, a variable appearance on T2W imaging, usually low–intermediate signal, and variable post-gadolinium enhancement. In the advanced stages, erosions occur, often juxta-articular rather than periarticular and with a 'punched-out' or scooped appearance. Differential diagnosis includes other crystal arthropathies, pigmented villonodular synovitis, and amyloidosis (Figure 68.6).[71]

Miscellaneous

Benign proliferative disorders of the synovium

Large-joint monoarthritis refractory to conventional treatments can represent a considerable diagnostic challenge for the clinician. MRI can occasionally be helpful in this scenario. Three major subtypes of benign proliferative disorders of the synovium are readily identified by MRI: pigmented villonodular synovitis, lipoma arborescens, and synovial osteochondromatosis. For cases that do not show the typical imaging characteristics of these subtypes, diagnosis is more difficult. Despite the aid of various imaging modalities, histological assessment from synovial biopsy may be required to exclude a malignant synovial disease in some cases, especially where there is a single focus of synovial proliferation (i.e. nodular synovitis).

Pigmented villonodular synovitis

Pigmented villonodular synovitis (PVNS) typically presents as a non-inflammatory, occasionally erosive, monoarthropathy, most commonly affecting the knee or hip joints. MRI appearance is often characteristic, demonstrating nodular synovial proliferation with synovial haemosiderin deposition, typically evident as multiple low-signal foci on T1W and T2W sequences.[72] The low signal is further enhanced by the use of gradient echo sequences, which are even more susceptible to the ferromagnetic haemosiderin. Synovial masses can be substantial (Figure 68.7).

Lipoma arborescens

Lipoma arborescens is characterized as subsynovial villous fatty proliferation, most commonly occurring in the knee joint. Although the pattern of fat deposition within the synovium can be variable, MRI can easily characterize this condition[73] where joint effusions as well as periarticular erosions can be found. Onset of symptoms tends to be insidious over years, although the condition can eventually be quite debilitating, requiring synovectomy (Figure 68.8) Chronic oligoarthritis with low-grade synovial inflammation can give a similar appearance.

Synovial osteochondromatosis

Primary synovial osteochondromatosis is essentially a monoarthropathy due to chondroid metaplasia of the synovium, resulting in multiple synovial chondroid bodies which may eventually ossify. Large joints are most commonly affected. The condition is often more easily diagnosed radiographically due to the characteristic pattern of multiple intra-articular osseous bodies. The MRI appearance of these intra-articular bodies varies depending on the proportion of chondroid to osseous material.[74]

Bone marrow oedema syndrome

Bone marrow oedema syndrome (BMOS) has evolved over the last decade as an umbrella term for benign conditions previously known as transient osteoporosis, regional migratory osteoporosis,
Fig. 68.6 Prepatellar tophi in gout. (a) Low signal on T1W (white arrow) and (b) intermediate–high signal on PDW/T2W (black arrow). Intra-articular tophus (thick black arrow).

or reflex sympathetic dystrophy (RSD). Differentiation between these conditions is usually by clinical presentation. The painful joint is characterized on MRI by rapidly spreading bone marrow oedema in a localized area of periarticular bone. The hip joint is most commonly affected, but the condition can present in the knee[75] and the foot.[76] The aetiopathology remains unclear; several theories have been proposed, but there is lack of evidence and concordance with the various manifestations. Clinical presentation with a painful limp of insidious onset typically occurs in young men, or in women in the third trimester of pregnancy. The condition may recur in other bone areas, hence the use of the previous term 'migratory'. Radiographs are insensitive in the first months.

MRI is very sensitive to bone marrow oedema, soft tissue and intra-articular synovial involvement and can also exclude diffuse articular surface damage, which is not a feature of BMOS. Focal regions of radiographic osteopenia may be evident later in the course of the condition. There are currently no useful laboratory diagnostic tests, except for exclusion of other diagnoses. In the majority of cases, transient osteoporosis will regress spontaneously after a period of 3–9 months.[77] RSD is a somewhat atypical manifestation as the pain may persist and result in chronic morbidity, and can be associated with skin changes and peripheral nervous symptoms.[78] BMOS is a diagnosis of exclusion and differentiation of other early presentations of conditions requiring prompt intervention such as
Fig. 68.7 Pigmented villonodular synovitis (PVNS): (a) Axial T2W image showing effusion and typical low-signal synovial thickening. Large erosion in the lateral femoral condyle (white arrow). (b) Gradient echo (T2* weighting). This sequence is useful in diagnosing PVNS, producing characteristic low-signal 'blooming artefact' from synovial haemosiderin deposition.
Fig. 68.8 T1W coronal and axial PDW fat-saturated (FS) images showing diffuse lobulated fatty proliferation of the knee synovium characteristic of lipoma arborhescens. PDW-FS images show increased signal laterally indicating superimposed oedema/inflammation.

avascular necrosis can be challenging. It has been suggested that BMOS and osteonecrosis are entities at different ends of the same spectrum. Sequential MRI is can be useful in these cases of diagnostic uncertainty (Figure 68.2b).[79]

Advanced MRI applications

Advanced imaging techniques

Ultrashort echo time imaging

Ultrashort echo time imaging (UTE) is a technique providing detailed visualization of short-T2 tissues. Tendons, entheses, ligaments, menisci, and cortical bone, which have T2 relaxation times of the order of 0.1–10 ms, are no longer 'invisible' and internal structure can be visualized.[80] Contrast enhancement can be detected, showing neovascularity more extensively than power Doppler ultrasound.[81]

Whole-body MRI

Whole-body imaging (WB-MRI) has recently emerged as a screening technique applicable to several areas of musculoskeletal radiology. The main challenges to overcome are changes of patient positioning and manipulation of radiofrequency (RF) coils around the patient within a reasonable scan time and without compromising on spatial resolution. Multichannel MRI scanners, improved coil and sequence technology, and a continuously moving table within the bore have allowed advances in WB-MRI to occur with promising results so far. Scan techniques are different from tumour scanning techniques, with emphasis on peripheral assessment (see Figure 68.9). Weckbach et al. demonstrated that WB-MRI led to

upscaled therapy, particularly with anti-TNFα-blockade in 22 of 30 subjects with PsA.[82]

Compositional imaging of cartilage

Imaging tissue function rather than anatomical structure is a relatively new concept, with the potential to detect disease prior to structural damage has occurred. 'Mapping' image representation is often employed, whereby the value of a tissue parameter is calculated per voxel and represented as a colour-coded image. Some techniques have been employed investigating cartilage repair in clinical studies.[70] Further optimization of these techniques is required to demonstrate adequate robustness for large or multi-centre clinical intervention trials. Proteoglycan depletion has been imaged by several techniques such as T1 rho mapping, sodium (Na) imaging, and delayed gadolinium enhancement MRI of cartilage (dGEMRIC). The T2 relaxation time of cartilage is considered to be a reflection of cartilage water content and the integrity of collagen fibril microstructure. In healthy cartilage, a characteristic variation in T2 from superficial to deep layers is depicted (Figure 68.10).

MRI as an outcome measure: applications in clinical trials

Imaging biomarker development

Recent growing interest in detection of OA in early or preclinical disease has been driven by the desire to identify potential therapeutic targets for early intervention. The National Institute of Health Osteoarthritis Initiative (NIH OAI) is a large study in the United States which has recruited almost 5000 subjects with the aim to identify biomarkers of early OA. Non-invasive methods of joint evaluation sensitive to early disease will require advanced MRI

Fig. 68.10 T2 map of the knee overlaid on corresponding PDW MRI, showing per pixel variation in T2 relaxation reflecting collagen microstructure integrity. Courtesy of C.E. Hutchinson & T.G. Williams University of Manchester (UK), J.C. Waterton, AstraZeneca (Cheshire, UK) and M. Bowes, Imorphics (Manchester, UK). From work presented in ref. 94, partially funded by TSB and EPSRC.

techniques to investigate earlier changes of cartilage degradation, prior to the occurrence of cartilage loss.

Semiquantitative assessments

These systems are useful in giving a comprehensive overview of the joint, as opposed to quantitative imaging which assesses a single feature. Several scoring systems exist, e.g. for OA,[64,83] RA,[84,85] and SpA.[86,87]

Composite baseline semiquantitative scores encompassing synovitis, tenosynovitis, erosions and bone marrow oedema have been shown to exceed the ability of individual feature scores to predict future MRI erosions at 1 year in RA.[88] When the composite score is combined with clinical scores, long-term prediction of disease can be further enhanced, explaining 59% of the variation, as shown by McQueen et al.[89]

Quantitative assessments

The more precise measurement in quantitative analysis is considered to have better reproducibility, accuracy, and sensitivity than semiquantitative techniques. In general, the parameters measured fall into one of two categories: morphology (e.g. volume, thickness, surface area) or quality (e.g. signal intensity, enhancement rate, signal heterogeneity). These techniques have drawbacks, often requiring specialized software and trained operators, and are much more time consuming and costly than semiquantitative techniques.

Image analysis

Simple measurements of signal intensity can be made from a region of interest superimposed on the area of the feature to be analysed. Entire soft tissue structures or regions or pathology may be outlined in order to measure the volume of that structure. Various semi-automated techniques have been developed to assist segmentation, as the manual process is time consuming. Thresholding-related methods enable outlining of areas of a specified signal intensity range. Recent advances include the incorporation of statistical shape modelling into software which develops models which 'learn' the shape and appearance of particular structures of interest (e.g. cartilage, bone) from a pre-existing image dataset. The models can then be used to 'search' and automatically segment new images. These automated methods have yet to be widely validated, but will no doubt have an important role to play in future quantitative MRI research (Figure 68.11).

Dynamic contrast MRI

Dynamic contrast MRI (DCE-MRI) has been used in arthritis imaging, assessing enhancement rates of structures involved in active inflammation, e.g. synovitis, enthuses, and bone marrow. Multiple T1W acquisitions are obtained at intervals of several seconds, allowing a curve of signal intensity over time to be obtained. In active synovitis, curves characteristically demonstrate an initial rapid increase within the first 60 seconds then slow to eventually reach a plateau. Measures of synovial relative early enhancement rate (RER) measured within the first 60 seconds have been shown to correlate strongly with histological inflammation in several studies.[5,17] Higher RERs are considered to reflect increased synovial vascularity and capillary permeability, features of more aggressive active inflammation. Quantification of synovial vascular flow with power Doppler is possible; however, DCE-MRI enhancement

Fig. 68.11 Quantitative image analysis methods in cartilage quantitation: (a) Manual delineation (segmentation) of cartilage plates in the knee on single sagittal dual echo steady state (DESS) image. (b) Subsequent 3D rendered segmentation of total knee cartilage obtained from manual segmentation demonstrating patellar (green), femoral (red), medial tibial (yellow), and lateral tibial (blue) cartilage plates. Analysis performed using Analyze 10.0 (AnalyzeDirect, Overland Park, KS, USA). Courtesy of NIHR Leeds Musculoskeletal Biomedical Research Unit, Leeds, UK.

rates also reflect vascular permeability and allow for improved global synovial volume assessment.

DCE-MRI has been used both as a tool to probe further into the understanding of inflammatory arthritis and as an indicator of the 'aggressiveness' of disease activity. Synovial early enhancement rates correlate well with power Doppler ultrasound assessment of active synovial inflammation.[16] As a surrogate marker, DCE-MRI has proved useful in assessing response post-treatment to disease-modifying drugs and biological therapies in RA.[90,91] Baseline DCE-MRI measures have been found to predict RA progression in some studies.[92] One advantage of DCE-MRI is clear; being sensitive to small changes, it allows study cohorts to be small. The main drawback is that many methodological factors that can affect results, e.g. gadolinium injection dose/rate, or patient movement between series. Entire synovial assessment is preferable to single region of interest or single slice, due to substantial regional variation of synovitis within large joints in particular,[93] and this is increasingly being facilitated by advanced image analysis software applications.

CHAPTER 69

Computed tomography

Geoff Hide and Jennifer Humphries

Introduction

Computed tomography (CT) was developed by Godfrey Hounsfield in 1973[1] and rapidly acquired an essential role within diagnostic imaging. Images in CT are produced using a uniform X-ray beam produced in an X-ray tube which passes through the patient, is modified by interaction with the tissues it encounters, and is detected beyond the patient in a manner similar to the production of a conventional radiograph. However, CT differs from conventional radiography in that the X-ray source and the bank of detectors are mounted on opposite sides of a rotating circular gantry. Rotation of this gantry results in the beam passing through the patient's body from all sides during the course of a complete 360° rotation. The data obtained from the detectors can then be reconstructed by computer to produce an axial (horizontal) sectional image (or slice) of the area assessed.

In an older CT scanner, the table on which the patient was lying would then be advanced further through the gantry, typically by the same distance as the thickness of a slice, and another rotation would occur to produce the next image. The end result would be a series of images of the area scanned, much like the slices making up a loaf of bread. These images provided good anatomical detail within each slice but examinations were slow and the reconstruction of a series of slices to produce images in other planes (e.g. coronal or sagittal) yielded poor-quality results, even with the thinnest of slices. Modern CT scanners combine constant, synchronous gantry rotation and movement of the table to allow faster scanning and more importantly, permitting the entire area of interest to be scanned in a single, continuous X-ray exposure. This results in the X-ray beam effectively passing around the patient in a spiral fashion, and producing a single volume of data, rather than a series of individual slices. Such data can still be used to produce axial sectional images, but also permits high-quality reconstructions in other imaging planes as well as allowing volumetric and other three-dimensional images to be produced. Most recently, technological developments have allowed multiple banks of detectors to be placed adjacent to each other, with each bank obtaining its own dataset at the same time. These 'multislice' scanners can now be manufactured with several hundred detector banks, allowing exceptionally rapid scanning of large patient areas in polytrauma situations, or alternately, if the table remains stationary, imaging of the entire heart in a single contraction.

CT images

CT images are digital, consisting of multiple small squares or pixels (picture elements) arranged in a grid or matrix (Figure 69.1). Each pixel corresponds to a small volume of tissue (voxel) and is assigned a number which indicates the degree to which tissue in the voxel absorbs or deflects the X-ray beam. Such CT numbers (also known as Hounsfield units) range from 1000 (air) to +1000 (bone), with water assigned a value of zero. The CT number broadly reflects the average density of the tissue contained within that voxel. Although it is possible to display the entire range of CT numbers from 1000 to +1000 on a single image, it is difficult for an observer to perceive differences between some tissue types and usually the image
Fig. 69.1 CT image of the left chest wall which has been magnified to demonstrate the individual pixels making up the image. The black triangle top left is lung. Adjacent to this (from left to right) are rib (arrow), chest wall muscle (long arrow), subcutaneous fat and skin (arrowheads). Note how the edges of structures such as the rib demonstrate the square nature of the individual elements making up the image.

is shown in a manner which makes it easier to identify such differences (or contrast); this is termed 'windowing'. Here only a proportion of the possible CT number range is displayed, determined by the numerical width of the 'window' and its centre value. Window settings are used to highlight detail of soft tissue (where a typical width of 400 with a centre value of 40 is used), lung (width 1000/centre 700), or bone (width 2400/centre 200). In many situations, each CT image must be viewed on several different window settings in order to extract all of the available diagnostic information. For example, a CT examination of the chest must be viewed on soft tissue settings to identify lymph nodes at the hilum, at lung settings to detect small pulmonary metastases, and at bone settings to demonstrate destructive metastatic bone deposits. Window settings can be readily altered on most picture archiving and communication system (PACS) workstations. Similarly, CT numbers can be measured and give an indication of the prevalent tissue type in an area of interest. This can be useful to aid the detection of fat tissue, and is helpful in assessing certain bone and soft tissue tumours, and in detecting the presence of acute haemorrhage, which has a higher CT number than most other fluids because of its iron content.

The size of each individual pixel depends on the number of pixels making up the rows and columns within the image (termed the matrix size) and the extent of the anatomical tissue included within that matrix (termed the field of view). With a typical field of view of 25 cm × 25 cm and using a matrix size of 512 × 512, each pixel within the image would be approximately 0.5 mm in height and width. Previously in most CT systems, the pixel depth (which is equivalent to the thickness of each image slice) is considerably greater than this and consequently image detail (resolution) is higher in the original axial plane than when images are reconstructed in other planes. However, modern CT scanners with multislice technology are capable of producing such images with slice thicknesses also of 0.5 mm. In this situation, pixels are said to be 'isotropic', with height, width, and depth comparable, and hence essentially cubic in shape. As a consequence, reconstructed coronal or sagittal images have equivalent resolution to those in the axial plane, allowing high-quality reconstructions and volume images to be produced.

Radiation dose

Medical devices have contributed to an ever-increasing population radiation dose, and CT is now believed to contribute over 68% of the total dose from medical and dental examinations.[2] The use of CT has increased, with an estimated 3.4 million CT scans performed in the UK during 2008 compared to 1.4 million in 1997.[2] The dose received from a single CT scan of the pelvis is equivalent to the effective background radiation dose received by an individual over a period of 4.5 years or to 500 chest radiographs.[3] Health professionals consequently have a responsibility on to minimize dose received from CT examinations. First, and most importantly, any exposure to medical ionizing radiation must be justified and the use of other imaging modalities which do not use ionizing radiation should be considered before requesting a CT study. Referrers are required to understand the implications of their referrals for diagnostic imaging using ionizing radiation, including the responsibility to ensure the examination is not being repeated with excessive frequency, for example in the case of CT screening for recurrent malignant disease or pulmonary complications of drug therapy.

Where CT imaging is justifiable, several tactics can be implemented to ensure patient dose is 'as low as reasonably practicable' (ALARP) as set out in ICRP 2007,[4] such as scanning minimal anatomical area and using low-dose technique where this can maintain scans of adequate diagnostic quality.

A feature of modern CT scanners which has the potential to reduce radiation dose is the use of an automatic exposure control (AEC) system[5] which determines the required dose quantity by taking into account patient size and the variation in attenuation due to different anatomical structures within the scan field.[6] Use of AEC has to be monitored, however, as there are instances where image quality can be voluntarily reduced, for example when checking needle position during joint injections, and where the inadvertent use of AEC would result in an unnecessary attempt by the scanner to increase quality and consequently the patient dose.

Clinical applications

Trauma

Spinal and pelvic trauma

Rapid CT scanning, where necessary from 'head to heels', has become an integral component of the initial assessment of patients who have sustained major trauma. In such situations, time is critical and CT has contributed to a reduction in mortality and morbidity.[7] This imaging approach allows the acquisition of images of the head, chest, abdomen, pelvis, and extremities as necessary, which can all then be analysed for the presence of injuries while the patient is removed to a suitable area for further resuscitation and the scanner made ready for another casualty where required. The continuous dataset also allows the production of images of the spine, both axial sections and multiplanar reformats, the latter having been shown to be more accurate in the detection and characterization of spinal injuries than radiographs or axial CT images alone.[8]

Most traumatic fractures in the thoracic and lumbar spine occur at the most mobile region, the thoracolumbar junction (Figure 69.2). Injuries are rare below L2 and the thoracic cage acts as a splint, relatively protecting the thoracic spine between T1 and T10. Sagittal reconstructions in the thoracic region should include the sternum, as injuries in this area require high force and are often associated with other, non-contiguous spinal fractures or sternal fractures as well as spinal cord injury. Certain types of patient are at increased risk of spinal fracture with minor trauma, such as those suffering from ankylosing spondylitis or diffuse idiopathic skeletal hyperostosis, and MRI alone can be confusing. CT can readily clarify the nature of such injuries (Figure 69.3).

The complex nature of pelvic anatomy can make bony injuries difficult to identify and appreciate fully on plain radiographs, even when using supplementary views such as the Judet series. Axial CT images allow injuries to the bony pelvic ring or sacroiliac joint diastasis to be readily identified. Reconstructions in other planes allow more accurate assessment of the acetabular roof, and thick slab reformatted data can produce a 'CT equivalent' Judet series if required by surgeons less comfortable working directly with the CT images. Furthermore, since pelvic bone injuries are commonly associated with injuries to other pelvic structures, including major blood vessels, contrast enhancement may be used to detect arterial bleeding,[9] provided the modest additional time required is not considered to be detrimental to patient safety.

Fig. 69.2 Sagittal CT reconstruction of the lumbar spine showing a burst fracture of the L1 vertebral body. Note the buckling of the posterior vertebral body wall which can occur in such injuries.

Fig. 69.3 Sagittal reconstruction CT image of the cervical spine in a patient with diffuse idiopathic skeletal hyperostosis who described neck pain following minor trauma. Note the extensive flowing ossification of the anterior longitudinal ligament (small arrows) and the oblique fracture line crossing the C4 vertebral body (long arrow). This continued through the posterior elements (not shown), indicating an unstable fracture.

Extremity trauma

CT plays a useful role in the management of patients with extremity fractures. The degree of comminution, position and size of fragments, integrity of articular surfaces, and some associated soft tissue injuries are frequently better shown on CT than on radiographs. Selection of patients for CT is usually determined in an orthopaedic trauma meeting, with radiography remaining the initial imaging modality—there are currently no centres in the United Kingdom using CT as a first line imaging investigation. There is consequently variation between (and frequently within) units as to which patients undergo CT, and the potential impact and cost of more extensive use is difficult to assess.

In the lower limb, complex injuries of the tibial plateau, ankle, and calcaneum may all benefit from the greater detail provided by CT (Figures 69.4 and 69.5). Management of tibial plateau fractures is determined by the pattern of injury, including depression of the articular surface. Such depression is better appreciated on CT than on radiographs, as is the morphology and position of fragments. CT modifies treatment in a significant proportion of patients with lower-extremity fractures.[10,11] CT similarly assists in planning management of complex ankle fractures, increasing the likelihood of satisfactory reconstruction of the articular surface in cases of displacement. CT is now pivotal in the diagnosis and management of intra-articular calcaneal fractures. The pattern of injury to the posterior facet of the subtalar joint, the degree of comminution of

Fig. 69.4 Coronal reconstruction CT image of the right knee in a patient with a comminuted fracture of the tibial insertion of the anterior cruciate ligament. It was not possible to appreciate the degree of comminution on the corresponding MRI scan.
Fig. 69.5 Sagittal reconstruction CT image of the ankle in a patient with a displaced fracture of the body of the talus.

the lateral wall of the calcaneum and the sustentaculum tali, and the detection of involvement of the calcaneo-cuboid joint are all relevant features best shown on CT.[12] Associated soft tissue injuries may also be demonstrated such as dislocation or entrapment of tendons,[13] which may require surgical attention.

In the upper limb, experience of use of CT is greatest in injuries to the scaphoid (Figure 69.6), where it can identify fractures occult on radiographs.[14,15] Reconstructions aligned parallel to the long axis of the bone are particularly useful. These previously required precise patient positioning within the CT gantry, but modern CT systems are capable of obtaining volume data with isotropic voxels allowing rapid reconstruction in any desired imaging plane and from any original wrist position. CT may still have difficulty confirming an undisplaced fracture. Here, the ability of MRI to determine the presence of bone marrow oedema is advantageous.

CT provides useful information in suspected stress fracture (Figure 69.7) where the periosteal reaction and bone sclerosis observed on radiographs, occurring in a patient with a history of increasing pain and often no immediate link with trauma, raise understandable concerns about possible bone tumours. CT will frequently demonstrate the fracture line with the sclerotic region, as well as excluding other conditions such as osteoid osteoma.

Fig. 69.6 Coronal reconstruction CT image of the wrist. Note the undisplaced fracture of the waist of the scaphoid (arrow).

Fig. 69.7 Coronal reconstruction CT image of the tibia in a patient with a stress fracture. Note the periosteal reaction (small arrows) and the fracture line visualized within sclerosis affecting the medial cortex (long arrow).

Complications of trauma and its treatment

CT plays a useful role in the assessment of healing and the evaluation of complications related to surgical fixation.[16] The superior ability of CT to demonstrate cortical bone and medullary trabeculae makes it more useful than MRI in identifying fusion and callus bridging the fracture site. Following fracture healing, bone marrow appearances on MRI may remain abnormal for some time, leading to a false impression that fusion may not have occurred. Radiography can confirm bone healing, but overlapping of structures on the radiographs, even when two projections at 90° have been obtained, can lead to either under- or overestimation of the amount of fusion which has occurred.

Failure of bone healing to progress correctly following fracture can result in a range of complications. Malunion refers to fusion occurring with the final fracture positioning being abnormal and unsatisfactory. Non-union is classified as failure of fracture healing. There are several types of non-union: atrophic, hypertrophic, and infective. CT demonstrates differing appearances in each case.

Metalwork failure

Requests for evaluation of potential problems with orthopaedic hardware can be challenging to deal with satisfactorily, as the metalwork can interfere with all diagnostic imaging modalities. Radiographs remain the initial examination of choice and careful attention is required to identify subtle fractures of rods or screws which are sometimes diagnosed in hindsight. MR images
Fig. 69.8 Axial CT image of the lower thoracic spine in a patient with a scoliosis and fixation. Note the streak artefact from the metalwork (short arrows) and that the left-sided screw is malpositioned, crossing the spinal canal (long arrow).

are usually degraded by the distortion of the magnetic field such that they provide no useful information about the metalwork itself, although techniques now exist to allow assessment of soft tissues close to implants, particularly in patients with hip joint prostheses. CT is also affected by the presence of metal within the imaging field.[17] The density of the metal is significantly higher than that of bone and consequently considerably higher than the usual range of CT numbers. Attenuation of the CT beam due to interactions with the metal causes image deterioration and streak artefacts extending into surrounding tissues (Figure 69.8). Careful radiographic technique can reduce the effect of artefact observed. It is frequently possible to position the patient and/or the CT gantry in order to bring the long axis of metal screws into the imaging plane, concentrating the streak artefact into a minimum number of slices and improving the quality of the remainder of the examination. This manoeuvre is only applicable if the screw is known to be normal. Increasing image factors such as the tube voltage and current settings will improve image appearances, reducing noise and artefact but at the cost of increased dose and greater stress on the CT X-ray tube.

Producing images from the data using smooth reconstruction algorithms (similar to those used for soft tissue image reconstruction) rather than the harder algorithm more typically used for bone window images results in reduced artefact, and reconstructing image series with thicker slices may also improve quality by reduction of noise. Different sizes of implant and types of metal used in their construction can result in differing, not always predictable, degrees of artefact. It is frequently necessary to experiment with reconstructions in differing imaging planes and with various slice thicknesses before determining the optimum combination in

any single case. Artefact is generally less conspicuous on images displayed on wide window settings.

Non-traumatic applications

Tarsal coalition

Tarsal coalition refers to the abnormal bridging of two or more tarsal bones by bony or fibrous tissue. Although congenital, the condition most commonly presents in late childhood or young adults, causing pain and stiffness in the foot. Secondary changes can occur in the ankle as a result of the restricted range of movement, resulting in a 'ball and socket' rather than hinge configuration. Other radiographic signs include the 'uninterrupted C' visible on lateral radiographs in bony talocalcaneal coalition (Figure 69.9). The condition is often difficult to assess adequately on radiographs and CT is helpful in further assessment, or in establishing the diagnosis in radiographically occult cases. Complete (osseous) coalitions are readily identifiable on CT due to the abnormal bony bridging of the affected structures. Incomplete coalitions (due to abnormal fibrous or cartilaginous bridging) are less obvious and best identified by observing the narrowed joint spaces and frequently associated secondary osteoarthritic changes. Talocalcaneal (Figure 69.10) and calcaneonavicular coalitions are the most commonly encountered, although other more unusual combinations also exist.

Spinal fusion/spondylolysis

CT provides better detail of cortical bone than does MRI and generally suffers less than MRI as a consequence of metal artefact. CT is therefore preferred for the assessment of bone fusion in the spinal column following surgery. In patients with scoliosis, MRI is used to identify underlying disorders of the spinal cord and craniocervical junction. MRI will demonstrate some bony segmentation or formation anomalies of the spinal column, but CT may be necessary to fully evaluate complex disorders (Figure 69.11). This is particularly

Fig. 69.9 Lateral radiograph of a patient with talocalcaneal coalition. Note the complete sclerotic line from the inferior aspect of the sustentaculum tali to the posterior aspect of the body of the talus (arrowheads). This line is normally interrupted.
Fig. 69.10 Coronal CT image in the same patient as in Figure 69.9 demonstrates the talocalcaneal coalition (long arrow).

Fig. 69.12 Oblique axial CT image demonstrating a fractured left pars (arrow). Note the intact right pars (long arrow).

the case for the posterior elements where the small amount of medullary bone makes resolution of structures on MRI more difficult.

For similar reasons, CT provides additional information to MRI in cases of spondylosis (fracture of the pars interarticularis). On MRI, when continuous high T1 signal is seen through the pars, from the superior to the inferior articular facet, it can be considered normal as the examination has confirmed the presence of medullary fat. However, when continuous high T1 is not shown, there are several possible explanations. The pars medulla may be sclerotic, or simply too narrow in comparison to the thickness of the MRI slice, such that 'partial volume' artefact from the average of

fat and cortical bone lowers the signal. Alternately, the pars may be fractured. CT can directly identify either intact or fractured cortex (Figure 69.12) and hence provide a more specific diagnosis, albeit at the cost of radiation exposure. Consequently, CT is often used in a second line 'targeted' manner when spondylolysis is considered a potential cause of low back pain.

Sequestrum/bone tumour characterization

Characterization of bone tumours remains most accurate on plain radiographs and this is unlikely to change. MRI is used for local tumour staging and is currently the optimal imaging modality to demonstrate the presence of fluid levels within a tumour and extension of tumour into joints. The role of CT in the local assessment of bone tumours is mainly in demonstrating and characterizing calcifications formed within and by the tumour, termed tumour matrix. The matrix produced by bone-forming (osseous) tumours is typically much more amorphous and cloud-like than that produced by cartilage-forming (chondroid) tumours, which is described as 'punctate' and commonly arranged in rings or arcs (Figure 69.13). CT provides greater detail of matrix than does either MRI or radiography, and hence can assist in identifying the likely cellular tumour type. CT also allows more accurate assessment of the degree of scalloping of endosteal cortex which can be seen in certain cartilage bone tumours. Enchondromas (benign) may scallop cortex, reducing its thickness by up to 66%,[18] but scalloping in excess of this is much more likely to indicate that a tumour is a malignant chondrosarcoma (Figure 69.14).

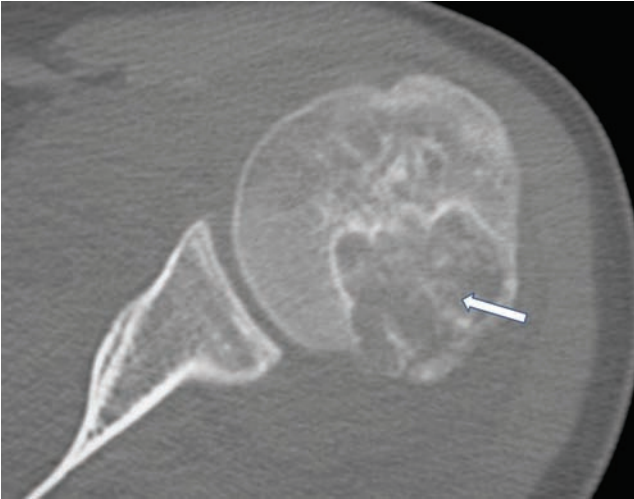
CT is the best imaging modality to demonstrate the nidus of an osteoid osteoma (Figure 69.15). within its surround shell of thickened, most typically cortical or periosteal, bone. Despite MRI being better for identifying bone marrow oedema, and the synovitis associated with those osteoid osteomas occurring within a joint, the nidus is frequently difficult to identify on MRI, with potential
Fig. 69.11 Coronal CT image in a patient with a left-sided hemivertebra at the lumbosacral junction (long arrow) which is fused with the left sacral ala. Note the resulting right convex scoliosis (small arrow).


Fig. 69.13 Axial CT image of the left humeral head in a patient with a chondroblastoma. Note the 'rings and arcs' appearance of typical chondroid (cartilage) matrix within the lesion (long arrow).

for misdiagnosis as either a stress fracture or as an inflammatory arthropathy.

CT is a useful adjunct to MRI in the assessment of osteomyelitis. Although MRI is preferred for the demonstration of bone marrow oedema, bone and soft tissue fluid collections, it is less accurate at detecting the presence of a sequestrum, or sclerotic, avascularized bone fragment, which can act as a focus for recurrent infection following antibiotic therapy and frequently requires surgical removal. CT readily demonstrates such fragments (Figure 69.16) and is the better technique for confirming or excluding continuity of fragments with the remainder of the bone.

Fig. 69.15 Axial CT image in a patient with a tibial osteoid osteoma. Note the nidus (long arrow) and the surrounding reactive cortical thickening (arrowheads) and medullary sclerosis (small arrow).

Interventional CT

Arthrography

Conventional arthrography is now performed mainly to confirm accurate needle position prior to aspiration of joint fluid or more commonly, injection of anaesthetic and/or steroid. Diagnostic arthrography is more frequently combined with cross-sectional

Fig. 69.14 Sagittal CT image of a cartilage tumour in the distal tibia. The lesion has caused significant scalloping and expansion of the posterior cortex (arrows), features much more typical of a malignant tumour than a benign enchondroma.

Fig. 69.16 Longitudinal CT reconstruction of a sequestrum with an area of osteomyelitis in the femur. Note the cavity within the area of cortical sclerosis containing the sequestrum (arrow).
Fig. 69.17 Sagittal reconstruction image from a CT arthrogram of the elbow. Note how contrast displaces both the anterior and posterior fat pads from their normal locations (arrows)

Fig. 69.18 Axial image from a CT-guided sacroiliac injection procedure. The image is relatively noisy due to the low-dose technique employed, but both needle and joint space can be easily identified. Note the subchondral sclerosis and erosions seen anteriorly, particularly on the iliac side of the joint, indicating sacroiliitis (arrows). Such features are typically more extensive on the iliac side because of the protective effect of the thicker sacral articular cartilage.

imaging to take advantage of the latter's ability to produce detailed, sectional images through the joint of interest. MRI is the more common modality of choice, favoured partly because of its greater soft tissue and bone marrow imaging capability, and partly because of its lack of associated ionizing radiation. CT arthrography (Figure 69.17) may be used in patients in whom MRI is not possible, but also where the superior spatial resolution of CT is considered to be of paramount importance.[19] CT is also preferable when attempting to identify small calcified intra-articular loose bodies, which may be difficult to confirm on MRI. In such cases, CT is frequently performed both before and after contrast injection as small calcified bodies may become obscured within the pool of contrast.

CT-guided biopsy/injection

Interventional procedures may be performed in the CT suite itself. CT allows precise guidance of needles and is useful when performing injections into complex areas such as the sacroiliac joint (Figure 69.18). CT is also the most accurate modality to assist biopsy of bone lesions (Figure 69.19). It suffers from several disadvantages, however. Ionizing radiation dose may be higher than that from a similar fluoroscopic procedure where one is possible, and this is clearly significant if ultrasound guidance is a realistic alternative. Procedures are generally more time consuming when performed under CT guidance rather than with the 'real-time' modalities of fluoroscopy and ultrasound. Although many CT scanners have a 'CT fluoroscopy' option, this is less useful in musculoskeletal system interventions where bone access is inherently slower and requires the operator's hands to be within the scanner, exposed to the primary beam. Using CT fluoroscopy further increases the patient's cumulative skin radiation dose as well as that to the operator because the scanning plane is kept constant and continually exposes the same area of tissue.

Radiofrequency ablation of osteoid osteoma

Just as CT is the best modality to demonstrate an osteoid osteoma nidus, it also assists in percutaneous treatment. CT guidance allows positioning of a needle with a laser (or more commonly a radiofrequency tip) which can be used to ablate the nidus, avoiding the

Fig. 69.19 Axial image from a CT-guided biopsy procedure performed for the patient with the lesion in Figure 69.14. The needle is well demonstrated. Note the streak artefact proceeding away from the needle tip (arrow). The biopsy confirmed the imaging suspicion of a chondrosarcoma.
Fig. 69.20 Axial image from a CT-guided radiofrequency ablation procedure performed to treat a right femoral osteoid osteoma. Under CT guidance, such needles can be positioned with considerable accuracy.

need for a more extensive surgical resection with the associated risk of fracture (Figure 69.20). Radiofrequency ablation of osteoid osteoma has an extremely high therapeutic success rate of around 90%[20] from a single treatment and a minimal complication rate. Ablation has become the treatment of choice for osteoid osteoma except for the occasional lesion lying close to the spinal cord, typically in the pedicle or posterior vertebral body wall, where the potential risk of thermal injury to the cord in an anaesthetized patient makes a surgical procedure preferable.

New developments

Dual-energy CT is a recent development, not yet in widespread clinical use, which could offer potentially interesting features in several areas of musculoskeletal imaging. Dual-energy CT scanners produce images using two different X-ray sources of different energy levels (typically 80 kV and 140 kV) housed within the same gantry. The sources scan the patient simultaneously, resulting in two sets of spiral CT data. X-ray absorption within tissues is energy dependent and hence alters at different energy levels. Individual substances have their maximum X-ray absorption at different levels (e.g. iodine absorbs maximally at low energy levels and its absorption reduces significantly at higher levels) and this allows dual-energy CT to provide specific information about the chemical composition of individual tissues and areas within images. In rheumatology, the most obvious potential application is in the detection of monosodium urate tophi in gout,[21] allowing the diagnosis to be made without

recourse to joint aspiration and microscopy. Dual-energy CT also allows more refined assessment of ligament and tendon structures than has previously been possible with CT, but it is currently unclear whether this refinement will translate to a genuine clinical role for the modality in the assessment of soft tissue structures in the musculoskeletal system. MRI and ultrasound remain the modalities of choice, but dual-energy CT may be able to provide useful additional soft tissue information in patients undergoing CT for suspected fracture, for example after trauma to the knee. Dual-energy CT allows reduction in the artefact from metal implants and can consequently improve image quality and diagnostic value.[22]

CHAPTER 70

Nuclear medicine

Adil Al-Nahhas and Imene Zerizer

Introduction

The science of using radioactive tracers in the investigation and treatment of disease began in the early 20th century, and was soon followed by its introduction into clinical practice. The application was initially aimed at thyroid diseases, because early experiments used radioactive iodine, but the wide spectrum of diseases that could benefit from this novel technique was soon realized. Now nuclear medicine plays an important role in the management of cancer as well as diseases affecting cardiovascular, endocrine, renal, and musculoskeletal systems. This has been achieved through the introduction of hundreds of radiopharmaceuticals that target cellular and subcellular structures and functions, such as cell membrane receptors, glucose metabolism, hypoxia, and angiogenesis. These developments were paralleled by continuous innovation in imaging of these in-vivo events, through the introduction of high-resolution gamma cameras, positron emission tomography (PET) scanners, and more recently hybrid PET/CT cameras.

The principal of achieving a diagnostic or therapeutic effect using nuclear medicine techniques is the administration of a radioactive tracer in vivo (by IV injection, inhalation, or ingestion) that can target a physiological or pathological process. Once there, its distribution can be mapped by detecting its emitted gamma rays through special gamma cameras. However, radiotracers have no targeting potential and have to be 'made' to target disease process. This is achieved by binding the tracer with a chemical messenger (ligand) that is known to be attracted to a particular cellular or subcellular structure, or be part of a physiological process. This chemical bonding (labelling) is vital for the success of imaging or therapy. Examples in clinical practice include the labelling of technetium-99 m (^{99m}Tc) with methylene diphosphonate (^{99m}Tc-MDP) to visualize hydroxyapatite in bone scanning, or macraggregated albumin (^{99m}Tc-MAA), which is used in detecting pulmonary emboli. A novel method of detecting cancers is to detect their metabolic activity through increased glucose metabolism by labelling fluorine-18 (^{18}F) with a glucose precursor (^{18}F-FDG).

The real strength of nuclear medicine imaging is its ability to highlight the physiological nature and development of disease rather than its anatomy. A good example is the detection of bone metastases due to subtle changes in the hydroxyapatite structure caused by increased bony turnover, which will take up to 9 months to produce a sufficient shift in calcium mass to make it visible on traditional imaging. Likewise, small lymph nodes of 5–10 mm in diameter that are affected by lymphoma would be regarded as normal by CT criteria (lymph nodes need to be >1 cm to be regarded as malignant) while they can show intense metabolic activity on PET. In certain diseases, nuclear medicine is the only modality that can separate disease from normality, as in the use of postsynaptic imaging in Parkinson's disease.

Since the early 1950s, nuclear medicine procedures have been used in the investigation, treatment, and follow-up of major rheumatologic conditions. This chapter will focus on their use in imaging rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), ankylosing spondylitis (AS), vasculitis, and myopathy as well as in treatment of inflamed joints (radiosynovectomy).

Rheumatoid arthritis

The pathophysiological processes involved in RA (activation of leucocytes, infiltration of the synovium, and neovascularization) have become the target of several nuclear medicine procedures—including bone scintigraphy, molecular targeting of inflammation, and glucose metabolism—that are used in the staging and follow-up of RA.

Bone scintigraphy

Since the 1970s there have been several reports that describe the utility of bone scintigraphy (BS) using ^{99m}Tc-labelled phosphonates in RA.[1] Ideally, a three-phase acquisition is performed to depict inflammatory changes. The perfusion phase (1 image per second for 60s) allows visualization of the increased vascularity that is commonly found in acute inflammatory processes. A blood-pool phase is then acquired to demonstrate equilibrium of arterial and venous flow, followed by a bone phase demonstrating the osteoblastic activity. Bone scans have been used to both confirm the diagnosis by identifying involved joints and in assessing response to treatment.

An acute inflammatory arthritis is characterized by increased vascularity and blood pooling in the affected joint and surrounding soft tissues as well as increased uptake in the periarticular bones on the bone phase (Figure 70.1). This is due to the synovitis and inflammation of the chondro-osseous zone which leads to oedema, blood vessel proliferation, and synovial hypertrophy.[2] Some authors have also described flushing of the fingers in the blood flow phase of the bone scan, due to vasodilatation secondary to microcirculatory disturbances that occur in RA.[3]
Fig. 70.1 Bone scan with [99 mTc] HDP showing typical example of increased bone uptake in the small joints of both hands in acute rheumatoid arthritis (a) compared to uptake in a normal hand (b).

An early study by Mottenen et al. evaluated the role of BS in predicting the development of erosions in early RA in 13 patients.[4] The authors performed serial scintigraphy in patients diagnosed with RA at 0, 6, and 12 months. All except one of the joints that were to become eroded during the first 12 months were active on serial bone scans. Inactive joints on BS did not demonstrate erosions throughout the period of follow-up. The scintigraphic results also correlated with clinical activity and Larsen's index. The authors concluded that persistent activity on BS predates the onset of erosions and a negative BS excludes an active synovitis. This was supported by another retrospective study of 22 patients with RA which demonstrated that after a mean follow-up period of 3.6 years, none of the cohort with a negative BS had evidence of inflammatory joint disease.[5] Another study by Duncan et al. assessed the impact of BS

on patients' management.[6] A total of 136 bone scans were evaluated to confirm or exclude a clinical diagnosis and to localize the site of pain. BS was successful in excluding a diagnosis of RA in 87% and confirming a diagnosis in 80%. The patients' management altered based on the bone scan report in 43% of patients and the results prevented further investigations in 60% of cases. Despite these encouraging results, BS has several disadvantages, such as lack of specificity. This has led to the introduction of several other more specific agents to image inflammation.

Molecular targeted imaging

Radiolabelled white cells have been utilized to image inflammatory processes such as RA. Radiolabelling is carried out by separating leucocytes from the patient's own blood, which are incubated with radioactive tracers ([99 mTc]-HMPAO or [111In]-oxine), washed, and suspended in plasma before being readministered intravenously to the patient. An early study has demonstrated that labelled white cells accumulated in clinically active knee joints and a 50–60% reduction in uptake was observed following treatment with local steroid injections.[7]

Antibodies against granulocyte-surface antigens, molecules within microorganisms, or antigens of such disease-related molecules have been radiolabelled to image inflammatory processes. Specific polyclonal IgG-type antibodies labelled with [99 mTc]-HIG have been shown to accumulate in inflamed joints by binding with lymphocyte-surface antigens, which are found at sites of chronic inflammation. [99 mTc]-HIG was shown to be more sensitive and accurate in diagnosing active, histologically proven synovitis,[8] and could predict the development of RA in patients with arthralgia, providing additional information to rheumatoid factor measurements.[9]

Immunoscintigraphy has also been utilized in monitoring disease and response to immunotherapy.[10] Recently, several antibodies, either chimeric or humanized, have been introduced into clinical practice to control the autoimmune inflammatory process that is the basis of RA. These can also be labelled, mainly with [99 mTc] or [111In], for imaging. Several monoclonal antibodies and their fragments such as anti-TNFα, anti-CD20, anti-CD3, anti-CD4, and anti-E-selectin antibody have been successfully used in imaging. These labelled antibodies not only offer the ability to stage the disease accurately and identify involved joints but can also offer a unique opportunity to identify patients who will benefit from treatment with therapeutic unlabelled antibodies.

Imaging with [99 mTc]-labelled infliximab before and 3 months after intra-articular infliximab therapy has shown very specific uptake of [99 mTc]-infliximab in inflamed joints, unlike normal joints that did not show any uptake,[11] with good correlation between pretherapy uptake and improvement in clinical symptoms post-treatment. Clinical improvement of symptoms and reduction of swelling were higher in patients with the higher uptake of [99 mTc]-infliximab pretherapy and decrease of uptake after therapy.

Anti-E-selectin monoclonal antibody, overexpressed on the vasculature of inflamed tissue, has been labelled with [111In] or [99 mTc]. A comparison between [111In] anti-E-selectin antibody and [99 mTc]-HIG in 11 patients with active RA showed the former to have a higher sensitivity in the detection of active disease and correlated well with clinical scores of joint involvement.[12] Another study by the same authors demonstrated the feasibility and advantages of [99 mTc] anti-E-selectin (1.2B6) antibody fragment over conventional [99 mTc] HDP bone scanning and [111In]-anti-E-selectin.[13]

¹⁸F-FDG PET/CT

¹⁸F-FDG is a widely used PET radiopharmaceutical for tumour imaging. However, increased uptake of ¹⁸F-FDG in inflamed joints has incidentally been noted in two oncology patients who were also suffering from RA.[14]

In addition, animal experiments have demonstrated that up to 29% of ¹⁸F-FDG is not taken up by tumour cells alone but also by macrophages and surrounding granulation tissue.[15] Lin et al. demonstrated a correlation between TNFα, which enhances glucose entry into macrophages and metabolism in fibroblasts, and ¹⁸F-FDG accumulation in experimental animal models.[16] These factors make ¹⁸F-FDG PET a highly sensitive imaging modality for the detection and monitoring of inflammatory diseases and in particular synovitis. An early study comparing ¹⁸F-FDG PET with gadolinium-enhanced MRI in 12 patients with RA demonstrated a correlation between enhancing pannus on MRI and ¹⁸F-FDG accumulation.[17] The volume of enhancing pannus also showed a liner relationship with the total uptake value of the wrist and the regional uptake value.

Beckers et al. assessed ¹⁸F-FDG uptake in 356 joints in 21 patients with active RA.[18] These authors found that ¹⁸F-FDG uptake in the joints correlated well with clinical parameters (disease activity score, swelling, and tenderness), ultrasound findings of synovitis and synovial thickening, neovascularization as assessed on Doppler, and laboratory inflammatory markers (ESR and CRP). In addition, this study evaluated response to therapy. Sixteen knees in 16 patients with active RA were assessed using ¹⁸F-FDG PET, dynamic MRI, and ultrsound pretreatment and at 4 weeks after anti-TNF treatment. The imaging studies were also correlated with CRP and matrix metalloproteinase-3 (MMP3) measurements. Changes in ¹⁸F-FDG uptake after 4 weeks were observed in responding joints which correlated with reduced enhancement on MRI and serum CRP and MMP-3 levels. However, measurements of synovial thickening on ultrasound did not show a response, confirming the superior role of ¹⁸F-FDG PET in depicting early metabolic changes following anti-TNF treatment. There is continued interest in the role of ¹⁸F-FDG PET/CT in the assessment of RA, and a recent study has confirmed the correlation between CRP levels and ¹⁸F-FDG uptake in large joints.[19]

All of the above studies emphasize the role of ¹⁸F-FDG PET in the accurate staging of RA and assessment of joint activity following therapy with disease-modifying and anti-inflammatory drugs. However, despite its high sensitivity, ¹⁸F-FDG PET lacks specificity since it accumulates in osteoarthritis. This has led to the introduction of novel PET tracers that can potentially be more accurate for RA diagnosis and treatment response.

Non-FDG PET/CT

Several experimental PET tracers have been investigated in an attempt to make an early diagnosis of RA by detecting subclinical synovitis. This is highly important to identify patients who are at risk of potentially serious RA complications, such as atlantoaxial subluxation, that require more intensive drug therapy and possible early intervention.

Imaging of macrophages was investigated using the PET tracer ¹¹C-(R)-PK11195, which binds to peripheral benzodiazepine receptors (PBRs) on macrophages. The study was performed in knee joints of 11 patients with RA and the findings were correlated with arthroscopy and immunohistochemistry staining of obtained samples.[20] The uptake of ¹¹C-(R)-PK11195 was significantly higher in severely inflamed joints than in joints with moderate or mild signs of inflammation. In addition, there was a significant correlation between tracer uptake and PBRs and CD68 staining of macrophages. There was significantly higher uptake in contralateral non-inflamed knee joints of RA patients than in the non-inflamed joints of control patients. This may indicate that ¹¹C-(R)-PK11195 can play a prognostic role since its uptake preceded clinically evident synovitis.

Van der Heijen et al. demonstrated that synovial tissue from RA patients expressed folate receptor beta on activated macrophages; this can be targeted for therapy using high-affinity-binding folate antagonists such as BCG 945.[21] A recent study investigated the use of ¹⁸F-PEG-folate PET to image arthritis in a rat model and therefore facilitate the selection of patients for folate antagonist therapy.[22] Rats with induced arthritis showed a macrophage-rich inflammation in the synovial tissue of the affected joint, resembling synovitis in RA patients. ¹⁸F-PEG-folate PET images in these rats clearly demonstrated the arthritic joints. Further studies are awaited to evaluate the role of ¹¹C-(R)-PK11195 in humans.

Systemic lupus erythematosus

Several clinical, laboratory, and imaging modalities are available for the diagnosis and assessment of response to treatment in SLE. Anatomic imaging modalities (CT/MRI) provide a high-quality assessment of structural changes relating to inflammation. However, these secondary changes take time to develop and therefore do not allow early detection of disease. Nuclear medicine studies offer the possibility of early disease detection before anatomical changes occur and follow-up of response to therapy.

Bone scintigraphy

The most important role of BS in SLE is in the detection of osteonecrosis, which occurs in 5–50% of SLE patients and mainly affects weight-bearing joints.[23] The femoral head is most commonly affected, followed by the humeral head, femoral condyle, and tibial plateau. ⁹⁹ᵐTc HDP depicts early osteonecrosis as a photopenic area in the affected bone due to necrosis of the bone with lack of osteoblastic reaction. This is followed by a hyperaemic stage with increased vascularity and tracer uptake at the margins of the infarction on a three-phase bone scan. Although a three-phase bone scan is highly sensitive in the detection of osteonecrosis, MRI has been found to be more sensitive in the early detection of osteonecrosis, depicting changes in bone marrow as a result of vascular insufficiency.[23]

Gallium-67 citrate scintigraphy

Gallium-67 (⁶⁷Ga) scintigraphy has been widely used in the assessment of suspected inflammation. Various mechanisms have been proposed for the accumulation of ⁶⁷Ga in inflammatory lesions, including binding to transferrin and lactoferrin, uptake by lysosomes in mononuclear phagocytes, and direct binding to the lymphocyte membrane.[24] Although its use in detecting inflammation has been reduced in favour of ¹⁸F-FDG because of its unfavourable physical properties, it has been used in SLE is in the detection of nephritis and pulmonary complications among others.

Several studies have demonstrated that ^{67}Ga scintigraphy is an excellent screening test for the presence of acute interstitial nephritis.[25,26] Pagniez et al. demonstrated that significant renal ^{67}Ga uptake indicates active, potentially curable lesions.[25] Bakir et al. performed ^{67}Ga scans in 43 patients with SLE and reported that 89% of patients with active renal disease had positive ^{67}Ga scintigraphy whereas only 17% of patients with inactive renal disease had positive findings.[26] Lin et al. studied the role of ^{67}Ga scans in 47 patients with SLE in predicting a response to therapy.[27] They showed that patients with a positive ^{67}Ga renal scan (71.4% of the cohort) had a good response to treatment, while more than 88% of patients with a negative ^{67}Ga scan had a poor response.

Many patients with SLE will develop involvement of the lung, its vasculature, the pleura, and/or the diaphragm during the disease course. [67]Ga scintigraphy has been evaluated in the detection of alveolitis in SLE. Witt and colleagues found that significant ^{67}Ga accumulation was present in patients with alveolitis confirmed on brancheoalveolar lavage.[28] The severity of lung inflammation in 34 patients with SLE was also measured by quantitatively measuring the level of ^{67}Ga in the lungs (gallium uptake index, GUI) compared to 20 normal controls.[29] Higher values of GUI in SLE patients were detected compared to normal controls, and in patients with a flare-up or a negative chest radiograph compared to patients who have stable disease or a positive chest radiograph. This indicates that a positive chest radiograph finding may be a later manifestation of lung involvement in SLE. There are few publications describing the use of ^{67}Ga in myocarditis[30,31] and other vascular complications.[32,33]

Lung permeability studies

Measurements of the vascular permeability have been used for early detection of lung involvement in SLE. Dalcin et al. performed ^{99m}Tc-DTPA clearance in active and inactive SLE, compared with clinical data and disease activity, and showed pulmonary clearance to be faster in SLE patients with active disease compared to normal controls.[34] Lung uptake of ^{99m}Tc-HMPAO was compared in 20 SLE patients and 25 controls; uptake was higher in the patients with SLE, suggesting that this method may be useful in assessing pulmonary injury in SLE patients.[35]

^{18}F-FDG PET/CT

Lymph node involvement is a common early manifestation of active SLE, correlating well with constitutional symptoms. Patients with active SLE have been found to have activated T and B lymphocytes in their lymph nodes compared to those with inactive disease. Therefore, ^{18}F-FDG PET/CT has been utilized to visualize active lymphadenopathy in patients with SLE[36] as well as detecting early hepatosplenomegaly in SLE patients presenting with pyrexia of unknown origin.[37] ^{18}F-FDG PET/CT has also been shown to detect alteration in cerebral glucose uptake, oxygen consumption, and cerebral blood flow in SLE patients and was superior to MRI studies, which did not demonstrate any structural changes.[38]

A study that evaluated the role of ^{18}F-FDG PET/CT in 28 SLE patients with varying degrees of severity demonstrated reduced metabolic activity in at least one brain region in all patients with severe or mild central nervous system (CNS) symptoms (100%) as compared with patients without symptoms (40%).[39] In contrast, MRI images were abnormal in only 50% of patients with neuropsychiatric symptoms and in one of four patients (25%) without symptoms.

This suggests a correlation between metabolic changes on PET/CT and clinical symptoms that can be useful during follow-up.

In summary, 18F-FDG PET/CT is a useful imaging modality in the diagnosis of CNS involvement in SLE, particularly in the diagnosis of unclear cases, when other imaging modalities are negative and only minor neuropsychiatric symptoms are present. However, MRI scans are highly sensitive in detecting infarction and white matter lesions.

Ankylosing spondylitis

There is an estimated delay of approximately 8–10 years between the onset of symptoms and diagnosis of AS.[40] Early detection is therefore highly important to avoid delays in diagnosis and commence appropriate disease-modifying treatment. [99m]Tc HDP is commonly used in the diagnosis of sacroiliitis, which occurs early in the disease course. The most widely used method of assessment is the calculation the ratio of radiotracer uptake over the sacroiliac joint (SIJ) compared with the sacrum as a reference point (SIJ:S ratio). A study that assessed 137 patients with inflammatory back pain and 31 controls, found that ^{99m}Tc HDP had a sensitivity of 52.7% in the diagnosis of sacroilietis[41] in 112 of patients with AS (according to the modified New York criteria). A recent systemic review of published studies that evaluated the value of ^{99m}Tc HDP BS in the detection of sacroilieits has found an overall sensitivity of 50–55% and a specificity of 80%.[42] However, scintigraphy is usually negative in the fibrosclerotic stage compared to the persistence of radiological changes. Further studies have shown that MRI is more sensitive in early detection of sacroiliitis and, because of its lack of radiation burden, may be a preferred method for diagnosis particularly in young patients.[42]

Vasculitis

As in other rheumatologic conditions, the mechanism of uptake of radiopharmaceuticals in imaging vasculitis relies on its pathological features. Regardless of the different classifications, vasculitis is basically an inflammatory condition of blood vessels associated with leucocytic infiltration of the vessel wall with eventual destruction of the wall and surrounding tissues, resulting in serious consequences such as infarction. Conventional cross-sectional imaging can demonstrate the anatomical changes once the inflammatory process is well established but lack the ability to diagnose early inflammatory changes, which are potentially reversible and, if treatable, may have an impact on the long-term management of this condition.[43] Taking into account that the majority of patients present with non-specific symptoms, there is a need for a physiological imaging procedure that can show early disease for biopsy guidance.

[67]Ga-citrate has been used in the detection of inflammation in certain vasculitic conditions such as Wegner's granulomatosis and Kawasaki's disease since the early 1980s.[44,45] However, its mechanism of uptake (described earlier) and unfavourable physical criteria have reduced its use in clinical practice. Similarly, the use of labelled white cells[46] in this condition has been deemed inappropriate because of its complexity and low sensitivity.[47]

^{18}F-FDG PET

For reasons to do with the resolution of PET scanners (currently around 5 mm), the types of vasculitis most successfully

evaluated with PET and PET/CT have been medium- and large-vessel vasculitis, particularly giant cell arteritis (GCA) and Takayasu's arteritis (TA).

Progress in this area has been aided by better understanding of the immunohistopathology underlying the inflammatory mechanism.[48] The 'respiratory burst' phenomenon occurs when resting cells are activated to phagocytes (i.e. neutrophils, eosinophils, and mononuclear phagocytes) and start metabolizing large quantities of glucose with increased rates (>50-fold) of oxygen uptake.[49] In addition, micro-autoradiography has shown high levels of ^{18}F-FDG accumulation in macrophages, activated lymphocytes, and granulation tissue,[50,51] mostly due to increased oxidative metabolism.[52]

In normal ^{18}F-FDG PET scans, the aorta and its main branches usually only demonstrate normal background uptake of activity due to the low numbers of metabolically active cells dispersed between the elastic layers of the arterial wall. This pattern becomes distinctly abnormal in large-vessel vasculitis. Individual case reports have documented a pattern of linear uptake along the walls of the involved vessels on ^{18}F-FDG PET scan in vasculitis associated with SLE,[53] TA,[54] and GCA.[55] Blockmans and colleagues studied 25 subjects with GCA or polymyalgia rheumatica (PR) with ^{18}F-FDG PET and compared them with 44 age-matched control subjects. Vascular uptake in the vessels of the thorax and legs was found in 76% of the affected group compared to 23% of normal controls (p < 0.0001) They reported a sensitivity of 56%, specificity of 98%, positive predictive value of 93%, and negative predictive value of 80%.[56] Another study by Meller et al. compared ^{18}F-FDG PET and MRI in 15 patients with GCA and TA. ^{18}F-FDG PET was shown to be better than MRI in identifying the extent of vasculitis, monitoring disease activity, and response to therapy; it correlated well with clinical and laboratory findings.[57] The study showed that early diagnosis is possible with ^{18}F-FDG PET in the absence of late complications

such as stenosis or aneurysmal dilatation detected by angiography. This was also shown by our group in a smaller series of six newly diagnosed TA patients.[58] The high sensitivity of ^{18}F-FDG PET in detecting vasculitis was used as an argument to characterize PR as a type of vasculitis.[59] The value of ^{18}F-FDG in detecting brain abnormalities relating to TA has been shown in 4 out of 5 patients with TA.[60]

The hallmark of diagnosis is the linear increase in ^{18}F-FDG uptake along the vessel walls when compared to background (Figure 70.2). Quantitation of uptake using the standardized uptake value (SUV) does not necessarily reflect the disease severity and may be normal in highly active disease.[61] However, SUV is very useful in the follow-up of the same patient. A study by our group showed that ^{18}F-FDG PET was helpful in assessing response to therapy and reducing the need to perform arterial biopsies or repeat angiography. It involved 18 patients with TA who had ^{18}F-FDG PET, the results of which were compared with angiography and clinical scoring. The sensitivity, specificity, negative and positive predictive values for ^{18}F-FDG PET were 92%, 100%, 85%, and 100% respectively.[62]

Using an aorta-to-liver ratio in 23 patients with aortic involvement in GCA, Hautzel et al. recorded a sensitivity and specificity for ^{18}F-FDG PET of 89% and 95% respectively.[63] Using a similar technique, another recent study correlated ^{18}F-FDG uptake with clinical and laboratory parameters in 78 patients with vasculitis.[64] The authors concluded that FDG PET/CT could detect the extent and activity of large-vessel vasculitis in untreated patients with lower uptake in patients on steroids. This confirms the value of a baseline study before the initiation of therapy.

A recent systematic review of the literature on the diagnostic performances of ^{18}F-FDG PET for GCA found that linear or long-segmental pattern of ^{18}F-FDG uptake along the vessels is a
Fig. 70.2 Coronal images of CT (a), FDG PET (b), and fused PET/CT (c) of a 90 year old woman with bilateral axillary artery thrombosis, arthralgia and fatigue. Images (b) and (c) demonstrate increased FDG uptake in the carotid, subclavian, and axillary vessels, consistent with large-vessel vasculitis.

characteristic pattern of GCA, with meta-analysis of data showing sensitivity, specificity, positive and negative predictive values of 80%, 89%, 85%, and 88% respectively.[63]

Other rheumatologic conditions associated with vasculitis such as PR and GCA can benefit from PET imaging, although the literature is sparse and consists of small series or case reports.[65–68] In addition to increased ^{18}F-FDG uptake in involved large vessels, it was also documented that ^{18}F-FDG uptake was increased in involved joints.[66] Blockmans et al found uptake in large vessels to be a sensitive marker for GCA while uptake in the shoulders correlated significantly (p = 0.005) with the presence of PR.[67] More recently, Camellino and Cimmino conducted a literature search to look at the role of imaging in the management of PMR.[68] They found that MRI and PET were most promising in demonstrating interspinous bursitis, with PET frequently showing large-vessel vasculitis. They concluded that the full potential of these techniques is still unexplored.

Inflammatory myopathy

The aetiology of inflammatory myopathy is described elsewhere in this book. It is thought that the mechanisms leading to muscular damage include infiltration by T lymphocytes and macrophages, indirect effect of cytokines, and disturbance of the microcirculation. An increased risk of malignancy (lymphoma, lung, ovary, breast, and colon) at the time of diagnosis or later is associated with dermatomyositis (DM).

An accurate diagnosis of inflammatory myopathy requires a muscle biopsy, which may be difficult because of the heterogeneous nature of muscle involvement.[69] There is therefore a need for an imaging procedure that can depict the disease activity in involved muscle(s), identify a biopsy site, assess response to therapy, and aid in detecting associated malignancy.

^{18}F-FDG PET

There is no visible uptake in voluntary muscle during normal ^{18}F-FDG PET scan due to the low metabolic rate induced by strict prescan avoidance of almost all activities for 1 hour. If this restriction is ignored, variable muscle uptake is noticeable and may render the scan non-diagnostic.[70] Other than that, any muscle uptake would indicate abnormal metabolic activity such as that induced by inflammatory disease.

Early reports of the use of ^{18}F-FDG PET in assessing muscular disorders date back to the early 1990s. A report by Frey et al. described the metabolic activity of lumbar spine muscles involved in fibromyalgia using dynamic ^{18}F-FDG PET and found a significant backflow of glucose from affected muscles back into the vascular pool.[71] An interesting case report was published by Agriantonis et al. showing intense and diffuse muscle uptake in a patient as a manifestation of chronic graft versus host disease (GVHD). The authors highlighted the value of early detection of GVHD-associated polymyositis since it is readily treatable with immunosuppressive therapy to prevent devastating consequences.[72] Another case report showed the value of ^{18}F-FDG PET in revealing diffuse proximal muscle hypermetabolism in keeping with the inflammatory nature in a patient with DM. PET also showed the underlying adenocarcinoma involving the mediastinum.[73] We presented our limited experience in a small series of four patients who underwent ^{18}F-FDG PET for assessment of different types of inflammatory myopathy.[74] One of our cases

had a drug-induced myopathy in which ^{18}F-FDG PET showed significant uptake in upper and lower limb girdle muscles with resolution of uptake 4 months after stopping the offending drug. Our results suggested that ^{18}F-FDG PET is better suited to detect florid necrotizing/inflammatory myopathies and their response to therapy rather than low-grade disease, which needs further and larger studies.

A literature search for articles dealing with the role of PET in the diagnosis and assessment of response to therapy in inflammatory myopathy would, so far, reveal a small number of case reports and small series. This may reflect the fact that PET was, until recently, restricted to research purposes. Concern about using repetitive PET imaging in a benign conditions such as inflammatory myopathy is unjustifiable, because of the debilitating nature of the condition and the fact that PET can detect the associated malignancies, as discussed in the following section.

Use of PET in screening underlying malignancy

There are relatively more studies that show the role of ^{18}F-FDG PET and PET/CT in detecting malignancies associated with inflammatory myopathies. Current opinion suggests that polymyositis (PM) and dermatomyositis (DM) are potential paraneoplastic diseases that require cancer screening. Employing a multitude of conventional imaging techniques may not succeed in this task and a number of studies have demonstrated the value of ^{18}F-FDG PET in this respect.[73,75–77]

A recent study by Selva-O'Callaghan et al. assessed the cost-effectiveness of PET/CT in conventional cancer screening for patients with inflammatory myopathy.[75] They performed ^{18}F-FDG PET/CT in 55 patients with recent diagnosis of myositis and compared the results with those obtained using conventional screening including thoracolumbar CT, mammography, gynaecological examination, ultrasonography, and tumour marker analysis. Malignancies were detected in 9/55 patients with positive and negative predictive values for PET/CT of 85.7% and 93.8% compared to those obtained with conventional screening of 77.8% and 95.7%, respectively. The overall predictive value of both approaches was the same (92.7%). This indicated that the value of a single imaging procedure (PET) was comparable to that of broad conventional screening that included multiple tests.

Unfortunately, the role of PET is not well defined in the guidelines of the European Federation of Neurological Societies' task force report for screening in paraneoplastic syndromes.[78] However, a recent review recommends yearly PET/CT study for at least 3–5 years in patients with PM (moderate risk of associated cancer) and DM (high risk of associated cancer), especially those with positive anti-p155 autoantibodies.[75]

Radiation synovectomy

Radiation synovectomy/radiosynoviorthesis (RS) is the intra-articular injection of beta-emitting isotopes into joints to deliver a local radiation dose to the inflammatory process in the synovium. This direct irradiation of the synovial membrane can produce a therapeutic effect on persistent synovitis that is resistant to traditional drug treatment. The radiopharmaceuticals that have been used for RS are composed of small colloidal particles labelled to beta-emitting isotopes (yttrium-90, rhenium-186, erbium-169, samarium-153). Once injected into the joint these compounds are

taken up by phagocytes, which are abundant in inflamed tissues, hence providing a localized radiation source within the joint. This allows these compounds to deliver a cytotoxic dose to the inflamed synovium.

The procedure is simple to carry out in the outpatient department, although it needs particular attention to radiation protection measures. Availability of the radioisotopes needs to be considered. The injected joints are immobilized for the first 24 hours and the patient may experience some increased pain for the first few days, which can be treated with simple analgesia. Most patients will experience a therapeutic effect within 3–4 weeks after treatment, and therapy can be repeated if clinically indicated.

RS has been successful in the treatment of early stage RA due to its effect on controlling the proliferation of the inflammatory process in the synovial membrane. However treatment may not be effective in advanced cases where there is significant secondary osteoarthritic damage[79]; significant osteoarthritis remains a contraindication for its use.

A meta-analysis of published data on the efficacy of RS has reported 51–100% success rates.[80] A placebo-controlled study evaluated RS in patients with mostly bilaterally affected joints.[81] Random selection of one knee to be treated with ^{90}Y colloid showed more than 50% of patients to benefit from RS 12 months after treatment. This was also found to be superior to other therapeutic procedures (except for surgical synovectomy) such as corticosteroid injections. Further studies have demonstrated the efficacy of RS in patients who became refractory to intra-articular injections of steroids. Jahangier et al. performed RS for RA knees in patients who had at least two failed injections of corticosteroids.[82] After 12 months, 78% of the knees in RA patients had been effectively treated with a sustained improvement in 57% of cases with resolution of joint effusion in 30% of patients. Another study has evaluated the role of ^{90}Y colloid injection alone compared to triamcinolone alone and combination treatment of triamcinolone and ^{90}Y colloid in the treatment of RA knees.[83] The authors found that ^{90}Y colloid alone was more effective in long-term control of symptoms than triamcinolone alone. However, short-term control of pain and joint effusion was similar using either ^{90}Y colloid alone or the combination of ^{90}Y colloid and triamcinolone.

In addition, RS has been used successfully in a wider spectrum of inflammatory arthritides ranging from spondyloarthropathies such as AS to Paget's disease, hæmophiliac synovitis, and pigmented villonodular synovitis. Jahangier et al. observed good effects in psoriatic arthritis in 75% of cases and in AS in 76%.[84] Dawson et al., reported success rates of 50–90% in the control of pain in haemophilic arthritis.[85]

Conclusion

Nuclear medicine procedures are well suited to assist in the management of a variety of rheumatological conditions. Traditional tests such as bone, lung, gallium, and labelled white cell scans continue to be used in the diagnosis and follow-up of RA, SLE, and AS as well as in monitoring response to therapy. However, the recent introduction of PET/CT into clinical practice has provided an excellent imaging procedure that is capable of detecting molecular and submolecular changes with superb resolution and accurate localization. PET/CT has been used successfully in the detection of inflammatory changes in vasculitis, RA, and inflammatory

myopathy with the additional benefit of cancer screening in the latter. Newer PET radiopharmaceuticals that target activated macrophages such as ^{11}C-(R)-PK11195 and ^{18}F-PEG-folate are expected to improve the imaging of inflammation, which is the hallmark of most rheumatological conditions. In addition to imaging, nuclear medicine offers pain relief and improved joint performance through the intra-articular administration of beta emitters (radiosynovectomy), which has been found very useful in resistant synovitis.

Imaging in children

Karl Johnson

Introduction

In principle, the imaging of children with rheumatological disorders is no different from imaging adults; namely the most appropriate test done in a timely manner causing the least amount of distress or long-term complications. Any investigation needs to be clearly considered and affect clinical management. Successful imaging in children requires an understanding of the disease process, the anatomical variants that can occur in childhood, and the developmental needs of the child. As with all aspects of radiology, close collaboration and discussion between the requesting physician and radiologist will improve the quality of the service provided.

This chapter illustrates the specific demands of paediatric imaging. While reference will be made to the important radiological features of individual diseases, they are described in more detail in their appropriate sections.

Clinical indications

The imaging of children with rheumatological conditions is very patient specific with no absolute indications, or contra-indications, for any investigation at any point in the patient's clinical pathway. It is important that any investigation is used to influence management, be it to confirm a diagnosis, exclude potential other diagnoses, or alter management. It must be realized that attending a radiology department, regardless of how child-friendly, may be a daunting experience for a child, not to mention the potential resource implications on the parents/carers who have to accompany them, as well as the demand on the service provision and staffing of the radiology department. The exact choice of imaging will depend on the clinical question and the available resource.

Although radiographs are the commonest used investigation, in childhood arthropathies as well as other musculoskeletal conditions, the diagnosis of juvenile idiopathic arthritis (JIA) is a clinical one and does not depend upon the radiographic findings.[1] The routine screening of a child's bones with radiographs is not indicated. Also, in the early stages of JIA the radiographic features may be normal or relatively non-specific, such as periarticular osteopenia and soft tissue swelling. More importantly, radiographs are important in excluding other causes of joint symptomatology.[2]

Ultrasound is being increasingly used in the management of JIA, but the absolute indications for its use are more difficult to clearly define. The quality of the imaging is very much

operator dependent, whether the operator is a rheumatologist or a radiologist. Obviously, rheumatologists may have access immediately within the clinic setting to confirm or refute the presence of synovial thickening or effusion in the joint, whereas if an appointment needs to be made with the radiology department, this would be less amenable to immediate diagnosis. Ultrasound has the advantage of not involving ionizing radiation, but is relatively time-consuming.

The use of more complex investigations, such as CT and MRI, usually involves booked appointments and is less readily available. In some children, there may be requirement for sedation or general anaesthesia and their use should be more considered. MRI will often provide the most information about joint inflammation and underlying abnormalities.

The advantages and disadvantages of different methods are summarized in Table 71.1. With all investigations, discussion with a radiologist as to the most appropriate test which would answer the diagnostic question most easily and promptly is important. A strong working relationship between rheumatologists and radiologists is to be fully supported. The use of multidisciplinary team meetings can only aid this interaction.

Issues for paediatric imaging

The indications and appropriateness of any investigation which involves ionizing radiation (radiography, screening studies, CT and nuclear scintigraphy) needs to be fully justifiable as they all carry some long-term risk. The true long-term effects of diagnostic radiation exposure are not fully known, but any effects on young children are greater than that in adults.

To aid compliance, optimize image quality, and thus improve the diagnostic yield of an investigation, it is important that the child is pain-free, comfortable, and reassured.

The department should be 'child-friendly', but this is an euphemistic term and difficult to implement in practice: what might seem friendly and welcoming to a small child would be regarded as patronizing by a teenager. Regardless of the content, the decoration should extend down to the eye level of a child and try to appeal to all age groups. Bravery certificates and stickers are useful additions to help the compliance of younger children.

The child being pain-free is one of the best ways to achieve good compliance for any radiological investigation. It is important that adequate and timely pain relief is optimized to the time of the

Table 71.1 Advantages and disadvantages of different modalities in paediatric musculoskeletal imaging

Modality	Advantages	Disadvantages
Radiography	Low cost Good detail of bone injuries Readily available Relatively cheap High availability Good anatomical detail Helpful in differential diagnosis Reproducibility Validated assessment methods	Use of ionizing radiation Not sensitive in detecting inflamed and enhanced synovium, fibrocartilaginous structures, or bone marrow changes due to limited soft tissue contrast Limited and non-specific for diagnosis of early JIA changes at diagnosis Reveals late and often irreversible structural damage Projectional superimposition Unable to directly detect cartilage changes or damage 2D representation of a 3D body part
Ultrasound	Lack of ionizing radiation Non-invasive, well tolerated Relatively low cost Repeatability Possibility of examining several joint regions at one session Ability to visualize both inflammatory and destructive disease manifestations Potential for guiding interventions (e.g. intra-articular steroid injection) Portable Good anatomical detail Dynamic so can be used to assess function and useful for guided procedures such as biopsies and aspirations	Operator dependence Not all joints accessible, the whole joint space not assessed Reduced joint movement in case of joint tenderness and pain Small field of view Acoustic shadowing from overlying bones Difficult to standardize and centralize for clinical trials In small children, compliance may be difficult Relatively poor for air-filled and bony structures as these do not transmit sound. Deep structures can be difficult to visualize
MRI	Lack of ionizing radiation Marked soft tissue contrast Multiplanar tomographic imaging Early detection of erosive changes Soft tissue inflammation detection Direct visualization of cartilage Bone marrow oedema visualization	High cost Longer examination time Claustrophobia Relatively expensive Sedation or general anaesthesia required in the younger or uncooperative child Potential allergic contrast reaction Evaluation limited to one target joint Availability varies worldwide Cannot put pacing wires or patients with metallic fragments near the magnet
CT	High availability Multiplanar tomographic imaging Early detection of erosive changes Can be used for image guidance Relatively quick Good anatomical detail and bony detail	Use of ionizing radiation Not sensitive in detecting inflamed and enhanced synovium Reveals late and often irreversible structural damage Unable to directly detect cartilage changes or damage Sedation or general anaesthesia required in the younger or uncooperative child Potential allergic contrast reaction
Nuclear scintigraphy	Information about organ function Useful whole-body screening investigation Relative sensitive to bone turnover	Radiation dose Poor anatomical detail Use of ionizing radiation Sensitive but non-specific Need for sedation

examination and is age appropriate. Suitable explanation of the procedure and the reasons and consequences of the examination are important, and should be related to the child's age and development. Care must be taken not to exaggerate or elaborate, since one does not want to elicit fear in the child. Play specialists are useful in forming and developing a relationship of trust with the child and devising games and procedures which often help the child understand and cooperate with the radiology staff while being imaged. There is very little indication for the parents/carers of a child not to be present during the examination.

For longer examinations, particularly MRI and, to some extent, CT and nuclear scintigraphy, good compliance is needed. In the younger child, typically those under the age of 5 years, or those with developmental problems, cooperation for longer than a few minutes is often not possible and as a consequence, either sedation or general anaesthesia will be required. With a child under 1 month of age swaddling them after food allow them to fall asleep.

For most radiographic procedures, the required level of sedation is one which allows the child to remain stationary and asleep during the entire imaging acquisition time, but they should be relatively rousable if necessary.[3,4] General anaesthesia requires a suitably trained paediatric anaesthetist, as the child is in an unrousable state associated with loss of airway, control and respiratory depression. Full support staff, anaesthetic machinery, and monitoring equipment is needed and so may not be readily available in all institutions.

Imaging modalities

Radiography

Role of radiography in musculoskeletal practice

Radiographs have historically been the mainstay of imaging in paediatric joint disease. However, they involve a radiation burden to the patient and their sensitivity and specificity in detecting joint damage is less than that of ultrasound or MRI. In view of this, they should no longer be regarded as the routine monitor of disease progression in JIA (Figure 71.1).

The immature skeleton differs considerably from that of an adult, most notably due to the presence of cartilaginous elements and the presence of physes. Interpretation of imaging studies therefore requires an understanding of normal anatomy, normal development, and those variations in normality which could be confused with disease processes. There are exhaustive texts which provide
Fig. 71.1 Serial images in the same child showing the value of different imaging modalities: (a) Radiographs of the knee show extensive soft tissue swelling. No significant bony changes identified. (b) Ultrasound of the same patient shows a joint effusion and synovial thickening. (c) Postcontrast T1 fat-saturated MRI shows synovial thickening and a large joint effusion.

an extensive atlas of these normal variants.[5] In the growing skeleton, there are secondary cartilaginous growth centres around joints (epiphyses) and at the attachment of tendon ligaments to bone (apophyses) An epiphysis typically contributes to longitudinal growth of a bone while an apophysis does not, acting primarily as an insertion site. Both apophyses and epiphyses are separated from the adjacent bone by a physis. These cartilaginous structures are radiolucent on plain radiographs and CT scans and distinction from fractures and bone defects needs to be considered.[6] In the younger child, the epiphyses only become invisible after ossification, with the growth plate between the epiphysis and long bone being identifiable as a lucent line.

Differential diagnosis of joint disease

The differential diagnosis of arthritis in children is extensive and radiographs can be useful at diagnosis in either excluding or confirming the cause for the child's symptoms. An overview of the differential diagnosis of a childhood arthropathy is shown in Table 71.2 and the radiographic features of a number of conditions are shown in Figure 71.2.

Radiographs are most useful for traumatic and mechanical causes of damage. They are valuable in diagnosing avascular necrosis, at whatever site. Depending on the systemic disorder, they may either be diagnostic (such as skeletal dysplasias and storage disorders) or be essentially normal, such as in systemic lupus erythematosus (SLE). Typically, radiographs will diagnose focal malignant conditions (e.g. primary bone tumours), but are less sensitive for systemic malignancy (e.g. leukaemia). With infection, radiographs are often normal within the first few days or weeks and are of minimal value for septic arthritis. If septic arthritis is suspected, this should be regarded as a relative emergency

and diagnosis made by aspiration culture of the joint fluid rather than from imaging.

Radiography in juvenile idiopathic arthritis

In JIA, there are a number of radiographic features which may or may not be present. These are not specific to JIA and need to be placed in the appropriate clinical context. The level of sensitivity for radiographs in detecting inflammatory arthritis, particularly in the acute phase, is very low. The timing and development of any radiographic features will depend on disease duration, severity, and the child's response to treatment.

In early disease, where there is often a hyperaemia associated with the joint inflammation, there may be visible soft tissue swelling and the development of periarticular osteopenia. The osteopenia may become more generalized if the child is treated with steroids or becomes generally immobile due to more widespread disease activity.[7–8]

Periostitis, often around the phalanges, metacarpals, and metatarsals, due to tendon and ligamental inflammation as well as joint disease, can occur relatively early. Classically, but not exclusively, this is seen in psoriatic arthropathy.[7,8,9]

Growth disturbance in the early stages of disease can result in advanced skeletal maturation and epiphyseal enlargement. This is a result of chronic hyperaemia and growth factor release. In more progressive disease, the accelerated maturation will result in early growth-plate fusion and eventually long-term limb shortening. Generalized skeletal remodelling is the result of abnormal muscle tractions, generalized growth disturbance, and limited mobility (Figure 71.3).[7–10]

Abnormal joint alignment, either subluxation, dislocation, or flexion extension deformities, can either result from synovial-based

Table 71.2 The differential diagnoses of childhood arthropathy

Inflammatory	Inflammatory disease: inflammatory bowel disease, sarcoid
	Malignancies: leukaemia, lymphoma, neuroblastoma
	Infection: septic arthritis, osteomyelitis, tuberculosis, lyme arthritis
	Systemic disease: systemic lupus erythematosus, vasculitis, juvenile dermatomyositis, systemic sclerosis
	Chronic recurrent multifocal osteomyelitis
	Transient joint effusion/synovitis
Mechanical	Trauma: accidental and non-accidental injury
	Osteochondroses
	Avascular necrosis and other degenerative disorders: Perthes', slipped upper femoral epiphysis, idiopathic chondrolysis
	Inherited: skeletal dysplasias, congenital dislocation of the hip
	Collagen disorders: e.g. Ehlers–Danlos, Marfan's, Stickler syndromes
	Tumours of cartilage, bone, or muscle:
	benign: osteoid osteoma, pigmented villonodular synovitis, haemangioma, lipoma arborescens
	malignant: synovial sarcoma, osteosarcoma, rhabdomyosarcoma
	Inherited metabolic disorders: hypophosphataemic rickets, hypo/hyperthyroidism, diabetes, purine metabolism
	Storage disorders e.g. mucopolysaccharidoses/lipidoses
	Haematological: haemophilia and haemoglobinopathy (sickle cell disease predominantly)
	Chronic infantile neurological cutaneous and arthritis syndrome (CINCA)
Idiopathic pain syndromes	Local: reflex sympathetic dystrophy
	Generalized: fibromyalgia

Fig. 71.2 Radiographic features of pathological process that can mimic juvenile idiopathic arthritis (JIA): (a) Early fragmentation and irregularity of the proximal left femoral epiphysis. Early Perthes' disease in a 4 year old. (b) AP radiograph in an 8 year old showing fragmentation and sclerosis of the left femoral epiphysis, a shallow left acetabulum, and some remodelling of the left femoral neck. These are the features of chronic Perthes' disease of the left hip. (c) Extensive sclerosis with some cortical expansion of the proximal right femoral metadiaphysis. Within the marked sclerosis, there is a small lucency. Features are of an osteoid osteoma. (d) An unexplained metaphyseal fracture of the distal left tibia in a 9 month old child. There is sclerosis and metaphyseal irregularity. Appearances are of a healing metaphyseal fracture of the distal left tibia. (e) Generalized osteopenia with some more focal lucency within the distal left femoral metadiaphysis and some very early periosteal new bone formation. There are corresponding changes within the femoral epiphysis. These are features of osteomyelitis of the distal left femur. (f) Extensive metaphyseal irregularity, metaphyseal widening, cupping and splaying with widening of the physeal growth plate around the knee joint and the wrist joint. Bones are osteopenic. Classic features of rickets. (g) Metaphyseal lucency of the distal left tibia in a child with leukaemia. (h) AP and frog lateral views of the pelvis in a 12 year old girl showing bilateral slipped upper femoral epiphyses. (i) Metaphyseal fracture (bucket-handle type) of the proximal left tibia. There is cortical destruction, soft tissue expansion, extensive spiculated periosteal reaction, and mixed sclerotic and lytic appearances in the distal left femoral metaphysis in a child with osteosarcoma.

disease or extra-articular damage and processes. In the more chronic treatment-resistant cases, synovial-based disease will lead to joint space narrowing, both cartilaginous and bony erosions, eventually leading to ankylosis (Figures 71.4 and 71.5).[7–10]

With the increasing use of disease-modifying and biological agents in the treatment of JIA, it is important that any assessment of response is reliable, objective, and safe. Consequently, because of the variations in growth and development which occur in the paediatric skeleton, the routine use of radiographs to assess disease, as is often used in adult practice, is questionable. Although a number of radiographic scoring systems have been proposed (Table 71.3) and a number of them validated, with the increasing use of ultrasound and MRI, their role is uncertain.[11–18] However, because of the easy availability and objectivity of scoring systems, their role cannot be completely dismissed.[19] Radiographs are limited in that they do not give any assessment of synovial thickness, size of effusions, or degree of inflammatory change.

Extra-articular rheumatologic disease

Radiographs have a significant role in detecting and monitoring extra-articular aspects of autoimmune and rheumatological conditions.

With the musculoskeletal system these may be complications of the primary disorder such as soft tissue calcification seen in juvenile dermatomyositis (JDMS; Figure 71.6) or iatrogenic, such as the extra-articular calcification seen after steroid joint injections in children with JIA. The differential diagnosis for soft tissue calcification in childhood is given in Table 71.4.

With autoimmune pulmonary disorders, radiographs may show progressive interstitial lung disease, which can be split into three groups based on the imaging findings: nodular, reticular (linear opacities), and reticular nodular (linear and nodular opacities).
Fig. 71.3 Left and right AP radiographs of the wrist joint. The ossification of the right wrist joint is accelerated as a consequence of active disease within the joint. There is some generalized loss of joint space and cortical irregularity as a consequence of the disease process.

Fig. 71.4 AP and lateral radiographs of the left ankle showing severe joint destruction, extensive bony erosive changes, some early ankylosis, and fragmentation.

Fig. 71.5 Lateral cervical spine in a child with longstanding juvenile idiopathic arthritis shows extensive fusion of the facet joints and squaring of the vertebral bodies.

Pulmonary nodules are a relatively unusual finding on a chest radiograph in children. The clinical history is very important in determining the cause of lung nodules (Table 71.5). The use of high-resolution CT (HRCT) will improve the detection and determination of the lung changes.[20,21]

Ultrasonography

Ultrasound is increasingly being utilized in the management of paediatric musculoskeletal disorders. Apart from the fact that it does not involve ionizing radiation, it is relatively portable and can be used by a clinician within the consulting room, without the need for a referral to the radiology department. Ultrasound has the great advantage of being able to image joints, muscles, and tendons in real time motion. This allows the patient to reproduce signs and symptoms during the examination, and the stability and integrity of the joint can also be assessed. Any clinician using ultrasound must be aware of their own limitations and view the images within the appropriate clinical context, to avoid medico-legal consequences of missed pathology.

Role of ultrasound in musculoskeletal practice

Normal synovial membrane is too thin to be seen on ultrasound. Obviously with synovial hypertrophy, it becomes more visible. Synovium can be differentiated from joint effusion due to its vascularity and the fact it can be deformed with probe pressure (Figure 71.7). Increased blood flow on Doppler imaging is indicative of active synovitis, whereas it may be absent in chronic disease.

The joint capsule is a hypoechoic line separating the joint and para-articular soft tissues. Ligaments are also hypoechoic structures about the joint. Importantly, because of their fibrillar structure, they are anisotropic. When the ligament is perpendicular to the ultrasound beam it appears hyperechoic, and when visualized obliquely to the beam there is decreased reflection of sound, making it more hypoechoic.[22]

Tendons are also hyperechoic with a fibrillar echotexture and, like ligaments, demonstrate anisotropy. In children, the tendons often attach to hypoechoic cartilage that surrounds the ossification centre of the bone rather than the bone itself. A small amount of fluid around the tendon sheath is within normal limits.

Ultrasound in juvenile idiopathic arthritis

Within routine rheumatological practice, ultrasound is becoming of increasing clinical importance, and in a variety of anatomical areas it has been shown to be superior to clinical examination. There is increasing evidence that in children with JIA physical examination is neither highly sensitive or specific in identifying synovitis in a wide variety of joints. Ultrasonograhy has shown that subclinical synovitis is not uncommon. Some patients who meet the clinical criteria for remission may continue to show ongoing pathological features on joint ultrasound which may be suggestive of persisting

Table 71.3 Scoring systems

Scoring methods	Type of joints	Sample size	Authors	Reference number
Knee score	Knee	15	Pettersson et al.	18
Poznanski score	Wrist	94	Poznanski et al., Magni-Manzoni et al.	19, 20
Conventional and the modified Larsen's system	Wrists/hands	60	Doria et al.	21
Dijkstra composite score	Hand, foot and knee	66	Van Rossum et al.	22
Sharp and Larsen scoring systems	Wrist/hand	25	Rossi et al.	23
Adapted version of the Sharp/van der Heijde score	Wrist/hand	177	Ravelli et al.	24
Childhood arthritis radiographic score of the hip	Hip	148	Bertamino et al.	25

inflammation.[23–27] Within the ankle joint, ultrasound is more sensitive than clinical examination in determining tibiotalar joint effusions and for assessing tendonopathy.[28]

The implications for ultrasound screening in disease subclassification have yet to be fully evaluated, particularly with reference to subclinical synovitis which is detectable by ultrasound (and in some studies MRI as well). The current International League of Associations for Rheumatology (ILAR) classification determines if a child has oligoarthritis, extended oligoarthritis, or polyarthritis depending on the number of affected joints, based on clinical examination. Obviously, the addition of subclinical joint disease

Table 71.4 Causes of radiographic soft tissue calcification

Clumped/irregular calcification	Scleroderma
	Haemangioma
	Trauma (haematoma/burns/myositis ossificans)
	Synovial sarcoma
	Juvenile idiopathic arthritis (post joint injection)
	Tuberculosis.
	Parosteal osteosarcoma
	Parasitic infection
	Hyperparathyroidism
	Ehlers–Danlos syndrome
'Sheets' of calcification	Myositis ossificans progressiva
	Juvenile dermatomyositis

Table 71.5 Pulmonary nodules

Large pulmonary nodules	Metastatic lung disease, e.g. Wilm's tumour
	Single large nodule: consider round pneumonia
	Wegener's granulomatosis
	Aspergillosis
	Multiple haemangiomas
Small pulmonary nodules	Miliary TB
	Septic emboli (e.g. from central line infection)
	Fungal/candida disease in immunosuppressed patients
	Metastatic disease, e.g. rhabdomyosarcomas, osteosarcoma
	Past history of chickenpox pneumonia (calcified)
	Tuberous sclerosis and histiocytosis (usually cysts are also present)
	Sarcoid
Interstitial lung disease	Interstitial lung disease can be split into: nodular, reticular (linear opacities) and reticular nodular (linear and nodular opacities present)
Reticular	Heart failure causing interstitial oedema
	Idiopathic interstitial lung disease
	Alveolar proteinosis (ground-glass alveolar opacity also present)
	Radiation therapy
	Sarcoidosis (rare in children) nodules usually also present
	Lymphoma (rarely involves the lung parenchyma)
	Secondary to treatment, e.g. immunosuppressants such as tacrolimus
Reticular nodular	Histiocytosis (irregular cysts and nodules usually present)
	Sarcoidosis
	Tuberous sclerosis and neurofibromatosis

will alter a patient's classification, which may have important implications for inclusion in clinical trials or in the use of biological agents.[29,30]

The serial use of ultrasound is valuable in supplementing clinical assessment for disease monitoring and therapy. Ultrasound can be used to objectively assess the size of effusions and the degree of synovial proliferation. Response to steroid injections within the hips and knees has been documented. Colour Doppler provides an indication of the degree of vascularity of the synovial hypertrophy, and assessment of this vascularity may be useful in monitoring disease response.[31,32]

As well as detecting synovitis, ultrasound has been shown to have a role in the detection and evaluation of enthesitis in JIA. The detection of enthesitis is improved by the use of power Doppler and this has been shown to be superior to clinical examination. Particular areas which are useful for ultrasound evaluation are the Achilles, quadriceps insertion, gluteal insertion, and plantar fascia. Ultrasound can be used not only to visualize cartilage, but also assess its thickness.[33] However, ultrasound appears to be less
Fig. 71.7 Ultrasound of the distal femur show marked synovial thickening which is hypoechoic.

reliable in detecting bony erosions than MRI.[33–36] Tenosynovitis can often be detected by ultrasound and this is aided by the peripheral location of many structures. Distinguishing tenosynovitis from joint effusions is useful when subcategorizing JIA.[37,38]

Ultrasound contrast agents will improve detection and evaluation of the vascularity of synovium. This may prove useful in staging disease activity and monitoring disease response.[39,40]

Extra-articular rheumatological disease

The widespread use of ultrasound beyond the joint is well established and its use in rheumatological conditions will depend on the clinical situation. It is well recognized as a sensitive investigation of intra-abdominal pathology and for the assessment of vascular flow. Ultrasound can be used to determine the presence of pleural effusions within the chest and potentially as a guide to aspiration.

Ultrasound has been used to assess the signal intensity of muscle in children with JDMS. Inflamed muscle is relatively hyperechoic and the muscle fibres are typically slightly expanded in more active disease. However, in adult patients suspected of having dermatomyositis or polymyositis, contrast-enhanced ultrasound has been compared with MRI and biopsy findings and the sensitivity, specificity, and predictive values of ultrasound were found to be less than MRI.[41]

Magnetic resonance imaging

MRI does not use ionizing radiation, but utilizes the interaction of magnetic fields and radio waves to create an image. MRI scanners use very strong magnets, which can vary in strength from 0.25 to 3 T. (For comparison, the strength of the Earth's magnetic field is less than 60 µT.)

Positioning of the child within the magnet is important, so that they lie as close to the centre of the magnetic field as possible to improve signal homogeneity and reduce image artefacts. The use of a larger field of view (FOV) will improve the signal-to-noise ratio, but lead to reduction in spatial resolution. A smaller FOV will increase spatial resolution, but will result in loss of signal, and there may need to be a compensatory increase in imaging time and the number of acquisitions.

Typical imaging systems are 1.5 T but there is an increasing availability of 3 T systems; the increased strength can be used to shorten examination times or improve image resolution. Tissue contrast on higher-level systems is not always reproducible, which may lead to interpretation problems if follow-up imaging is performed on different strength magnets, and consequently there may be a need to alter imaging sequences and parameters. With 3 T systems, there is potentially an increased risk from heating effect, noise, and bore size causing claustrophobia, which may cause some problems for some imaging of children.[42]

Depending on the send and receive parameters, the same tissue may appear bright or dark on the resultant image. In routine practice, the spin echo sequences are commonly used. These are termed either T1 weighted or T2 weighted, depending on the send and receive time of the radio waves used. A joint effusion is high signal on a T2-weighted sequence, and low signal on a T1-weighted dequence. Signal intensities of common structures on different sequences are listed in Table 71.6. In addition to these baseline echo sequences, vast numbers of other sequences and image protocols are available. Many of these are specific to certain manufacturers' own systems, but essentially they enable

Table 71.6 Common cause of high and low signal intensity appearances on T1- and T2-weighted spin echo sequences on 1.5 T MRI

T1-weighted image	
Low signal (dark)	Increased free water (oedema, tumour, infarction, inflammation, infection)
	Haemorrhage (hyperacute or chronic)
	Low density of protons (calcification, fibrous tissue, bone cortex)
	Flow void
High signal (bright)	Fat
	Subacute haemorrhage
	Melanin
	Protein-rich fluid
	Slow-flowing blood
	Paramagnetic substances: gadolinium, manganese, copper
	Calcification (rarely)
T2-weighted image	
Low signal (dark)	Low density of protons (calcification, fibrous tissue)
	Paramagnetic substances: deoxyhaemoglobin, methaemoglobin (intracellular), iron, ferritin, haemosiderin, melanin
	Protein-rich fluid
	Flow void
High signal (bright)	Increased water (oedema, CSF, tumour, infarction, inflammation, infection)
	Methaemoglobin (extracellular) in subacute haemorrhage
	Fat

the radiologist to tailor an MR examination to the exact clinical requirements.

Gadolinium is an intravenous contrast agent which is used with T1 weighted sequences; its uptake causes enhancement (increased signal) in areas of hypervascularity and disrupted cell membranes, hence inflamed synovium shows marked enhancement.

Role of MRI in musculoskeletal practice

The multiplanar ability, excellent image contrast, and tissue resolution of MRI is well recognized and its role in paediatric musculoskeletal disease is firmly established. In view of its relatively high cost, lengthy imaging time, and availability, MRI is not predominantly used as a first line investigation.

A water-sensitive sequences is needed for the detection of fluid, marrow oedema, and soft tissue inflammation. The most widely used are either short tau inversion recovery (STIR) or fat-suppressed T2-weighted spin echo sequences. On both these sequences, water is seen as high signal intensity. The signal intensity of muscle is typically higher on STIR sequences, so subtle change in muscle inflammation may be missed. Fat-suppressed T2 weighted sequences are more efficient, with more slices per given unit of time, but more susceptible to magnetic field in homogeneities and where the body part is outside the centre of the magnetic field.[42]

For general anatomy and assessment of the bone marrow, which is typically fatty from early childhood, a T1-weighted sequence is very useful. Proton density or intermediate weighted images have a relatively high signal-to-noise ratio and are helpful in depicting finer detail around joints. There are continuing developments in MR technology to create specific sequences for different anatomical areas within the joint. For instance, considerable research is being performed on imaging the cartilage and creating sequences which show the cartilage as high signal, and postprocessing techniques that allow measurements of the cartilage volume. Other sequences can demonstrate the level of hydration of the cartilage.[43–45]

Following gadolinium administration, normal enhancement occurs within the physis, the adjacent metaphyseal tissue, and the vascular channels supplying the epiphyseal ossification centre. Normal synovium, if not undetectable, may be seen as a thin, uniform rim around the articular surface. The addition of fat saturation techniques are valuable following gadolinium administration to suppress the high signal (T1 weighted) from adjacent fatty marrow, increasing the sensitivity of the imaging. STIR sequences should not be used in this regard as signal from gadolinium will also be suppressed.[5,42,43]

Contrast-enhanced MRI more reliably differentiates synovial inflammation, which shows increased contrast enhancement as it is of high signal on T1-weighted images, from non-enhancing joint effusions (Figure 71.8). Gadolinium will also discriminate between active hypervascular destructive pannus and inactive fibrous tissue. It is useful in evaluating infection, areas of avascular necrosis, and abscess formation.[46]

Clinical indications

MRI is sensitive and quite specific in detecting the site and severity of joint disease in children with arthritis, as well as assessing soft tissue and muscle involvement in other inflammatory conditions. It is the most sensitive imaging modality for the detection of ongoing synovial inflammation. MRI is superior to clinical examination and has been shown to detect persistent synovitis in subclinical patients as well as potentially predicting synovial disease in unaffected joints.[47] Its role is pivotal in selecting children for treatment options and monitoring treatment efficacy.[46,48]

It allows assessment of joints which are clinically difficult to image in other ways as well as being challenging to examine clinically, particularly the sacroiliac, temporomandibular, and subtalar joints (Figure 71.9).

Synovial inflammation

MRI is very sensitive in detecting synovial proliferation and assessing its extent and, in some cases, volume. The use of post gadolinium imaging is the most sensitive technique; this is either used with fat saturation techniques (where the signal intensity of fat is reduced) or with subtraction techniques (pre- and postcontrast images are subtracted from each other, just leaving the postcontrast changes). Gadolinium improves the contrast between enhancing hypervascular synovium and surrounding tissues. Post gadolinium images allow reliable differentiation from joint effusion and differentiation between destructive hypervascular synovium and more chronic inactive fibrotic tissue. It has been shown that the sensitivity of MRI is greater than that of clinical examination, and detection of subclinical synovium may predict disease extension.[46–49]

To assist in more objective measurement of disease, there has been an emphasis on measuring the degree and nature of inflammation with MRI. The measurement of synovial volume as a way of evaluating disease activity and response to treatment has been assessed within adult practice,[50] and the feasibility to do this in children is being researched.[51] It may be that synovial volume as a whole rather than maximum synovial thickness is the better marker for the degree of clinical synovitis. Certainly, reduction in synovial volume and a degree of enhancement correlates with improved clinical response.[52,53]

The other potentially objective measure of synovial activity is assessing the dynamics of contrast enhancement. Since the rate of contrast enhancement is increased by greater hypervascularity and capillary permeability, then the greater the inflammatory response within a tissue, the higher the rate of contrast enhancement. Dynamic contrast enhancement has been shown to be a sensitive and relatively accurate method of assessing synovitis and therapy response in adults.[54–55]

While both volume assessment and dynamic contrast enhancement are being increasingly utilized, they require a significant amount of postimaging processing, significant research resource, and appropriate computer software.

Bone marrow oedema

On MRI, the signal intensity of bone marrow will alter depending on the amount of haemopoietic and fatty marrow. Bone marrow oedema reflects the increased signal seen within the bone marrow on T2-weighted images, which in most cases reflects localized inflammation and increased water content (marrow oedema). Caution must be taken, as in certain individuals signal intensity changes may occur within the marrow which just reflects normal growth and maturation of the bone marrow.[55] This can cause confusion between normal physiological change and bone marrow oedema/early erosions. An understanding of normal physiological changes and the age of these changes is required. In particular, patchy signal change within the foot is well recognized and should not be confused with erosive disease.[56,57]

Localized bone marrow oedema has been shown to correlate with erosive damage in adults with rheumatoid arthritis.[58–60]
Fig. 71.8 Serial MRI demonstrating the use of gadolinium as a contrast agent: (a) T2-weighted sagittal image of the knee showing a large effusion and popliteal lymphadenopathy. (b) T1-weighted images in the same patient confirm the presence of the effusion and lymphadenopathy. (c) Postcontrast T1 fat-saturated image demonstrates the marked enhancement of the synovium (high signal intensity) surrounding the fluid (low signal intensity) within the suprapatellar bursa. The popliteal lymph nodes are also enhanced.

Histological studies in adults have shown that areas of bone marrow oedema on MRI contain inflammatory cellular infiltrates which may suggest a mechanism to explain the development of erosions.[61] The exact significance of bone marrow oedema and its prognostic evaluation in terms of erosive change in JIA is undefined. The presence of bone marrow oedema and its implication in terms of treatment in JIA is unknown.

Cartilage imaging

MRI is able to directly visualize both articular and growth (epiphyseal and physeal) cartilage. Consequently, a proper assessment of cartilage damage is possible. The assessment of cartilage has been significantly improved in recent years by the use of dedicated MR sequences, allowing assessment of thinning, erosions and signal change.[42,43,45]

With ultra-short TE sequences, driven equilibrium Fourier, and steady-state free procession sequences, high-resolution volume acquisitions allow significant postprocessing manipulation to detect subtle surface irregularity and tiny focal defects of the articular cartilage.

Bone erosions

Bone erosions are typically well-defined subcortical lesions and may contain either fluid or synovial tissue. MRI is able to detect
Fig. 71.9 Axial T2-weighted images through the ankle joint showing effusions around the extensor and peroneal tendons.

Fig. 71.10 Coronal STIR images in a child with juvenile dermatomyositis. There is bilateral symmetrical muscle oedema with a preponderance for proximal muscle involvement.

subchondral changes within the bone prior to any obvious radiographic changes. The significance and long-term outcome of the subchondral changes and whether or not they are true early erosions is a cause for debate. However, it is recognized that MRI is more sensitive in detecting erosions than either ultrasound or radiography.[33,34,58,61] Studies in adults demonstrate significant prognostic value of MR-detectable lesions with respect to long-term radiographic damage.[55,61,62,63] Erosions on MRI may be associated with cartilage loss. The bone defect may be fluid filled or filled with synovium; with the latter, there will be enhancement following gadolinium administration.

Muscle disease

MRI is the most sensitive investigation for evaluating myositis. Its specificity in classical JDMS is high. Abnormal increased signal intensity on T2-weighted images is seen in skeletal muscles in nearly all patients with acute symptoms of myositis; in JDMS, the distribution is typically proximal (Figure 71.10). The increased T2 signal is believed to represent an acute accumulation of extracellular water and recent-onset microinfarction. The use of whole-body MRI permits a global view of the muscle groups and is useful in clinical monitoring and follow-up. MRI can also facilitate biopsy.[64–67]

MRI techniques can be used to evaluate the degree of inflammatory activity within the muscle, which may provide an objective measure of disease activity. Techniques that have been employed include T2 mapping, which relies on relaxation times of the muscle.[68] Diffusion-weighted MRI can provide tissue fluid motion data to differentiate capillary blood flow from intra- and extracellular compartmental fluid.[67] Phosphorus spectroscopy has also been used to evaluate the constituents of inflammatory muscle.[69]

In more chronic disease, there is increased fat deposition within the muscle. Calcification deposition, which can occur in JDMS, may be related to signal change within the subcutaneous fat.[70]

Vascular imaging

Children who have a variety of autoimmune conditions may be at a significant risk of vascular and cerebral involvement. Magnetic resonance angiography (MRA) can provided detailed imaging of both peripheral and cerebral blood vessels and demonstrate stenoses or small aneurysms. HRCT is also very useful, but involves a radiation dose. In both CT and MRI the image quality is typically sufficient to avoid formal interventional angiography.

MRI is the modality of choice to assess for changes of cerebral vasculitis and SLE. In SLE, there may be focal infarcts and multiple areas of high signal on T2-weighted images, indicating microinfarcts. Multiple white-matter lesions are often associated with neuropsychiatric symptoms.

Computed tomography (CT)

CT utilizes X-radiation to produce an image. As opposed to conventional radiography where a single X-ray beam is passed through the body, with CT, multiple beams are passed through the patient and absorbed by a number of detectors. The current generation of dual-energy CT scanners have two X-ray beams of different voltage, allowing greater image manipulation, reduced radiation dose, and decreased scan times.

Role of CT in musculoskeletal practice

CT is very valuable in the assessment of skeletal injuries. It is the imaging modality of choice following major trauma, being both fast and sensitive in the detection of intracranial, thoracic, abdominal, and skeletal injures. It is essential in the acute management of the severely injured child.

CT is also useful in the assessment, treatment planning and follow-up of peripheral fractures. It is complementary to MRI in the evaluation of spinal pathology including spondylolysis.[71]

With regard to rheumatological conditions, the use of CT is relatively limited. It provides excellent resolution of bony detail, but it is not as sensitive as MRI in the assessment of soft tissues and intra-articular pathology. CT imaging involves a significant radiation dose and so there needs to be a clear indication for its use.

Within the chest, HRCT is the modality of choice for the assessment of lung parenchyma; it allows detection and characterization of the pattern of distribution of interstitial lung disease. CT angiography can be used to assess the vascular anatomy, including the detection of aneurysmal disease, stenosis, and thrombus.

Bone scintigraphy

Radionuclide imaging has a relatively limited role in the musculoskeletal system. It can be used to assess multiple foci, such as in multifocal osteomyelitis. It may be helpful in assessing for fractures or tumours. It has a limited role in the assessment of joint disease.

The procedures involve a relatively high radiation dose and while they are relatively sensitive, they are of low specificity. The most commonly used isotope is technetium-labelled methylene disphosphonate (^{99m}Tc-MDP). This isotope is taken up by osteoblasts and therefore reflects areas of increased bone turnover. ^{99m}Tc-MDP has a half-life of 6 hours, which means that half the radionuclide activity will have disappeared in 6 hours. The amount of activity to be injected will depend on the body weight and the age of the child. Less than 70% will be taken up by the bone and soft tissues, with the rest renally excreted. This will result in a relatively high affective dose to the body. Consequently, the use of bone scintigraphy should be reserved for specific cases.

The uptake of ^{99m}Tc-MDP in bone depends on the metabolism of phosphates which are absorbed by bone and absorbed into the matrix. The uptake is related to local blood supply, rate of bone turnover, the quantity of mineralized bone, local capillary permeability, and the fluid pressure within the bone. It is possible to image within an early vascular phase to assess the blood flow to a lesion followed by delayed static phases to assess bone turnover.

Single photon emission CT (SPECT) is a technique which increases spatial information, improving the sensitivity of the bone scan, particularly in those areas where there is overlapping bone, such as the spine.

The relative dose with radionuclide imaging is high and in most clinical situations an alternative, often non-ionizing investigation, can be employed. Whole-body MRI is being increasingly used instead of radionuclide studies to image the whole of the skeleton in order to assess for widespread skeletal lesions, such as metastases, and in Langerhans cell histiocytosis.

CHAPTER 72

Assessment of synovial joint fluid

Engy Abdelattif and Anthony J. Freemont

Introduction

Normal synovial fluid

Normal synovial fluid (SF) enables joint lubrication[1] and cartilage nutrition.[2] It is formed from a transudate of plasma supplemented by other molecules (complex lipids, proteoglycans, and peptides), synthesized largely by fibroblast-derived type B synoviocytes.

There is no physical barrier between SF and the matrix of articular cartilage or synovium. This allows fluid flow through the tissues lining the joint, particularly during loading, and the development of a relatively uniform chemical environment.

Debris and particulate material are cleared from the joint by macrophage-derived type A synoviocytes. A lack of physical barriers allows inflammatory cells to migrate into the synovial fluid and chondrocytes to enter SF from the cartilage surface.

Thus normal SF is a viscous, hypocellular, fluid containing a mixture of synovium and cartilage-derived cells. Its chemical composition reflects that within the synovium and cartilage.

Synovial fluid in diseased joints

During disease, joints often swell by accumulation of SF. This reflects alterations in the permeability of the synovial vasculature.

The chemical and cellular composition of SF changes in disease with alterations of the environment in synovium and cartilage. Although some of the biochemical changes are predictable, others can only be explained on the basis of a degree of partitioning between synovium, SF, and cartilage, based on differences in their composition and the ease with which cells and molecules move within and between them. In addition, during disease, particulate material derived from, or formed within, the joint accumulates in SF.

The fact that the chemical, particulate, and cellular composition of synovial fluid changes with disease means that analysis of these components of SF can be used as the basis of diagnostic (and prognostic) tests. Particles and cells can be recognized by microscopy, and chemical biomarkers by assay.

Synovial fluid microscopy

SF microscopy has been carried out as a diagnostic test for years. Unfortunately it is not always done well, limiting its value to the rheumatologist.[3] As such, it does not have a high credibility. However, detailed microscopic analysis of SF by specialist histopathologists/cytopathologists can yield useful information about the nature of joint diseases and their prognosis.[4,5] For instance, in one published study[6] using algorithms based on microscopy alone (Figure 72.1) we examined 200 consecutive SF samples without knowledge of any clinical details, comparing blinded cytological and clinical diagnoses at the end of the study. Matching diagnoses were made in 35.5% and a short list of differential diagnoses (e.g. seronegative spondylarthropathy), was proffered, which included the clinical diagnosis, in a further 21.5%. Of the rest, 31.5% were correctly described as inflammatory or non-inflammatory and in 2.5% no diagnosis could be made. Only in 3.5% was a false-positive cytological diagnosis made.

Basic approach to synovial fluid microscopy

The following is a guide to show the diversity of cells and particles and how their identification can be used diagnostically.[7–9]

Specimen handling

As SF is 'fresh', it should be examined within 24 hours of aspiration. Examination should be undertaken in such a way as to minimize potential infection risks. Similarly, as inflammatory SF contains fibrin and tends to clot, it is essential that samples should reach the laboratory in anticoagulant. Crystalline anticoagulants should be avoided, for obvious reasons.[4]

Visual and microscopic examination of synovial fluid

The examination of SF is in four parts.

Visual analysis

The colour, turbidity, and presence of obvious particles are recorded. Colour gives important information (e.g. presence of haemorrhage or chromogen-producing organism) and turbidity gives data on the number of particles (cells, crystals, etc.) in the fluid.

Nucleated cell count

Manual counting using a haemocytometer chamber is the traditional way to count nucleated cells; nowadays automated computerized instruments are available.

For convenience of handling large numbers, the SF nucleated cell count is traditionally expressed as cells/mm³. Normal SF contains

Cell count <1000/mm³

| 1) Urate crystals present
"Quiescent" gout | ↔ | 1) Prosthetic debris present?
Prosthesis wear |

| 1) OA cartilage OR
2) Hydroxyapatite OR
3) Pyrophosphate

OA | ↔ | 1) Frankly
haemorrhagic/xanthochromic OR
2) Fragments of meniscus or
ligament OR
3) Lipid droplets
Traumatic arthropathy |

Non-inflammatory arthropathy ←

Cell count >1,000/mm³ and <30,000/mm³
Ask – could cell count be due to haemorrhage?

| 1) Organisms present OR
2) Ragocytes >90% AND
polymorphs >90% OR
3) Patient has an arthroplasty and
cell count >1,700/mm³
Infective arthritis | ↔ | 1) Crystals present (Identify)

Acute crystal arthropathy |

| | | 1) Ragocytes   exceed 70% OR
2) >50% of polymorphs apoptotic
OR
3) Hydroxyapatite present?

Rheumatoid disease |

| 1) Mast cells or CPM present

***Seronegative
spondylarthropathy*** | ↔ | 1) Macrophages >80%

Viral arthritis |

| 1) Lymphocytes >70% AND LE
cells present

SLE | ↔ | 1) Lymphocytes exceed 70%

***Mycobacterial infection,
SLE, Good prognosis RA
Lymphocytic arthritis*** |

| 1) Macrophages or lymphocytes
exceed polymorphs?

***Seronegative type of
primary inflammatory
arthropathy*** | ↔ | ***Primary inflammatory
arthropathy*** |

Cell count >30,000/mm³

| 1) Crystals present (Identify)
Acute crystal arthritis | ↔ | 1) Bacteria present OR
2) Ragocytes >90% AND
neutrophils >90% OR
3) Patient has an arthroplasty

Septic arthritis |

| 1) CPM, mast cells or both
present
Reactive arthritis | ↔ | 1) Ragocytes >70%
Rheumatoid disease |

| ***Primary inflammatory
arthropathy*** | ↔ | |

Fig. 72.1 Three diagnostic algorithms starting with the nucleated cell count, for the analysis of synovial fluid by microscopy.

Fig. 72.2 Two different types of crystal (A, urate; B, pyrophosphate) viewed in polarized light with a quarter-wave interference plate. Note the difference in crystal shape and brightness, and the difference in colour of crystals with aligned long axes.

The sample is squeezed beneath a cover slip and examined for crystals, particles (synovial villi, fragments of meniscus/ligament, osteoarthritic cartilage), and one cell type, the ragocyte.

Crystals   Crystals are a common finding in joints. The most frequently encountered are sodium urate, calcium pyrophosphate, lipid and hydroxyapatite. Detection is not as straightforward as is sometimes believed, but being able to obtain accurate, reproducible results has important clinical implications.[10,11] The easiest way to distinguish between crystal types is on the basis of shape, size, brightness in polarized light and how they interact with a phase-shifted polarized light path. In the latter it is customary to set up the microscope with a quarter-wave interference plate between the crossed polarizers. This creates a red background. Crystals placed between the quarter-wave plate and the analyser plate will shift the wavelength of the incident light and render the crystal coloured. Depending on the orientation of their long axes, crystals appear yellow or blue (Figure 72.2). The direction of the long axis of a crystal of a specific colour varies with the crystal type.

In very general terms the common crystals are:

◆ **Urate**: Crystals are 5–35 μm long, highly birefringent, needle-shaped, and soluble in water. Lipid crystals mimic urate but are insoluble in water and usually found in lipid droplets. Urate crystals are usually found on the background of acute inflammation, the most common presentation of gout. However, in some cases the interval between presentation and aspiration is such that the disease may be in a relatively quiescent phase and the fluid 'non-inflammatory' when aspiration occurs. In 1–2% of cases of acute gout there is a concomitant infection which may be masked by the acute crystal arthropathy.

fewer than 200 cells/mm³. In inflammatory joint disease the cell count is greater than 1000 cells/mm³ and in non-inflammatory arthropathies it is lower. Cell counts in excess of 30 000 cells/mm³ are restricted to a few clinical conditions: acute rheumatoid flares (including disease flares in patients previously stable on treatments with agents such as anti-tumour necrosis factor (TNF) drugs and septic, acute crystal. and reactive arthritis.

'Wet preparation' (WP)

This is shorthand for an unstained preparation viewed in a disorganized light path, formed by partially closing the condenser diaphragm on a conventional light microscope. The WP is also viewed in polarized light.

The WP is made by agitating the sample and aspirating a small amount using a conventional bulb pipette. Every effort should be made to include visible particles in the sample as they often sequester crystals.

◆ **Pyrophosphate**: Crystals are rhomboidal and appear less bright in polarized light than urate crystals. They accumulate in joints with increasing age and may cause no symptoms (chondrocalcinosis). In osteoarthritis (OA) crystals accumulate on the background of a non-inflammatory arthropathy.[12] Microscopy is particularly useful in distinguishing pseudogout from gout.

◆ **Hydroxyapatite**: Crystals indicate damage to calcified cartilage or underlying subarticular bone. This occurs most commonly in the non-inflammatory OA and inflammatory rheumatoid disease (RA), following joint replacement surgery, and in avascular bone necrosis. The crystals are small and granular, are not birefringent but can be rendered so by staining with Alizarin Red stain. 'Milwaukee shoulder' (and equivalents in other joints), is characterized by SF microspheroidal aggregates of hydroxyapatite crystals.[5]

◆ **Lipids** enter the joint through 'leaky' vessels in either longstanding inflammation or haemorrhage. They often appear as droplets with a Maltese cross pattern (liquid spherical crystal) when polarized or as urate-like needle-shaped crystals within a droplet of neutral fat. Occasionally lipids may themselves be phlogistic.[13] Intra-articular depot corticosteroid crystalloids may still be found up to 10 weeks after injection and may lead to the wrong diagnosis of pyrophosphate arthritis.

Other rarer crystals are also found in SF. For a full description see Freemont and Denton.[4]

Non-crystalline particles   These can consist of fragments from damaged intra-articular structures, fibrin, and material introduced accidently or therapeutically. The most common examples of the former are fragments of articular cartilage or, specifically in the knee, internal ligament and meniscus; the latter include, particles of metal, plastic polymer, and bone cement.

In OA, the most common disorder in which cartilage fragments appear in SF, tiny fragments of fibrillated cartilage, often containing chondrocyte clusters, can be identified (Figure 72.3) In knee trauma diagnostically useful fragments of meniscal fibrocartilage and intra-articular ligaments can be detected.

Wear of implant material can lead to foreign material within the joint. Modern plastic polymers used as articulating surfaces in joint prostheses (such as ultra-high-density polyethylene), bone cement, and composite (e.g. carbon fibre) fragments can be mistaken for crystals when they fragment. The presence of wear particles is not, in itself, evidence of loosening or failure, but wear particles are a feature of both actual and incipient loosening and are frequently present in patients with painful arthroplasties.

Ragocytes   Ragocytes are cells first described in RA.[14] They are not a cell type as such but rather a phenomenon in which any cell type (but most commonly polymorphs) accumulate large refractile granules within their cytoplasm. Despite their name ragocytes are not restricted to the SF in RA; however, finding that 70–90% of the nucleated cells in the WP are ragocytes is practically diagnostic of RA. Similarly, greater than 90% is a very strong independent biomarker of septic arthritis (specificity and sensitivity >90%).

Cytocentrifuge preparation
Adequate cytological analysis of SF requires a cytocentrifuge preparation. Optimal SF preparations involve diluting to 400 cells/mm^3 and staining with Giemsa, except when septic arthritis is suspected, when the greatest likelihood of identifying organisms is afforded by diluting to 1200 cells/mm^3 and staining with Gram stain.
Fig. 72.3 Unstained osteoarthritic cartilage viewed in diffused light on a conventional light microscope. Note the chondrocyte clusters typical of osteoarthritis (arrowed).

Septic arthritis   Septic arthritis (SA) is an important but difficult diagnosis to make.[15] Careful microscopic examination of Gram-stained preparations is required (most SA is caused by Gram-positive organisms[16]). This approach detects microorganisms within 1–2 hours of the sample arriving in the laboratory (Figure 72.4). The greatest problems in diagnosing SA are failure to recognize Gram-negative organisms and distinguishing contaminating organisms from pathogens.

Immunosuppressed patients have an increasing incidence of non-suppurative infectious arthritis, particularly caused by mycobacteria and fungi.

In septic arthroplasty loosening SF cell counts as low as 1100 cells/mm^3 plus neutrophil differentials in excess of 64% are described as sufficient evidence to diagnose infection in 98.6% of cases.[17]

Cell types and diagnosis   Many cell types are identifiable in Giemsa-stained cytocentrifuge preparations. The nature, and in some settings the proportion of cells (polymorphs, lymphocytes, macrophages, cytophagocytic mononuclear cells (CPM), and mast cells) are key diagnostic tools.

Neutrophils   Neutrophils predominate in the SF in most inflammatory arthropathies, and in haemarthroses. In the seronegative arthropathies, however, lymphocytes and macrophages may exceed polymorphs in number. Acute crystal and SA are the only disorders in which neutrophils regularly account for more than 95% of nucleated cells.

Lymphocytes   Finding a predominance of lymphocytes in a sample of SF from a patient with RA usually indicates a better long-term
Fig. 72.4 Gram stain showing Gram-positive cocci in a sample of synovial fluid from a patient with septic arthritis.
Fig. 72.5 Cytophagocytic mononuclear cells in a Giemsa-stained sample of synovial fluid from a patient with a seronegative spondylarthropathy. The arrow points to a polymorph apoptotic body in the cytoplasm of a macrophage.

prognosis for the joint. Lymphocytes also predominate in systemic lupus erythematosus (SLE).

Macrophages and CPM   Macrophages predominate in viral arthritis, Milwaukee shoulder and prosthetic-debris-induced arthropathy. CPM are macrophages that have phagocytosed apoptotic polymorphs (Figure 72.5. They are abundant in the seronegative spondyloarthropathies,[18] and if they are found a confident diagnosis can be made. In RA, apoptosis occurs in the absence of CPM formation.

Mast cells   Mast cells are seen most commonly in the seronegative spondyloarthropathies and in traumatic arthritis.[18]

The place of synovial fluid microscopy in diagnosis

Synovial biopsy is the investigation of choice in diseases where morphology is an imperative for diagnosis (e.g. granulomatous inflammation, villonodular synovitis); however, in almost every other clinical setting SF analysis is a more powerful diagnostic tool,[19] particularly in:

- differentiating between inflammatory and non-inflammatory arthropathies
- identifying specific disorders within these two groups
- diagnosing mono- and oligoarthropathies
- the rapid diagnosis of joint disease, in particular in suspected cases of SA where prognosis is inversely related to the delay in diagnosis.

Synovial fluid microbiology

Diagnosing infective arthritis is a major clinical problem and, as described, microscopic SF analysis has an important part to play.[20]

Culture is also important, but it is essential (and quick) to exclude crystal arthropathies by SF microscopy before sending specimens for culture. In addition to common bacterial joint pathogens (*Staphylococcus*, *Streptococcus*, etc.), *Neisseria*, *Salmonella*, *Mycobacterium tuberculosis*, fungi, and viruses requiring special culture methods should also be considered.

New techniques, particularly polymerase chain reaction (PCR) of SF looking for widely expressed nucleic acid sequences such as the 16S ribosomal component shared by many bacteria, may expand the future pool of diagnostic techniques.[21]

Serum procalcitonin (PCT) levels, used to diagnose systemic infection, are elevated in SA.[22] PCT levels are very variable in the SF in infective arthritis because of sequestration in fibrin (Figure 72.6) The role of PCT in infection is unknown but in the SF it binds to bacteria internalized in neutrophils (Figure 72.7), so it may have a role in opsonization.

Chemical changes in the synovial fluid in disease

Normal SF chemistry is extremely complex, as outlined in Table 72.1. As SF is in part a transudate, variations in disease may reflect alterations in either the blood or the joint. There is still a great deal to learn about the biochemical changes that occur in specific diseases, but the application of emerging 'omics' technology will make this possible.[23]

Most of the alterations in the biochemistry of SF relate to non-disease-specific processes, nevertheless they may be very useful in guiding therapy.

Levels of inflammatory mediators (cytokines,[24] proteases,[25] eicosanoids[26]) are elevated in the SF of 'non-inflammatory' and
Fig. 72.6 Fibrin from the joint of a patient with septic arthritis stained by immunohistochemistry for procalcitonin (brown reaction product). Note the waves of deposition (arrowed).
Fig. 72.7 Ultraimmunohistochemistry to localize procalcitonin in the cytoplasm of a polymorph from the synovial fluid of a patient with septic arthritis. The black circles are reaction product and are attached to bacterial (B) cell walls. The polymorph nucleus (N) can also be seen.

Table 72.1 Biochemical parameters of normal synovial fluid (indicative levels)

Osmolarity	300 mosmol/L
pH	7.44
PCO_2	6.0 kPa
PO_2	<4.0 kPa
Potassium	4.0 mmol/L
Sodium	135 mmol/L
Calcium	1.8 mmol/L
Urea	2.5 mmol/L
Uric acid	0.25 mmol/L
Glucose	100 mmol/L
Chondrotoin sulfate	40 mg/L
Hyaluronate	2.2 g/L
Total protein	25 g/L
Albumin	8 g/L
α_1-Antitrypsin	0.8 µg/L
Haptoglobin	90 mg/L
α_2-Macroglobin	0.3 g/L
IgG	2.6 g/L
IgA	0.9 g/L
IgM	0.2 g/L
IL-1b	20 pg/mL
IL-2	15 U/mL
TNFα	1.4 ng/mL
INFα	350 U/mL

Ig, immunoglobulin; IL, interleukin; INF, interferon; TNF, tumour necrosis factor.

'inflammatory' arthropathies. Antibodies (e.g. rheumatoid factor) have been described in SF, reflecting local production.

Changes in SF complement levels occur with local joint inflammation and, in RA, complement breakdown products correlate with the extent of synovitis. There is evidence that complement can be regulated by cartilage oligomeric matrix protein (COMP) in a disease-specific manner.[27]

Products of cartilage degradation assayed in SF change with tissue degradation in an enzyme-specific manner, exposing unique sites within the peptide chain. Similarly, synthesis of new proteoglycan molecules may result in expression of sugar motifs not usually found in adult cartilage. Assays of potential markers of synthesis and breakdown of collagens, proteoglycans, and a variety of non-collagenous proteins with connective tissue matrices are now being developed for research purposes and may gain use as diagnostic and prognostic tools.[28,29]

Conclusion

SF is: easy to aspirate, intimately associated with potentially diseased joint tissues, and increased in a broad spectrum of joint disorders. Despite this, it seems to have been an underexploited source

of cellular and non-cellular biomarkers of diagnostic and prognostic value. An appraisal/reappraisal of new and old analytical technologies is required if the full potential of SF in patient diagnosis and management is to be realized.

Cardiopulmonary investigations

Benjamin E. Schreiber, Gregory J. Keir, and J. Gerry Coghlan

Introduction

Rheumatological conditions frequently involve the cardiac and respiratory systems. In this chapter we aim to survey appropriate investigations for common clinical indications and to review the strengths and weaknesses of the more commonly performed tests.

The need for cardiopulmonary investigations is driven by clinical concern. Cardiopulmonary investigations may be required as part of screening for disease in high-risk groups or to diagnose or guide treatment of disease.

There is a huge array of cardiac and pulmonary investigations available to the clinician. Obviously the clinical use of the tests cannot be encapsulated in one chapter. We present suggested investigation routes for particular clinical contexts, and then review individual investigations with their respective indications, strengths and weaknesses.

Indications

There is often considerable overlap in symptoms between diseases affecting the cardiac or respiratory symptoms in the setting of rheumatological disease. Shortness of breath, chest pain, and palpitations may be due to disease in either system and a detailed history and physical examination, coupled with an understanding of comorbidities common to individual rheumatological conditions, help to refine pretest probabilities. Furthermore, while virtually any component of the cardiac or respiratory system may be affected, 'typical' patterns of heart and lung involvement are recognized in individual rheumatologic diseases and this knowledge helps to further direct an appropriate investigation pathway.

Shortness of breath

Shortness of breath accompanied by symptoms of cough, wheeze, or sputum production suggests a primary respiratory process, and initial investigation with chest radiography, spirometry, and sputum analysis is appropriate. If cardiac involvement is suspected, electrocardiography, natriuretic peptides, and echocardiography may be useful.

At times, the cause for dyspnoea is not readily apparent following simple first-line investigations, and the diagnostic algorithm needs be broadened to include 'blind spots' which are more difficult to easily assess. Pulmonary vascular disease such as pulmonary hypertension, pulmonary thromboembolic disease and pulmonary vasculitis, interstitial lung involvement, and myocardial disease require a high index of suspicion to allow timely diagnosis.

Extrathoracic manifestations of rheumatological disease including musculoskeletal disease and deconditioning should also be considered when evaluating dyspnoea. Patients who are markedly short of breath without hypoxia may have non-cardiopulmonary causes of dyspnoea, and pulse oximetry with exercise, a simple, easily performed screening test, may provide vital information.

Cough

The British Thoracic Society distinguishes acute cough (<3 weeks) from chronic cough (>8 weeks).[1] Acute cough should be investigated with chest radiography if it is accompanied by haemoptysis, breathlessness, fever, chest pain, or weight loss. Patients with significant haemoptysis or any possibility of foreign body inhalation should be referred for urgent bronchoscopy. Patients with breathlessness and acute cough should be assessed for possible asthma or anaphylaxis. Patients with chronic cough should be investigated initially with chest radiography and spirometry with reversibility testing. If these show no obvious pulmonary pathology and there are no avoidable cough triggers, referral to a specialist clinic is recommended.

Chest pain

The current United Kingdom National Institute for Health and Clinical Excellence (NICE) guidelines (CG 95) group recommendations by the pretest probability of ischaemic heart disease. Patients with low probability (10–29%) are investigated with CT calcium scoring, those with intermediate probability (30–60%) are offered functional imaging, and those at high risk (61–90%) are offered coronary angiography.[2] Functional imaging modalities detect stress-induced wall motion abnormalities or hypoperfusion using nuclear medicine (MPS), echocardiography or MRI.

Syncope

European guidelines recommend initial investigation of patients with transient loss of consciousness with careful history, including assessing for a family history of premature coronary artery disease or sudden cardiac death, physical examination including orthostatic blood pressure measurements, and electrocardiogram (ECG). In patients with syncope even very subtle ECG abnormalities (such as T-wave inversion in septal leads) may be important. Additional investigations include carotid sinus massage in patients over the age of 40. Further investigations are guided by clinical suspicion: echocardiography in patients with known or suspected heart disease, ECG monitoring when there is suspicion of an arrhythmic cause, and orthostatic challenge when postural causes are suspected.[3]

Rheumatological considerations

The heart and lungs are affected in many ways in rheumatological disease, and the prevalence of differing complications is often difficult to accurately define. Many rheumatological diseases are relatively rare, with significant clinical heterogeneity in disease manifestations. Methodological differences in case ascertainment and differences in the definition of cardiac and pulmonary disease have further hampered accurate definition. Nonetheless, there are associations between certain rheumatological conditions and a predilection for particular cardiopulmonary complications. For instance, interstitial lung disease is seen as a complication of systemic sclerosis, rheumatoid arthritis, systemic lupus erythematosus, Sjögren's syndrome, polymyositis, dermatomyositis. and mixed connective tissue disease.[4] On the other hand, the aorta is commonly affected in temporal arteritis, long-standing ankylosing spondylitis, Cogan's syndrome, and relapsing polychondritis. Table 73.1 summarizes the more common cardiac and respiratory complications encountered in rheumatological disease, in addition to suggested investigations.

Cardiopulmonary tests

Chest radiography

Chest radiography is readily available, safe (with a radiation dose of 0.02 mSv per radiograph, equivalent to 3 days' background radiation in the United Kingdom[5]) and capable of detecting significant

Table 73.1 Common cardiac and respiratory complications, and suggested initial investigations, in various rheumatological diseases

Condition	Complications		Investigations to consider
	Cardiac	**Respiratory**	
Rheumatoid arthritis	Accelerated atherosclerosis	Pleural disease, interstitial lung disease, necrobiotic nodules, bronchiectasis, bronchiolotis	CXR, ECG
Gout	Increased risk of ischaemic heart disease		Address risk factors
Seronegative arthritides	Ischaemic heart disease. Aortic insufficiency	Apical lung fibrosis	Echo if suspicion
Systemic lupus erythematosus	Accelerated atherosclerosis, pericarditis, cardiomyopathy, myocarditis, endocarditis, conduction disorders	Pleural effusion, acute lupus pneumonitis/diffuse alveolar damage, interstitial lung disease, pulmonary haemorrhage, respiratory muscle weakness, pulmonary hypertension	CXR, ECG
Sjögren's syndrome	Interstitial lung disease. Lymphoma	Interstitial lung disease, bronchiectasis, lymphoproliferative disease	PFT, CXR, HRCT
Giant cell arteritis	Thoracic and abdominal aortic aneurysms	Pleural effusion (rare)	Regular CXR, abdominal ultrasound
Takayasu's arteritis	Large vessel vasculitis—stenoses, aneurysm	Pulmonary vasculitis, pulmonary haemorrhage	MRA, PET
Medium-vessel vasculitis (polyarteritis nodosa, Kawasaki's disease)	Coronary vasculitis	Pulmonary vasculitis, pulmonary haemorrhage	ECG, CXR, HRCT
Relapsing polychondritis	Valvular disease	Large-airway narrowing/collapse	Echo if suspicion
Behçet's disease	Coronary artery aneurysms, intracardiac thrombosis	Pulmonary artery aneurysms, pulmonary thromboembolic disease	V/Q, CTPA/MRA, pulmonary angiogram
Scleroderma	Chronic pericarditis, myocardial fibrosis	Interstitial lung disease, pulmonary hypertension	CXR, Echo, PFT, HRCT, RHC

CTPA, CT pulmonary angiography; CXR, chest radiography; ECG, electrocardiography; HRCT, high-resolution CT; MRA, MR angiography; PFT, pulmonary function testing; RHC, right heart catheterization; V/Q, ventilation–perfusion scanning.

pulmonary processes such as consolidation, effusion, pneumothorax and pulmonary oedema.

Diffuse pulmonary processes may be less reliably detected by chest radiography, and are more difficult to accurately characterize. About 10% of patients with significant diffuse interstitial diseases have normal chest radiographs.[6] Similarly, chest radiography has a high specificity but only a moderate sensitivity for diagnosing heart failure.[7–9] Importantly, it cannot reliably diagnose important causes of sudden shortness of breath as such aortic dissection, myocardial infarction, or cardiac arrhythmias.

Troponin

Troponin is released during myocardial ischaemia and is therefore important in the diagnosis of acute coronary syndromes. In patients with suspected myocarditis a raised troponin correlates strongly with presence of inflammation as detected by endomyocardial biopsy.[10]

A raised troponin is associated with higher mortality in several conditions, including heart failure,[11] acute pulmonary emboli,[12] severe exacerbations of chronic obstructive pulmonary disease (COPD),[13] and critical illness.[14]

However, raised troponins may also be seen in pericarditis, acute stroke, cardiac contusion, sepsis, and chronic kidney disease.

Brain natriuretic peptide

Brain natriuretic peptide (BNP) is released from the brain and from the heart. Cardiac secretion of BNP is seen in response to wall stress.[15] It may serve to counteract the vasoconstriction and sodium retention due to noradrenaline, endothelin, and angiotensin II in heart failure. It may also have a role in preventing cardiac collagen accumulation in heart failure.[16] It aids in diagnosis of heart failure in emergency settings.[17]

Raised BNP levels are associated with a worse prognosis in acute coronary syndromes,[18] stable angina,[19] chronic mitral regurgitation,[20] adult congenital heart disease,[21] pulmonary hypertension,[22] and non-cardiac surgery.[23]

Pulmonary function tests

Pulmonary function tests (PFTs) form a crucial part in diagnosis, staging of disease severity, and serial monitoring of many connective tissue disease (CTD)-associated lung diseases. Patterns of lung function impairment vary widely between rheumatological diseases, depending on the nature of the underlying pulmonary pathophysiological process as detailed in Table 73.2.[24]

Typical measurements made during pulmonary function testing include spirometric volumes, lung volumes performed with body plethysmography, and diffusing capacity of the lung. Spirometric volumes are the most readily available measures of lung function, and are highly reproducible when performed by trained personnel. Measurements consist of the forced expiratory volume in one second (FEV_1) and the total exhaled volume (vital capacity; VC) following a maximal inspiration. The forced expiratory ratio (FEV_1:FVC) is useful in differentiating obstructive (FEV_1:FVC <70) from restrictive (FEV_1:FVC >80) pulmonary processes, and flow–volume curves (which display inspiratory and expiratory flow rates for given lung volumes) provide similar information in a graphical form.[25] Examples of flow–volume curves in various diseases are provided in Figure 73.1.

Diffusing capacity of the lung (DL_{CO}) is a measure of the rate of diffusion of carbon monoxide (CO) across the blood–gas barrier into the pulmonary capillaries. DL_{CO} may be affected by a variety of pulmonary pathologic processes, including diseases of the lung parenchyma (e.g. emphysema), the interstitium, or the pulmonary vasculature, all leading to ventilation–perfusion mismatch. Of all lung function measures, DL_{CO} is most prone to measurement variation. The carbon monoxide transfer coefficient (K_{CO}) is derived by correcting the DL_{CO} for alveolar volume (DL_{CO}/V_A) and may be raised to supranormal levels (>100% predicted) in the presence of extrapulmonic restriction (respiratory muscle weakness, pleural disease).

The interpretation of PFT abnormalities can become considerably more complex where overlapping pathophysiological processes are present (e.g. concomitant pulmonary fibrosis and pulmonary hypertension in systemic sclerosis).

Bronchoscopy

Flexible bronchoscopy may aid substantially in clarifying the cause of respiratory symptoms in patients with rheumatological disease. It is a safe procedure (with an estimated mortality rate of up to 0.04%,

Table 73.2 Patterns of pulmonary function test abnormalities associated with rheumatological lung diseases.

	Restrictive lung disease	Obstructive lung disease	Pulmonary vascular disease	Extrapulmonary restriction
Total lung capacity	Reduced	Increased	Normal	Reduced
Spirometry	FEV_1 normal/↓ FVC ↓↓ FEV_1:FVC >80%	FEV_1 ↓↓ FVC normal/↑ FEV_1:FVC <70%	FEV_1 and FVC preserved	FEV_1 normal/↓ FVC ↓↓ FEV_1:FVC >80%
Diffusing capacity	Reduced	Reduced	Reduced	Normal/↓ K_{CO} ↑↑
Flow–volume curve	Preserved PEFR Tall, narrow expiratory curve	Reduced PEFR Upward concavity of expiratory curve	Normal	Normal or ↓ PEFR if muscle weakness is severe
Disease examples	Pulmonary fibrosis	Bronchiolitis, bronchiectasis Emphysema	Pulmonary hypertension	Pleural disease Respiratory muscle weakness

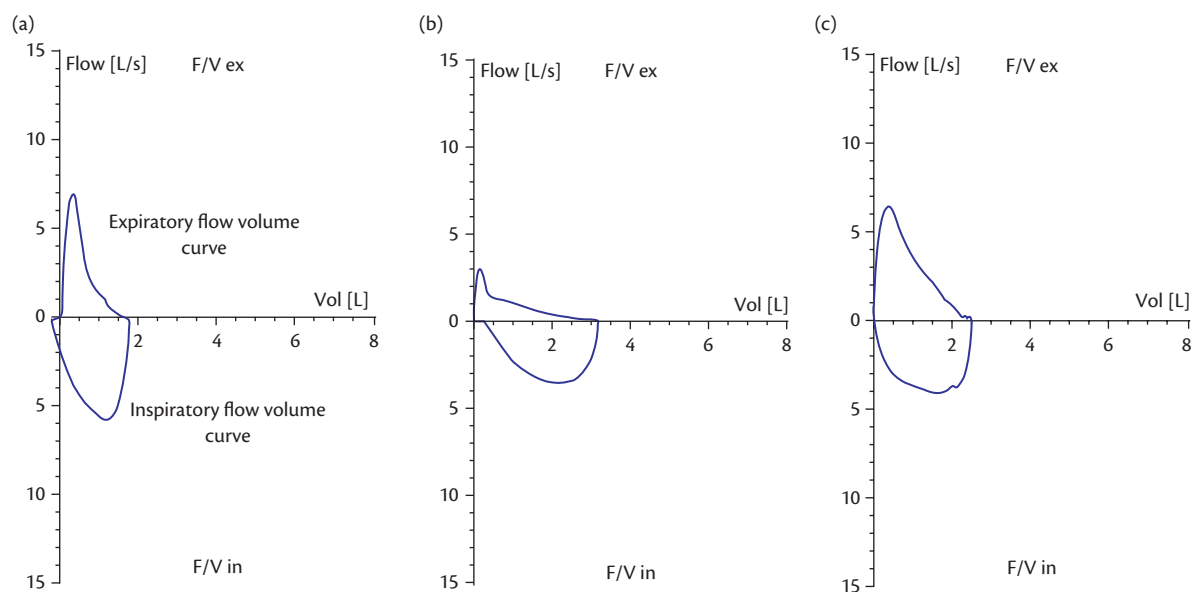
FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity; PEFR, peak expiratory flow rate; K_{CO}, carbon monoxide transfer coefficient: diffusing capacity corrected for alveolar volume (DL_{CO}/VA).


Fig. 73.1 (a) Flow–volume curves in a 58 year old woman with systemic sclerosis-associated non-specific interstitial pneumonia. The peak expiratory flow rate is preserved, but increased lung compliance results in rapid emptying of the lung and a tall, narrow expiratory flow–volume curve. (b) A 47 year old woman with rheumatoid arthritis associated obliterative bronchiolitis. The expiratory flow-volume curve demonstrates reduced peak expiratory flow rate and 'scooping out' of the curve, typical of small airways obstruction. (c) Normal flow–volume curves in a 37 year old woman with systemic sclerosis associated pulmonary hypertension. There was no significant interstitial lung disease or airways disease demonstrated on HRCT or at lung function.

and major complication rate of up to 0.12%),[26] and enables the direct visualization of airways to the level of the subsegmental bronchi, in addition to allowing various sampling manoeuvres to be performed.

Bronchoalveolar lavage (BAL) allows the sampling of cellular contents of the distal airways and alveolar space. When interpreted in conjunction with CT findings, BAL can be useful in distinguishing patterns of diffuse lung involvement, in identifying pulmonary haemorrhage, in the assessment of possible drug-induced pulmonary reactions, and in identifying pulmonary infections. The utility of BAL as a prognostic tool in CTD associated diffuse lung disease is unclear. One study has reported the presence of BAL eosinophilia to be associated with increased mortality in scleroderma associated non-specific interstitial pneumonia (NSIP), although similar data for other CTDs are lacking.[27]

In the setting of diffuse lung disease associated with rheumatological disease, transbronchial lung biopsy is often of limited diagnostic utility due to small biopsy size and sampling error due to the heterogeneous nature of lung involvement.[28] Furthermore, detailed clinical–pathological–radiological correlation of historical cohorts, and advances in CT imaging, have largely negated the need for surgical lung biopsy for diagnostic purposes in many rheumatologic diffuse lung diseases.

Electrocardiography

ECG provides information on cardiac rate and rhythm as well as indirect evidence of coronary artery disease, cardiomyopathy, pericardial effusion, pulmonary hypertension, and electrolyte abnormalities. It should therefore be performed in all patients with cardiac symptoms.

Echocardiography

Echocardiography has an established central role in the assessment of cardiac anatomy and function. In addition, it may detect rheumatic complications such as aortic root dilatation, Liebman–Sacks endocarditis, amyloidosis, pulmonary hypertension, and pericardial effusion. Limitations of the technique should, however, be recognized. Detailed assessment of ventricular function is suboptimal with two-dimensional echocardiography, and echocardiography cannot exclude coronary artery disease.

Specialized techniques are available for specific indications. Echocardiography with pharmacological stress or exercise may reveal ischaemic myocardium. Transoesophageal echocardiography has improved detection of valvular function and vegetations. Bubble contrast echocardiography improves recognition of right-to-left shunts.

Experimental techniques include three-dimensional echocardiography to more accurately assess cardiac chamber size and function. There is much debate about optimal advanced imaging analysis techniques for cardiac function, with little consensus as to date.

Computed Tomography

The widespread utilization of computed tomography (CT) has greatly improved diagnostic accuracy for many rheumatological lung diseases. High-resolution CT (HRCT), utilizing thin-slice reconstructions, has become invaluable in identifying patients with suspected diffuse lung involvement and airways involvement.

CT evidence of pulmonary disease in rheumatological disease varies widely between series, and depends partly on the diligence with which it is sought. In one series of consecutive unselected patients with rheumatoid arthritis recruited from a general rheumatology clinic, the prevalence of interstitial abnormalities on HRCT was 19%.[29] The high sensitivity of CT in detecting pulmonary abnormalities poses challenges to the clinician in distinguishing trivial change from clinically significant disease. In addition to pulmonary manifestations of the underlying rheumatological disease, CT also plays an important role in identifying abnormalities

associated with treatment (infection, drug-induced pulmonary reactions).

Figure 73.2 demonstrates common HRCT patterns of disease in various rheumatological diseases.

Cardiac catheterization

Left heart catheterization with percutaneous interventions (PCI) has an established role in patients with unstable angina and non-ST elevation myocardial infarction. It is associated with a reduction in myocardial infarction, refractory angina, and rehospitalization but not death. On the other hand, it is associated with periprocedural myocardial infarction and increased risk of bleeding.[30] Its role in patients with stable angina has been brought into question by the recent COURAGE and FAME trials. Major complications with PCI include a mortality rate of 0.4%, need for emergency CABG 0.2%, periprocedural myocardial infarction 0.8%.[31] The risk of stroke is 0.1–0.4%.[32]

Right heart catheterization is the gold standard investigation for the diagnosis of pulmonary hypertension. Pulmonary capillary wedge pressure or left ventricular end-diastolic pressure are measured to assess the contribution of the left heart to pulmonary pressures. Cardiac output is assessed by thermodilution or oxygen saturation (Fick method) to allow estimation of pulmonary vascular resistance. In some patients with pulmonary hypertension, a vasoreactivity test is performed to assess whether the patient may respond to calcium-channel antagonists.

Conventional pulmonary angiography may be performed at the same time, although nuclear medicine lung perfusion–ventilation scanning, CT pulmonary angiography, and MR pulmonary angiography are non-invasive alternatives.

Cardiac magnetic resonance imaging

Cardiac MR imaging (CMR) is a powerful non-invasive non-ionizing technique with the ability to depict cardiac anatomy, function, and tissue characterization. CMR can detect myocardial inflammation, perfusion defects, fibrosis, and coronary and great arteries aneurysms, making it a valuable tool for cardiovascular system assessment in selected patients with rheumatic diseases.

In the assessment of cardiac chamber volume and function, it has advantages over echocardiography in accuracy and reproducibility. The ability of CMR to assess myocardial inflammation is often useful in rheumatology. T2-weighted images detect tissue water content and cannot distinguish necrotic from inflamed tissue. Early and late gadolinium enhancement improves specificity for myocardial inflammation.[33] In addition, it can provide valuable information in autoimmune conditions affecting the cardiovascular system such as Takayasu's arteritis, Behçet's syndrome, and systemic sclerosis. The
Fig. 73.2 (a) Systemic sclerosis associated non-specific interstitial pneumonia (NSIP). There is extensive reticular shadowing and ground-glass change, with evidence of traction bronchiectasis (arrows). NSIP is the most frequently observed radiological and histological pattern of diffuse lung disease in systemic sclerosis. (b) Rheumatoid arthritis associated usual interstitial pneumonia (UIP). There is a coarse subpleural reticular pattern, with evidence of honeycomb lung destruction (arrow). UIP is the most frequently observed pattern of diffuse lung disease in rheumatoid arthritis. (c) Obliterative bronchiolitis associated with rheumatoid arthritis. A mosaic attenuation pattern is present, with a mixture of low attenuation (blacker) and normal attenuation lung. In the blacker lung, there is a reduction in calibre and number of vessels (due to hypoxic vasoconstriction). Mild bronchial wall thickening is also present. (d) Sjögren's syndrome associated with bronchiectasis. The airways are thick walled and dilated. In normal lung, the airway is of the same calibre, or smaller, than its accompanying blood vessel. (e) Organizing pneumonia associated with polymyositis/dermatomyositis. There are bilateral areas of patchy consolidation, in some areas displaying a perilobular pattern (arrow), characteristic of organizing pneumonia.

role of CMR is not fully elucidated in rheumatic disease and only small case series have been published to date.[34]

CMR has several drawbacks. It is expensive and time consuming. Good images require the patient to be able to breath-hold for 5–10 seconds, and most implanted pacemakers and cardiac devices are not MRI compatible. Patients with claustrophobia often find the procedure very difficult. Highly irregular rhythms can affect the image quality. Finally, nephrogenic systemic fibrosis due to gadolinium has increasingly been described and MRI with gadolinium is relatively contraindicated in patients with eGFR below 30 mL/min.[35]

Conclusion

There is a huge and growing array of specialized cardiac and respiratory tests, many of which are beyond the scope of this chapter. These include cardiopulmonary exercise testing, tilt table testing, CT angiography and coronary calcium scoring, intracardiac and intravascular ultrasound, sleep studies, lung perfusion scanning, VATS procedures, and lung biopsy. However, these tests are for use by cardiac and pulmonary specialists. We have emphasized initial investigations which are appropriate for common cardiac and respiratory symptoms, and highlighted cardiac and respiratory complications associated with rheumatological conditions.

CHAPTER 74

Electrophysiology

Julian Blake

Introduction

Clinical neurophysiology is a diagnostic discipline that uses the recording of bioelectrical signals from the central and peripheral nervous systems and from skeletal muscle in the examination of patients with neurological disease. It includes nerve conduction studies (NCS), needle electromyography (needle EMG), electroencephalography (EEG), and evoked cortical responses such as somatosensory and visual evoked potentials. Only those aspects related to the study of the peripheral nervous system and neuromuscular function are discussed in this chapter.

Neurophysiological consultation

A neurophysiological consultation includes taking an appropriate history and clinical examination as well as performing the neurophysiological assessment. Some patients may find the examination uncomfortable and they should be warned about this. However, it should not be over emphasized as anxiety prior to the examination undoubtedly increases the discomfort. Special care is needed with pacemakers and patients may need cardiac monitoring during the examination and a pacemaker check afterwards. The presence of implantable defibrillators is a significant contraindication. Pregnancy is not a contraindication to electrical stimulation. Needle EMG is often likened to acupuncture and is of similar discomfort to a venepuncture. Warfarin is a relative contraindication to needle examination and a recent INR of less than 2.5 is desirable. These aspects should be discussed with the neurophysiologist.

Methodology

Nerve conduction

Any sizeable nerve that is accessible can be studied. Action potentials are evoked by transcutaneous stimulation of a peripheral nerve with stimulus intensity more than sufficient to produce a maximum response. A supramaximal stimulus consists of a pulsed square wave current of 0–100 mA, usually of 0.1 ms duration. Where a nerve is deep or is hypoexcitable due to demyelination the duration may need to be increased up to 1 ms. The resultant evoked action potential is recorded with surface electrodes at a measured distance from the stimulating surface electrode. The amplitude of the evoked response is recorded and the conduction velocity calculated.

Needle electromyography

With a needle electrode placed in a muscle, action potentials can be recorded from individual muscle fibres or motor units (a group of muscle fibres supplied by one axon) in response to a voluntary contraction. Although there are objective quantitative techniques for this part of the examination, in routine clinical practice this assessment is most often performed subjectively by observation of the action potential representation on a display and listening through a loudspeaker. EMG is used to determine if a deficit of motor function is secondary to nerve dysfunction (neurogenic) or due to primary muscle disease (myopathic). It also allows one to work out the anatomy of a nerve lesion.

Spontaneous activity

The muscle being studied must be completely relaxed. A muscle should be nearly silent on insertion of the needle. If one is near the neuromuscular junction, a characteristic 'endplate noise' is heard. In acutely denervated muscle, myositis, and many myopathies, muscle fibres generate spontaneous, low-amplitude, very brief potentials called fibrillations which are a relatively non-specific feature of disturbed muscle physiology. Fibrillations may occur for months to years if a denervated muscle does not fully reinnervate.

Other spontaneous activity is also seen which may imply more specific diagnoses. Infrequent spontaneously firing motor units (fasciculations) are normal but, if plentiful, suggest chronic denervation as seen in motor neuron disease. Some types of spontaneous and rapidly firing motor units, complex repetitive discharges, and myokymic or neuromyotonic discharges may be seen in proximal compressive lesions, denervation and peripheral demyelination. Myotonic discharges are seen with clinical myotonia.

Motor unit

The shape, duration, firing rate, and amplitude of the individual motor unit action potentials are assessed.

Acute denervation results in a reduced number of motor units which fire at increased frequency. Their morphology remains normal for several weeks after axonal loss. Chronic denervation results in the reinnervation of previously denervated motor units by axonal regeneration and intramuscle collateral axonal sprouting, with consequent increase in amplitude and complexity resulting in polyphasia.

Primary muscle disease is characterized by the presence of many low-amplitude, brief, and polyphasic motor units which fire very

easily and rapidly in response to voluntary activation at low levels of muscle contraction.

Interference pattern

At maximal voluntary contraction the number of motor units and fullness of the overall envelope of electrical activity is assessed, referred to as the interference pattern. Denervation from any cause results in the reduction of the number of motor units that can be activated and thereby also a reduction of the interference pattern. In myopathic processes there is a very full, low-amplitude interference pattern at low levels of contraction.

Definitions

Amplitude

The amplitude of an axon-generated action potential recorded with intracellular electrodes is fixed around 100 mV. It is due to the depolarization of the cell (axon or muscle) from its resting membrane potential of around -70 mV to the maximum depolarized state of +30 mV. In the case of an axon this rise is due to the rapid opening of voltage-gated sodium channels clustered at the node of Ranvier.

Compound action potential

The compound action potential (CAP) is recorded using surface electrodes in response to stimulating a peripheral nerve with a supramaximal stimulus. It is the result of the summation of all of the individual axon-generated action potentials.

The CAP amplitude is related to the number of axons stimulated. There are several reasons (beyond the scope of this discussion) why this is an oversimplification but, in general, it holds true. Loss of axons therefore results in a fall in amplitude and loss of function, either loss of sensation or weakness.

The amplitude of the CAP using standard surface electrodes is greatly influenced by the distance from the generator (muscle or axon) to the recording electrode. This results in a very large variability of amplitudes between different nerves, muscles, and subjects, making the provision of normative data nearly impossible. The amplitude is affected by skin thickness, sex, occupation, weight, and age.

Sensory action potential

The sensory action potential (SAP) is the recorded surface potential change in response to the stimulation of only sensory fibres. These are the large myelinated fibres that are relayed centrally via the dorsal columns of the spinal cord.

The isolation of the SAP requires the ability to stimulate a pure sensory nerve such that no motor fibres are included. There are many pure sensory nerves such as the median and ulnar digital and superficial radial nerves in the upper limb and the sural and superficial peroneal nerves in the lower limb. Stimulation of any one of these nerves with a supramaximal stimulus generates a near-synchronized volley of action potentials in the large myelinated sensory axons. The amplitude is measured in μV and the normal amplitude falls in the range of 5–100 μV depending on the nerve examined (Figure 74.1).

Compound muscle action potential

Unlike the sensory recordings, there are no pure motor nerves that can be easily recorded from. The isolation of motor axons requires
Fig. 74.1 Median sensory action potential. Conduction velocity of 54.5 m/s is measured to the first positive peak, shown by vertical bar latency marker of 2.2 ms over a distance of 12 cm. The action potential amplitude of 18 μV is measured between the two horizontal bars.

an indirect approach, recording from a muscle. The action potential generated in a muscle in response to stimulation of a nerve must be the result of stimulation of motor axons only.

A supramaximal stimulus of motor axons causes activation of the muscle at the neuromuscular junctions and a near-synchronized depolarization of all of the muscle fibres, resulting in a compound muscle action potential (CMAP). CMAPs are much bigger than SAPs and are measured in mV in the range of 2–20 mV depending on the muscle and nerve being studied.

Conduction velocity

Conduction velocity (CV) of axons is largely determined by their diameter and myelination. The larger the axon, and the greater the distance between nodes of Ranvier, the faster it will convey the action potential.

A peripheral nerve is made up of a mixture of fibre types. The majority of the nerve fibres in a peripheral nerve are small-diameter, slowly conducting, unmyelinated or thinly myelinated fibres that convey autonomic functions and information about pain and temperature. Unfortunately routine neurophysiology cannot examine these and their assessment requires esoteric techniques.

Only the large, fast-conducting, myelinated fibres generate electrical signals big enough to be recorded with surface electrodes. CV is calculated by dividing the distance between stimulation electrode and the recording point by the time taken for the generation of an action potential at the recording point in seconds, and is measured in m/s. The first electrical deflection from the baseline represent the time at which the action potential arrives at the recording site due to the fastest conducting fibres. As a general rule the normal recorded velocities are in the region of 50–60 m/s in the upper limb and 40–50 m/s in the lower limb. This is due to the fact that axons taper, being large at the cell body and thinner at their distal end. The main variable influencing CV in the non-diseased state is temperature. Cooling by 1 °C may reduce velocity by 2 m/s. Temperature is therefore controlled to 30–32 °C during the examination.

Disturbance of the myelin or loss of large, fast-conducting axons results in a fall in CV. Conduction slowing on its own does not lead to symptoms or clinical signs.

Measuring sensory CV is simple. A sensory nerve is stimulated at one point and recorded from either upstream (orthodromic) or downstream (antidromic). The distance between these two points divided by the time taken by the action potential to travel between them gives the velocity.
Fig. 74.2 Ulnar motor study recording from abductor digiti minimi. Vertical bars mark the onset latencies of motor responses stimulating at the wrist, below the elbow, and above the elbow. The distal motor latency (DML = 2.5 ms) to stimulation at the wrist is measured to the top vertical bar. The conduction velocities are 65 m/s in the forearm and 45 m/s around the elbow. Motor amplitudes are 13.6 mV at the wrist, 13.0 mV below the elbow, and 10.9 mV above the elbow.

Motor CV is a little more complicated because of the indirect method of recording from motor fibres using the CMAP. It is not possible to calculate a velocity between the stimulation point of a motor nerve and the onset of the CMAP as there is an unknown delay in transmission across the neuromuscular junction and generation of an action potential in the muscle. Therefore motor fibres are stimulated at two separate points. The distance between these points is divided by the difference in onset of the CMAP generated by each stimulus. Motor CV is often measured in multiple segments along the nerve, stimulating at accessible points (Figure 74.2).

Distal motor latency

The distal motor latency (DML) is an important measure of the speed of motor conduction at the very distal end of the nerve. It is measured in milliseconds (ms). The DML is dependent on the distance from the stimulation point to the muscle and also on the CV of the motor axons. The recording distance is usually around 8 cm and results in a normal DML of 3–5 ms. This is variable between nerve–muscle arrangements being studied. There are a number of clinical situations where the distal motor nerve is more affected than more proximal parts.

Mixed nerve action potential

The mixed nerve action potential is the term used to identify the response to stimulation of a named nerve which includes both motor and sensory axons. Most of the amplitude is, however, due to stimulation of sensory fibres as these are usually more numerous than motor axons. It is measured in a similar way to sensory conduction, stimulating the nerve at one point and recording at another, either orthodromically or antidromically.

Conduction block and temporal dispersion

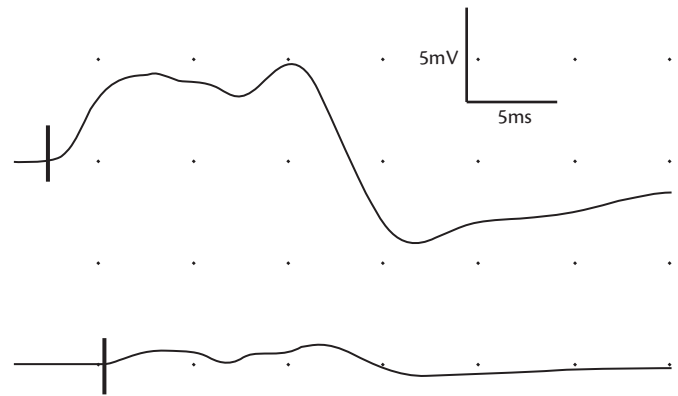
The concept of conduction block generates a lot of confusion. Most commonly it is seen in entrapment neuropathies and is the result of a segment of demyelination at a point of compression. An action potential cannot reliably travel along a demyelinated axon. The axon nevertheless remains viable and is also able to generate an action potential both proximal and distal to the segment that


Fig. 74.3 Motor conduction block at the fibula head. Amplitude of compound muscle action potential from tibialis anterior stimulating below the fibula head is 4.8 mV and stimulating above the fibula head is 0.9 mV. The conduction velocity across the fibula head is 27 m/s (RR >40 m/s).

has no myelin, but not through the segment. In the case of a motor nerve, stimulation distally elicits a motor response but not when the nerve is stimulated proximal to the demyelinated lesion. This usually affects only a proportion of axons in a nerve, so the result is a motor response that is smaller to proximal stimulation than it is to distal stimulation (Figure 74.3).

The amplitude of a motor response may be reduced not due to failure of conduction through a demyelinated segment but due to variable severity of demyelination resulting in an increased range of conduction velocities. This causes a prolongation of the CMAP or temporal dispersion. This is often wrongly described as conduction block.

Another situation where conduction block is seen is following trauma or peripheral nerve infarction where there is acute axonal damage An axon divided from its cell body may be able to generate an action potential for up to 10 days after injury. Thus in the early phase after injury, stimulation of the distal segment of the nerve elicits an action potential but stimulation of the proximal part of the nerve cannot. This is sometimes referred to as pseudo conduction block.

F wave and H reflex

Although in principle very proximal conduction velocities can be measured, the latency of the F wave is most often used as an indirect measure of proximal conduction. The F wave is a non-physiological reflex dependent on the retrograde stimulation of the motor nerve. A motor action potential can travel the wrong way along the axon to the anterior horn cell where it can generate a reflex action potential which then travels back down the motor axon in the normal physiological direction evoking a recordable motor response distally. Any delay in the time taken for this reflex (F latency) with normal distal conduction implies proximal slowing and demyelination. The Hoffman reflex (H reflex) is used in a similar way but is a physiological response dependent on the stretch reflex arc and stimulation of the 1A afferents from the muscle spindle. It is the neurophysiological counterpart of the tendon reflex.

Clinical application

Entrapment neuropathies

As already mentioned, entrapment of a nerve may cause a segment of demyelination but there is frequently axonal damage in varying amounts.

Demyelination causes a degree of focal conduction slowing at the compression point which can be measured by stimulation either side of the lesion most often recording from a muscle. This focal slowing is the most reliable way of localizing the lesion. Often motor conduction block is identified as well. The severity of axonal loss is estimated by the reduction in SAP and CMAP amplitude to distal nerve stimulation.

Where the lesion results in significant or complete loss of axons localization is difficult and is inferred from the needle EMG abnormalities, examining muscles innervated by branches distal and proximal to the site of nerve injury.

Carpal tunnel syndrome

The neurophysiological examination of patients with carpal tunnel syndrome (CTS) represents a paradigm of neurophysiology and of other entrapment neuropathies.

The aim is to confirm the focal nature of the neuropathy at the wrist and grade its severity. The median nerve SAP is normally recorded by stimulating a median-innervated digit and recording over the median nerve proximal to the carpal tunnel. This is compared to either the ulnar or radial SAP. In a mild or early neuropathy only slowing of conduction may be seen but as the condition progresses axonal degeneration occurs with a fall in SAP amplitude. The DML to abductor policis brevis is measured to determine the degree of distal motor slowing. As with sensory conduction, evidence of motor slowing and demyelination normally occur before loss of axons and CMAP amplitude reduction.

A variety of short-segment nerve studies are used to demonstrate focal carpal tunnel slowing such as a median palm to wrist sensory CV and a comparison of the DML to the second lumbrical (median innervated) to that of the second interosseous (ulnar innervated) muscles.

Endstage CTS results in the loss of recordable median motor and sensory responses, preventing confirmation of the focal nature of the original lesion. Neurophysiology for CTS is not usually required for diagnosis but is needed for planning treatment and predicting outcome. Patients with mild or severe neurophysiological abnormalities have been shown to respond less well to surgical decompression compared to those with moderate changes.

Other entrapment neuropathies

The principles used to study CTS apply to other entrapment neuropathies.

Focal slowing or conduction block in the radial nerve when compressed in the spiral grove is usually difficult to show but if a patient with a wrist drop has loss of radial sensation but a normal radial SAP it can be inferred that there is conduction block somewhere along the nerve. When accompanied by normal needle EMG of triceps and reduced motor unit recruitment in brachioradialis, the lesion would clearly localize to somewhere between the nerve branches to each of these muscles. One would also be able to say that the lesion is demyelinating and, as long as it was acute, it would be expected to recover within 8–12 weeks from onset (the time taken to remyelinate a nerve). Where the SAP is attenuated and the needle EMG demonstrates acute denervation a degree of axonal damage would be evident and the time to recovery would depend on axonal regeneration from the site of injury, traditionally said to occur at the rate of 1 mm/day.

Acute foot drop is assessed in the same way. The superficial peroneal SAP is measured in the foot; loss or attenuation of the response implies axonal loss. Motor conduction across the fibular head to either extensor digitorum brevis or to tibialis anterior is measured; focal slowing or conduction block localizes the lesion and would confirm it as at least in part demyelinating (Figure 74.3). If motor responses are absent or attenuated then axonal loss has occurred and further localization requires additional needle EMG of muscles both above and below the knee.

Axonal peripheral neuropathy

An axonal motor and sensory peripheral neuropathy is characterized by attenuation of SAP and CMAP amplitudes. In the early phase of a length-dependent pathological process this will affect distal fibres in the lower limbs before significant changes in the upper limbs. Conduction velocities are generally within normal limits but, in certain circumstances, the motor conduction velocities may be mildly slowed due to the preferential loss of the largest and fastest axons.

Pure sensory neuropathies are encountered where only attenuation of SAPs is demonstrated. This might be seen in some presentations of diabetic neuropathy and in hereditary sensory and autonomic neuropathies (HSAN). Diseases of sensory ganglia such as due to Sjögren's or paraneoplastic neuropathies will produce similar features but the neurophysiological abnormalities may be either patchy or uniform but not length dependent.

Pure motor neuropathies are also seen. These are usually distal hereditary motor neuropathies (dHMN). The diagnosis requires the demonstration of normal sensory conduction and attenuation of motor responses, along with denervation of distal limb muscles on needle EMG.

Demyelinating peripheral neuropathy

The cardinal feature of a demyelinating neuropathy is CV slowing. Uniform slowing of conduction is a feature of hereditary motor and sensory neuropathies (HMSN or Charcot–Marie–Tooth disease, CMT) and patchy, variable slowing suggestive of acquired neuropathies such as acute inflammatory demyelinating polyneuropathy (AIDP or Guillian–Barré syndrome) and chronic inflammatory demyelinating polyneuropathy (CIDP). It is increasingly recognized that this distinction is not absolute and the neurophysiologist's clinical experience and pattern recognition ability becomes important under these circumstances. A not infrequent cause of failure of CIDP to respond to treatment is a misdiagnosis of X-linked CMT (CMTX). The neurophysiological features of CIDP, CMTX, and classical diabetic neuropathy may be indistinguishable.

Radiculopathy

Neurophysiology does not have a significant role in the diagnosis of radiculopathy, which is investigated better with MRI. Consideration of the neurophysiology of radiculopathy, however, illustrates some important principles. When a nerve root is injured the lesion is usually proximal to the dorsal root ganglion and described as being preganglionic. Afferent sensory information to the spinal cord is interrupted and the patient will have sensory disturbance or numbness in the distribution of the nerve root but, because the peripheral sensory axons are still connected to the sensory cell body, the peripheral sensory conduction remains normal. Conversely the motor axons that are divided in the root lose their connection with the anterior horn cell body and degenerate, resulting in denervation of muscles in that root distribution. The combination of numbness

and weakness with normal sensory conduction but denervation usually indicates a preganglionic root lesion.

Vasculitis

Peripheral nerve vasculitis causes a variety of neurophysiological patterns, the most classical of which results from mononeuritis multiplex. This typically results in loss of both SAP and CMAP when stimulating the affected nerve at any point along its course. Occasionally there are a few surviving axons through the infarcted area of nerve with recordable, albeit severely attenuated, responses. Needle EMG of supplied muscles shows acute denervation changes. A source of confusion results from the fact that, if the nerve is examined within 10 days of symptom onset, the distal axons can still generate action potentials, mimicking the neurophysiological features of conduction block. In practice this should not present a diagnostic problem, and this possibility should not delay the neurophysiological examination. The suspicion of peripheral nerve vasculitis is a rare instance where the clinical presentation requires urgent neurophysiological examination.

Some more indolent vasculitic conditions may result in the gradual accruing of motor and sensory deficits with progressive attenuation of SAP and CMAP amplitudes in a distal and symmetrical fashion, which can be neurophysiologically indistinguishable from a length-dependent peripheral neuropathy. A high index of suspicion is required and the diagnosis may need to be confirmed with a nerve biopsy.

Motor neuronopathy

The term motor neuronopathy refers to diseases of anterior horn cells. When the neurophysiology shows isolated motor axon loss the possibility of anterior horn cell disease must be considered. The neurophysiological clue to the diagnosis is the lack of length-dependence of motor axon loss with proximal muscles such as paraspinal muscles showing similar signs of denervation to distal limb muscles. A prerequisite for this diagnosis is the absence of both sensory symptoms and neurophysiological sensory abnormalities.

Neurophysiologically the features are those of a preganglionic lesion and similar to a root lesion.

Primary muscle disease

The examination of a patient with a primary muscle disease needs needle EMG. As already mentioned the myopathic EMG pattern is of low amplitude, rapidly recruiting and polyphasic motor units. The pattern is often non-specific and the main role of neurophysiology is to exclude a neurogenic cause, suggesting the need for a muscle biopsy.

Neuromuscular junction disorders

Neuromuscular junction disorders are characterized neurophysiologically by a progressive fall in CMAP amplitude in response to repetitive motor nerve stimulation at 3 Hz. This is referred to as a decrement. Postsynaptic conditions such as myasthenia gravis are distinguished from presynaptic ones such as Lambert–Eaton myasthenic syndrome (LEMS) by the response of the CMAP amplitude to 15 s of maximal voluntary contraction. The latter condition shows a post contraction increment greater than twice the CMAP amplitude at rest. This is due to a presynaptic influx of calcium and results in increased acetylcholine release. The quantitative technique of single-fibre EMG is also used to measure the increased variability of conduction velocity and decreased reliability of synaptic transmission which occurs in neuromuscular junction disorders.

CHAPTER 75

Patient education

David Walker and Ben Thompson

Introduction

Patient education is recognized as essential for the management of musculoskeletal disorders. National and international guidelines invariably state its importance,[1,2] while moral and practical arguments for its value are persuasive. Patients have a right to know about their health and treatment, while education enables patients to contribute to decisions about their health, access appropriate help, and behave in ways which could improve their future health.

While there may be consensus that patient education is a 'good thing', evidence-based guidance describing how health professionals should develop and provide educational resources is not available, nor are tools to decide if education is effective. Equally, there is no clear consensus about what constitutes 'effective' education—i.e. the precise changes we should be expecting education to have on patients. This chapter therefore goes beyond this acceptance of patient education as beneficial for patients, and examines topics including its scope and aims, the practical steps patients take to learn about their condition, and the challenges faced by those who develop, provide or evaluate educational resources for patients. It summarizes the current evidence and opinion around patient education, and suggests methods to improve education and learning for patients in the future.

Definition and aims

Patient education is a broad term which is difficult to define. The term adopts different meanings in different circumstances, relates to a variety of resources and interventions according to the situation and audience, and aims to achieve broad but ill-defined benefits. Its use overlaps and is used interchangeably with concepts such as health literacy,[3] patient participation,[4] and self-management.[5] Kate Lorig's definition of patient education is the most widely used in rheumatology, and was adopted by the Cochrane review of education for people with rheumatoid arthritis[6]:

> any set of planned, educational activities designed to improve patients' health behaviors and/or health status. … The purpose is to maintain or improve health, or, in some cases, to slow deterioration.[7]

By suggesting that only *planned* activities meet her definition, Lorig excludes much of the learning that patients carry out independently, for example through searches for information on the internet, or during routine consultations with health professionals. These methods of education may be the most effective for patients,

or the most commonly used. Equally, while health professionals may view education as a way of '*improving* patients' health behaviours', this aim may not be shared by patients themselves. Instead, patients may view education as a way of obtaining new ideas about treatments, or evaluating the health care they are receiving. Thus, if an educational resource does not reflect the aims and needs of patients then they are unlikely to choose to use it, and it will be unsuccessful because of a lack of uptake. These differences between the aims of providers of education and patients themselves need to be considered, and should be reflected in the design and aims of such resources.

The World Health Organization (WHO) also offers a definition of 'Therapeutic Patient Education' which has influenced practice in Europe:

> Therapeutic Patient Education (TPE) helps patients acquire or maintain the skills they need to manage their life with a chronic disease in the best possible way. It covers organized activities, including psychosocial support, designed to make patients fully aware about their disease and to inform them about care, hospital organization and procedures, and health- and disease-related behaviours. It helps patients and their families understand and deal with the disease and its treatment together, in order to maintain or even improve quality of life.[8]

This definition does not limit patient education to processes separate from routine care and, in contrast to Lorig, focuses on *informing* patients about their behaviour rather than *improving* it. It also acknowledges the need for patients' families to be included in attempts to provide education for people with chronic illnesses.

The aims of patient education deduced from these definitions are therefore not only to increase patients' knowledge about their condition and treatment, but are also focused on changing their behaviour and, ultimately, improving their health. This perspective of education as a 'therapy' is supported by examining the outcome measures used in studies of educational interventions, which include a range of physical, psychological, behavioural, and health status measures. The potential of such interventions to achieve benefits for society by reducing economic costs through a decrease in participants' utilization of healthcare has also been recognized by both academics and policy-makers.[9]

However, there are wider functions of education which are not recognized by such definitions, or by the research studies designed to evaluate them. As well as broadly trying to help patients 'feel better' in terms of their physical, psychological health, and social participation, and the potential societal benefits of economic

savings, it can also improve relationships between patients and their healthcare professionals, providing patients with sources of help they can return to if they encounter problems in the future. There are also benefits for health professionals themselves. These are rarely emphasized in the literature but are important when deciding whether to invest resources in patient education; it can reduce health professionals' workload, and may increase patients' willingness to participate in research studies.

As well as educating patients it is also important to educate the wider population—health education—for two principal reasons. First, so that society does not disadvantage people with musculoskeletal conditions, making adaptations in the case of physical disability and understanding the symptoms and challenges they may face. Secondly, in the case of inflammatory arthritis, to encourage early presentation to medical professionals, in turn leading to earlier treatment which has been shown to be more effective.[10] Most of the delay to diagnosis for rheumatoid arthritis (RA) is the delay in the patient presenting to the GP rather than the GP referring to the hospital.[11] Health beliefs such as 'It's only arthritis and there isn't much they can do about that' should be challenged and consigned to the past.

Historical overview

Many of the social, demographic, and medical changes during the last century have contributed to the growing interest in and need for high-quality patient education. A greater proportion of the population now live for considerable periods with one or more chronic illnesses, and health systems have shifted focus from the treatment of acute illness to long-term 'incurable' conditions such as arthritis. These changes have in turn prompted changes to how healthcare systems are envisaged, with self-care at the base of a healthcare pyramid in the United Kingdom.[9] Self-care is the care taken by individuals towards their own health and well-being, including those of their family and communities. It increases the scope for patients to participate in decisions about their health care, a role in which they require both information and the skills to appraise it. The traditional model of a paternalistic doctor and a compliant patient has to some extent been replaced with ideas of partnership and 'patient participation'.[4]

Simultaneously, the concept of 'patient consumerism' has become more prevalent—the refusal of patients to accept the 'medical dominance' of doctors, and a desire to 'shop around' for the best health care available.[12] Patients are therefore more inclined to seek out the information on which to base these types of decisions. At the same time, such information has become more accessible, in part because of the growth of the internet.

However, this demand for information from patients is not universal and a proportion of patients are content not to know about their condition,[13] or do not wish to participate in decisions about their care.[14] Similarly, the idea that education can lead to a fully informed, autonomous patient has been criticized, especially if the aim of the intervention is to increase compliance with medical care.[15] At the same time, some commentators have suggested that 'patient empowerment'—the expectation that patients will take control of their illness and treatment—is not necessarily in their interests.[16]

Patient education has changed alongside these developments, from interventions which focused on the transfer of knowledge in the 1970s, to more sophisticated interventions which focus on patients' self-care and decision making, and are often based on psychological theory. Social learning theory,[17] and the related concept of self-efficacy, are fundamental to self-management programmes such as those developed by Kate Lorig. Social learning theory upholds the importance of demonstrating or 'modelling' appropriate health behaviours. Self-efficacy refers to an individual's confidence in their ability to perform a task or specific behaviour successfully.

Methods of delivering patient education

Learning can take place in many settings, and can occur independently of health care and health professionals. The first point of education may be at the time of diagnosis where information will be offered by the clinician, usually verbally and written. This will be against the background of a narrative that the patient has developed to explain their symptoms and current health state. The narrative is developed around their health beliefs on causation and treatment, which may not necessarily be credible to the clinician.[18] Further contact with professionals provides opportunities for question-and-answer learning as well as formal education about things such as drugs. Studies of where patients get information and how they value it suggest information from clinicians, particularly doctors, is rated most highly.[19] Good communication is at the heart of education and many communication models exist, of which the Cambridge Calgary model remains a current favourite.[20]

More formal education is often done in groups because they are thought to be efficient in terms of professional time. There has been speculation over whether a professional group leader is necessary and whether a lay leader may be equally or more effective.[21] This has led to initiatives around self-management and 'expert patients' and to the Expert Patient Programme in the United Kingdom.[22] It is proposed that the lay leader for such groups acts as a role model for attendees, making them more likely to change health behaviours. This has been both evaluated[23] and criticized.[24]

Research into such interventions for ankylosing spondylitis has shown that group self-management education could improve self-efficacy scores but not measures of the disease itself.[25] A study of physiotherapy-led education for exercises in anyklosing spondylitis (AS) showed better spinal mobility at 9 months.[26] Similarly, studies in RA and osteoarthritis (OA) have shown an effect of education on pain and self-management.[27]

Overall, studies have failed to show a clinically significant long-term benefit from group education, though in part this may reflect the challenges in designing appropriate trials and measuring any resulting changes. The benefits of groups include the ability of participants to share their experiences, and learn from each other. At the same time, they are less able to offer attendees specific advice and address their learning needs and queries. Equally, some patients are unwilling to attend groups because of the time commitment, or because they do not want to discuss their own health in a public setting.

One-to-one education by a health professional is more resource intensive, but commonly occurs as part of routine care. It has the advantage of offering information tailored to that individual, and has shown very good satisfaction with patients. Probably because the resource implications make it less attractive to healthcare providers, there is less published research on one-to-one education,

but there is a similar lack of long-term benefit.[28] One-to-one is the usual format for educating patients prior to commencement of new drugs and a study has shown better adherence to the medication following this.[29]

Written information is also widely used, and Arthritis Research UK has produced information in leaflet and booklet form for more than 50 years. They produce written information on diseases and drugs as well as more generic information on topics such as pain; footwear; gardening, and sex. They produce more than 2 million leaflets and booklets, delivered free to patients and professionals.[30] These have been evaluated[31] and, in a substudy on RA, were shown to increase knowledge, improve pain and depression, but no effect was shown on overall health. Such booklets are valued highly by patients, principally because they offer a definitive information source which, if handed to them by their clinician, has been endorsed by their health professional.

The use of written information raises the issue of language and the decoding and understanding of it, i.e. literacy. In a study from Glasgow[32] 15% of participants were found to be functionally illiterate. There was association between this and social factors and use of health services. It is therefore unlikely in this group that the handing out of a densely worded leaflet will produce much useful education. One initiative to make information more accessible is the production of 'mind maps' of some booklets by Arthritis Research UK (see Figure 75.1). These are much more visual, using pictures spreading out from a central icon, and use fewer words. Patients are able to look at the pictures while the text is read to them. It was expected that they would have utility for people whose first language was not English and in those with specific learning difficulties. In an evaluation for RA[33] the 15% functional illiteracy was confirmed, but knowledge transfer was greater for the literate participants and if anything enhanced by the mind map in these people. The illiterate participants in this study were generally globally challenged rather than having a particular problem with written English. The mind map may have utility in people with dyslexia and people whose first language is not English.

On the same theme there are diseases such as osteomalacia that are more common in people from ethnic minorities. Arthritis Research UK has translated the osteomalacia booklet into five languages with matching audiotapes. These have been evaluated[34] and show the huge problems of producing such translations that are culturally as well as language sensitive. Similarly, the images used on the osteomalacia mind map have been redrawn with input from the populations involved.[35] One set of images was found to be suitable for all languages including English.

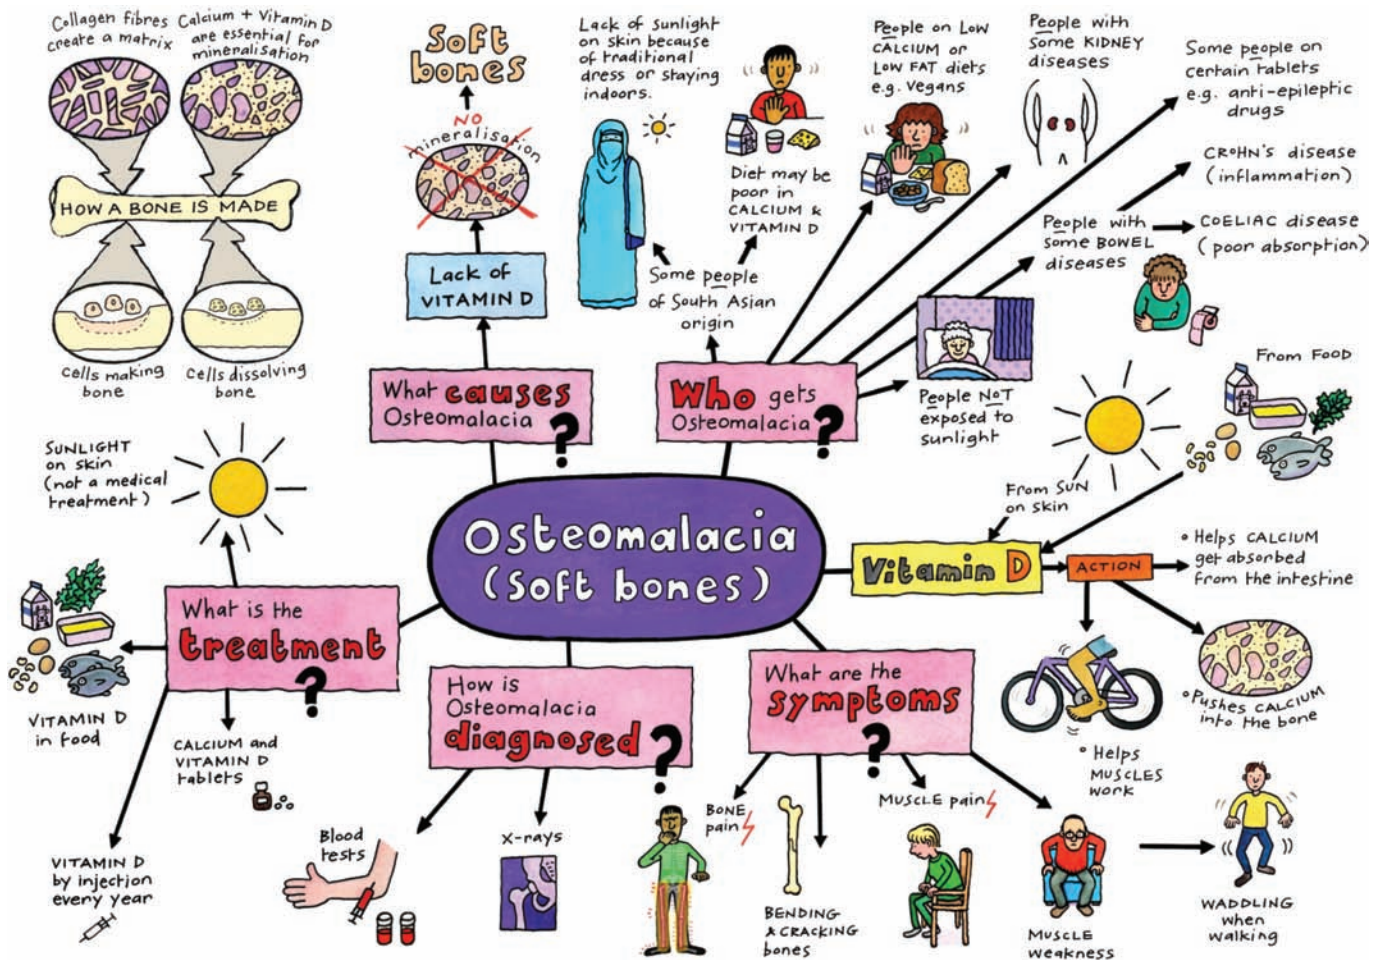
Beyond specifically produced and edited information as above there is the internet. There are huge resources of information out


Fig. 75.1 An example mind map, in this instance referring to osteomalacia. Reproduced with kind permission from Arthritis Research UK.

there and many of them are very good. However, there is also information that is misleading or taken out of context, which may not be helpful. Patients using the internet as a source of information need to be aware of the lack of provenance of some sites and choose what to access. Exactly how they do this will undoubtedly be the subject of research and debate. The internet is a very convenient way to access information and educational resources and allows greater interactivity and timeliness. In a recent survey of professionals accessing internet resources, the provenance of the material was judged the most important feature, followed by speed and ease of access.[36] It is hoped that patients will learn to make similar discriminations.

Content and timing of patient education

As part of the process of education, patients should accumulate knowledge and skills to help them manage and cope with their musculoskeletal condition. Knowledge may include such diverse topics as an understanding of the pathophysiology of their condition, action to take in the event of developing new symptoms, and how to take medication safely. Relevant skills include managing pain, appraising new information, negotiating the healthcare system, and learning to cope with chronic illness. However, there is such variation between individuals' conditions and backgrounds that a universal and comprehensive curriculum is not practical. There is also a balance between what patients want to know, and what health professionals judge is useful for them to know—that is, knowledge or skills that are likely to improve patients' health. These two viewpoints must be reconciled when considering the content of any education programme.

Needs assessment within the wider healthcare setting aims to bring about changes in the provision of care which benefit the population as a whole, usually within the context of finite resources. Within patient education, needs assessment has been used to determine the knowledge and skills required by individuals or a group. In some instances this has been in the form of a quantitative questionnaire regarding topics the patient would like more information about.[37] While these may offer healthcare providers some useful information about what patients want, they are unlikely to offer a comprehensive account of what they need, which relies on health professionals' assessment of their circumstances, and judgements about what they would find useful and potentially improve their condition.

Alongside debate about the content which should be provided for patients is a debate about when it should be provided. Issues related to timing have been considered in relation to patients' 'readiness to learn'.[38] and their 'stages of change'.[39] However, both these concepts view education as consistently and undoubtedly beneficial for patients, and view patients' judgements not to engage with education as inherently flawed.

Recent work focusing on the choices and practical steps patients with AS take to learn about their condition has proposed an alternative model with respect to the timing of education.[40] This work observed that patients' search for information was influenced by the stage of their condition (see Figure 75.2). When first diagnosed, patients began a rapid search for information, searching for the answers to three broad and challenging questions—'Why have I got AS?', 'What is going to happen to me and my family?', and 'What can I do about it?'. Later, when their health, their health care and their social lives are more stable, they become 'established'; their search for information slows, and is orientated towards solving or adapting to new problems as and when they arise.

It is therefore not possible to be prescriptive about the content of patient education, because the topics that patients are likely to find useful or beneficial are dependent on the health and social circumstances of the individual. The range of potential topics and quantity of learning available to patients are immense, and yet there are broad topic areas which patients consistently search for information.

Evaluating patient education

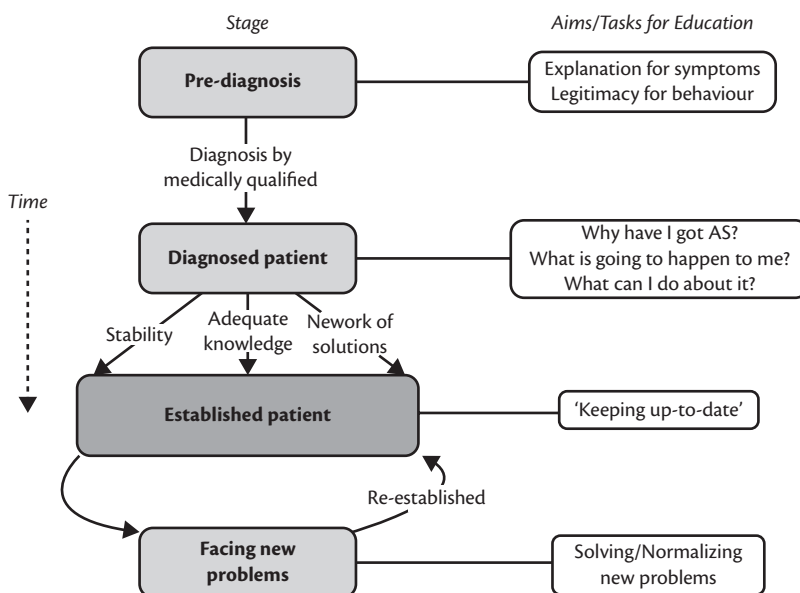
If one is expecting educational interventions to affect behaviour and outcome, then there is a similar need to have evidence of


Fig. 75.2 The established patient model.
From Thompson B. Education and learning for people with ankylosing spondylitis. MD thesis, Newcastle University, 2011.

effectiveness and lack of harm as with any other intervention. It has always been necessary to show effectiveness and lack of harm for a drug to get a licence, yet education is something health professionals do every day with patients. The need to examine this interaction and any supporting material scientifically to measure and improve effects has been adopted more slowly.

This partially explains the relative lack of studies; however, the complexity of the methodology and outcome measures required for educational interventions is also a major factor. Educational intervention studies have been judged to be of poorer quality than those of the pharmacological industry.[41] However, this is principally for structural reasons, as discussed below. A typical study of educational needs will involve a qualitative phase to identify the issues, then a quantitative phase to explore these in a larger population. A study of the effectiveness of an educational intervention will usually show a change in knowledge or confidence, but showing a change of behaviour is much more difficult. Kirkpatrick's hierarchy[42] (see Figure 75.3) displays this in pyramid form with patient satisfaction at the bottom, going through knowledge and skill acquisition, then change of behaviour to a peak of better health outcomes for the patient and society at large. Change is progressively more difficult to show, and confounding factors are more likely to explain the differences between study groups the further up the pyramid you go.

Equally, for the results of such studies to be generalizable, the study population should be adequately described and be similar to the population to which the results are to be applied. In pharmacological studies, this can usually be achieved by detailing variables which could influence the effect of the drug, such as the age, gender, ethnicity, comorbidity, or even genotype of the participants. While these variables are also likely to be important in deciding whether educational interventions are applicable to a particular population, an additional range of variables may influence the outcome of educational interventions, and less is known about their potential effect. Therefore, consideration should also be given to variables which are less easy to describe, such as participants' level of education, previous experience of patient education, social circumstances, personality, educational needs, and expectations. Patients who are recruited for group educational studies are not representative of the wider population with arthritis, with more female, elderly, and well-educated patients volunteering.[43] The discrepancy is probably influenced by the significant time commitment required from participants, and thus the need to either sacrifice other activities or to have sufficient leisure time in order to attend. This does reduce our ability to generalize the results of such trials to those populations who may actually have more to gain from education—those who have lower levels of previous educational attainment, lower social class, and who have poorer outcomes with respect to their arthritis.

Improving patient education

Patient education can be improved by health professionals increasing the quality of education they offer patients, and through the production of high-quality research which will inform our future practice.

In the case of the former, patient education can influence the greatest number of patients if it is part of routine care—not just an optional extra to be chosen by those who are highly motivated but may have less to gain. This routine care involves offering verbal and written information, especially at the time of diagnosis and changes to health or treatment, allowing time for questions, and even prompting to find out what information they have already found through their own searches. It is important to appreciate the role health professionals play in recommending educational resources to patients, endorsing their use, and acknowledging their need for information about their condition. Health professionals need to be aware of the resources, including groups, that are available locally, and be prepared to offer them to patients. They should also be alert for areas of unmet need, either for groups of patients or for individuals, and seek to address these. Strategies to identify those patients who would benefit from additional support and education should be utilized. However, education also needs to be convenient, and increasingly, this means using the internet. As part of education, patients gain from learning about the experience of other patients, and this too can be accessed through different online resources such as social media, charities, and resources such as healthtalkonline.[44]

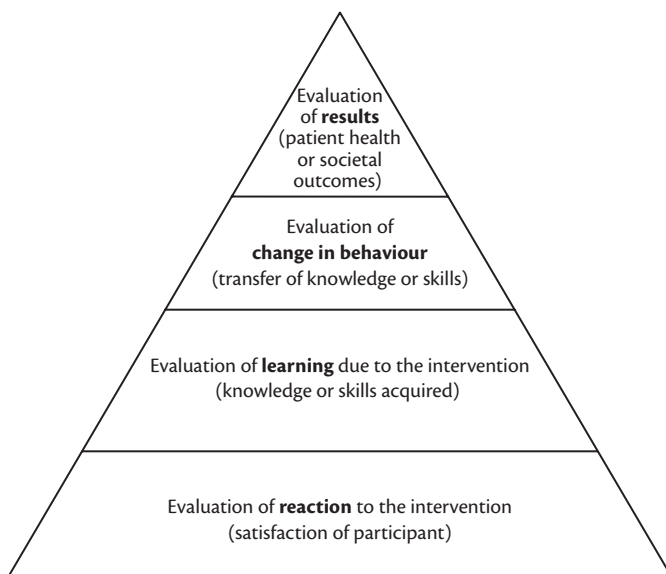
Research around this topic has focused on the evaluation of resources in the form of randomized trials, and 'measuring the measurable' is certainly useful when looking to compare interventions and learn more about their effects. However, as already discussed, this is challenging and may neglect important effects and benefits of education. At the same time, research which could be considered the 'basic science' of educational research can be enlightening and produce new ideas for methods of helping patients. Qualitative research has helped to describe and understand the questions and problems patients face as they learn to cope with their musculoskeletal condition, and the resources they choose to use, and how they use them. At the same time we can learn about groups of patients who may benefit from different approaches, such as those for whom English is not their first language, or have low previous educational attainment. There remains a great deal more to learn about the optimum methods to offer information to patients, and help them to learn the skills they need.


Fig. 75.3 Kirkpatrick's hierarchy—evaluating educational interventions.
Adapted from Kirkpatrick DL, Kirkpatrick JD. Evaluating training programs, 3rd edn. Berrett-Koehler, San Francisco, CA, 2006.

Conclusion

We have presented an overview of patient education for people with musculoskeletal conditions, illustrating the range of resources available, evidence regarding their effect on patients, and the challenges for researchers and practitioners in this field. It has become an increasingly important topic as patients become more involved in decisions about their care, and shoulder increasing responsibility for their own health and health care. However, the time, money, and expertise required to provide education can be substantial, and solutions need to be found from limited resources. The use of technology, including social media and online resources, is likely to continue to change this field. Overall, though, it is important to remember that patients will continue to learn about their condition and the best ways to cope and adapt to it; our challenge as health professionals is to aid them in their learning as effectively as we can. Patient education is not a process imposed on passive patients; instead, it is about enabling patients to learn, and identifying patients who would benefit from additional help in this process.

Multidisciplinary treatment

Sarah Ryan, Jo Adams, Anne O'Brien, and Anita Williams

Introduction

This chapter explores the evidence base for multidisciplinary treatment from four of the main disciplines involved in the care of people with a long-term musculoskeletal condition: nursing, physiotherapy, occupational therapy, and podiatry. Multidisciplinary treatments occur alongside medical and surgical treatment and involve working in partnership with the patient and with other members of the multidisciplinary team to optimize outcomes.

Nursing

Rheumatology nurse specialists (RNSs) are considered an essential member of the nursing team by both professional and patient organizations. The majority of RNSs are primarily involved in the care and management of people with rheumatoid arthritis (RA). The main role functions of a RNS[1] are shown in Box 76.1.

Three randomized controlled studies (RCTs)[2–4] have demonstrated the positive impact that the RNS can have on the patient's physical and psychological health, including improvements in pain, anxiety, function, and perceptions of self-control over the condition. Hill et al.[2] is a key reference, as this is the first RCT to evaluate the impact of a rheumatology nurse specialist.

Providing support following diagnosis

Following a diagnosis of RA the patient is often referred to the RNS to commence disease-modifying anti-rheumatic drug (DMARD)

Box 76.1 The role functions of the rheumatology nurse specialists

therapy and receive ongoing psychological support, as the patient commences the process of adapting to living with a long-term condition. In the United Kingdom, in accordance with the National Institute for Health and Clinical Excellence (NICE) guidelines,[5] patients will often commence more than one DMARD. As DMARDs may take several months to provide maximal efficacy, the nurse will carry out a biopsychosocial assessment to identify the impact of the condition and to work with the patient to address those areas of the individual's life where the condition is having the greatest impact.

Many rheumatology nurses also provide one-to-one education or develop multidisciplinary education programmes. In addition they will ensure that the patient has access to the rheumatology telephone advice line, which has become an integral part of most rheumatology services.[6] The telephone advice line is commonly used by patients when they experience an increase in their inflammatory symptoms or notice a possible medication side effect.

Many RNSs run their own follow-up clinics for patients with RA. The main objectives of these clinics are to ensure that the RA is well controlled and the patient is achieving optimum physical, psychological and social function. Monitoring the safety and efficacy of disease-modifying anti-rheumatic drugs (DMARDs) and biological therapies is also a major component of the RNS role as detailed in Box 76.2.[7–8]

Physiotherapy

Physiotherapy (physical therapy) is a key component of multidisciplinary rheumatology management. Physiotherapists, often key patient motivators, have important assessment, treatment and educational roles with patients of all ages. Physiotherapists undertake detailed musculoskeletal (MSK) assessments identifying key functional problems which are likely to impact on treatment outcome, negotiate functional goals with patients, and identify practical approaches to maximizing activities of daily living (ADL). During consultation, physiotherapists are well positioned to identify self-efficacy issues as well as education needs. Some physiotherapists work in extended practitioner roles which include the ordering of investigations, injecting joints and supplementary prescribing.

Box 76.2 The nurse's role in drug monitoring

- Assessing safety in administration, e.g. ensuring that methotrexate is taken on a weekly basis

- Monitoring for any drug reactions that have occurred, e.g. gastrointestinal, skin, urinary abnormalities, and chest manifestations

- Requesting and interpreting appropriate haematological and biochemical investigations

- Assessing for evidence of increased disease activity and increasing the dose of or adding additional DMARD treatment where indicated; some RNS also administer intra-articular joint injections

- Providing the patient with the opportunity to discuss any problems or concerns, e.g. whether they can have a vaccination

- Accessing other care needs and referring where appropriate to other members of the multidisciplinary team

The aims of physiotherapy are to:

- reduce pain/ stiffness

- improve (or maintain) joint range and muscle strength

- maximize physical functioning to achieve optimal quality of life.

The evidence base supporting physiotherapy continues to evolve and therapists continue to provide empirical evidence to support their treatments.

Exercise prescription may often be simple—e.g. encouraging postsurgical mobility, improving transfers from sitting to standing, climbing stairs—but will be fundamental to successful mobility in daily life. In other cases specific rehabilitation of key muscle groups or joints will be the key to return to function.

Exercises in arthritis are often prescribed in conjunction with other modalities to address pain[9] and swelling (e.g. using ice or heat therapy) but they are also used to improve joint range, proprioception, and/or muscle strength, all of which may have a prophylactic effect, as in osteoarthritis,[10] and a positive treatment effect.

Anxiety relating to exacerbating inflamed joints with exercise has been proven to be unfounded and physiotherapists continue to promote the positive effects of aerobic and strengthening exercises in particular[11] (this paper by Vliet Vlieland and van den Ende is a key reference, offering, a contemporary review of the literature focusing on conservative and self-management interventions.) Targeting key muscle groups around weightbearing joints will also aim to improve joint stability and thus optimize not only joint mobility, but functioning. Other exercise prescriptions will focus on optimizing cardiopulmonary fitness and aerobic capacity.[12] There is some evidence for the benefits of t'ai chi exercises (frequently popular with patients) in terms of balance and proprioception.[13]

Limited evidence supports electrical stimulation in management of RA.[14] Transcutaneous electrical nerve stimulation (TENS) intends to relieve pain with some arthritis patients,[15] but dosage is relevant: only 'acupuncture-like TENS' appears to have an analgesic effect. Low-level laser therapy is used less often, but has few side effects and has been shown to provide short-term relief of pain and morning stiffness in RA patients.[16]

Heat therapies are well liked, versatile, and commonly used at home e.g. in the form of hot packs. Wax and hydrotherapy are also used for analgesic purposes. Heat reduces muscle spasm and provides short-term reduction in pain and disability. Heat also reduces acute and subacute low back pain, especially if exercise is added,[17] and short-term analgesic benefits are reported for superficial moist heat in RA. Short-term pain relief has been described with hydrotherapy in osteoarthritis (OA), and it is generally enjoyed and accepted by patients.[18] Cryotherapy (ice), another easy modality to use at home, has been shown to have a beneficial effect on knee range of movement, strength, and function as well as reducing swelling, although the effect on pain is not significant in the OA knee.[19]

Pain reduction and improvements in physical functioning have been demonstrated in a few limited studies using acupuncture for peripheral joint OA.[20] However, other studies in low back pain suggest that acupuncture may be an effective adjunct to other physiotherapy techniques.[21]

A growing evidence base supports the physiotherapist's role in reducing impairment, minimizing disability, and maximizing patient participation. Exercise and education remain fundamental components of their interventions.

Occupational therapy

Occupational therapists aim to improve people's ability to perform daily activities and valued life roles at work, in the home, at leisure, and socially,[22] utilizing a biopsychosocial model.[23–25] The role of the occupational therapist within the multidisciplinary team is to:

- improve a person's ability to perform daily tasks and valued life roles

- facilitate successful adaptation to disruptions in lifestyle

- prevent loss of function

- improve and maintain psychological status.[26]

Occupational therapists evaluate people's specific activities that may be affected by their illness and work closely with them to help

adapt their occupation or activity, the person, and/or the environment. Occupational therapists work within primary and secondary health care delivering effective components to rheumatology rehabilitation,[27] and many are also based in community social services. Here, occupational therapists are ideally positioned to actively assist people to manage and adapt home, work, and community environments using housing adaptations and equipment to facilitate optimum functional ability.[28]

Using a biomechanical model, occupational therapists with specialist skills in regional upper limb and hand rehabilitation work with the person to provide active exercise home programmes[29] and splint provision.[30] These interventions aim to support and protect inflamed, damaged joints and maintain intrinsic muscle strength and functional ability in valued life roles affected by disease processes. Figure 76.1 illustrates an example of a tailor-made splint to provide additional support to metacarpal, proximal phalangeal,

and palmar arches affected by RA in a competitive professional horse rider.

Rehabilitative/compensatory techniques are used to assess and advise regarding the provision of assistive equipment such as chair raises, tap turners, adapted computer keyboards, and wheelchairs and can be supported by an ergonomic assessment of peoples' work and leisure performance.

Home structural adaptations assessed and managed by the social service occupational therapy team may include provision of grab rails, stair lifts, ramps, and ground-floor adaptations. These cost-effective interventions can maintain a person's functional independence, delay performance loss, reduce home falls, and maintain healthy life styles.[31,32] Occupational therapists will also be placed with work rehabilitation and employability schemes to support and enable active living. Access to these services and specialized occupational therapists is recommended within a national clinical care guideline for people with arthritis.[24]

An educational behavioural approach is employed by occupational therapists to encourage and support people to be active partners in their health care and to adopt a range of self-management behaviours such as joint protection and fatigue management.[33]

Podiatry

Many rheumatic diseases have the potential to impact negatively on the feet.[34–35] However, in those with RA, life-limiting foot problems are prevalent[36–37] and persistent, even when the disease is in remission or well managed by systemic therapy.[37–42] Pain and changes in foot structure can severely affect gait and mobility,[40] thereby impacting on quality of life.[41] Structural changes increase both the duration and magnitude of plantar pressures[42] resulting in the formation of hyperkeratosis, and the development of foot ulcers[43] and infection.

Podiatrists are considered the experts in foot health and have a crucial role in the diagnosis, assessment, management, and periodic review of foot and ankle problems for people with rheumatic diseases[44–45] including RA.[46–47] The use of foot orthoses and specialist therapeutic footwear are recommended by both the Arthritis and Musculoskeletal Alliance (ARMA)[46] and NICE,[47] who also recommend that people with RA should have access to foot health assessment and management early in the disease process.

Good links can be established with podiatry services, supported with local screening (Figure 76.2) and referral guidelines that will ensure that foot health is managed in the most appropriate way,[48] especially for those patients on biological therapy who may be at risk of foot ulceration.

Specialist podiatrists assess, monitor, and manage some of the more demanding complications such as significant structural changes, peripheral arterial disease, vasculitis, neuropathy, bacterial and fungal infections of the skin and nails, and ulceration, and can carry out nail surgery for persistent nail deformity and infections. Those specialist podiatrists with extended skills use ultrasonography to both aid diagnosis and guide steroid injections which are effective for targeting localized, inflamed joints when the general disease is controlled. Additionally, all podiatrists who are registered with the Health Professions Council are now able to safely and competently access, supply and administer the range of prescription-only medicines and pharmacy-only medicines available on the approved list of medicines.

In early disease, where there is minimal joint damage and capability for self-management, the combination of medical and local foot health management minimizes the effects of joint and soft tissue involvement. This is achieved through offloading the forefoot and rearfoot control with rigid foot orthoses (Figure 76.3) that aim to control the abnormal alignment of joints and improve function, but this has to be done before the joint changes become irreversible.[49]

Instruction on self-care of the skin and nails can be given to the patient so that they can carry out simple foot hygiene tasks.

Where there are established foot problems (intermediate stage) the focus is on minimizing progressive changes and reduction of symptoms, with maintenance of independence and participation a priority. Orthotic intervention tends to be more accommodative or palliative though still improving control and support. Footwear advice becomes more relevant as the structural changes in the feet (toe deformity, increased width, pressure areas, and hyperkeratosis) mean that patients need guidance as to the styles of footwear that can accommodate both the foot and the orthoses. Judicious sharp debridement of hyperkeratosis may have some therapeutic effect from the patient's perspective, but is not recommended if pressure relief is not provided.[48]

In longstanding disease (late stage), progressive structural changes contribute to further mechanical stresses causing pes plano valgus foot position with significant forefoot deformity. Management focuses on maintenance of good tissue viability, and palliative orthoses designed to protect the plantar aspect of the foot, often requiring specialist therapeutic footwear.[53] If the non-surgical interventions fail to relieve symptoms then a referral for consultation about surgical options is recommended.[47]

Conclusion

This chapter has identified the roles and functions of four different professionals involved in the care of people with musculoskeletal conditions. Where research evidence is available this has been used to discuss the merits and limitations of multidisciplinary treatments delivered by nurses, physiotherapists, occupational therapists and podiatrists. It is additionally recognized that people with musculoskeletal conditions will have varying physical, psychological, and
Fig. 76.3 Realignment of an everted rearfoot (left foot) with foot orthoses (right foot).

social needs that may require input from other health professionals including psychologists, dietitians, social workers, pharmacists, and orthotists.

Cyclooxygenase inhibitors

Burkhard Hinz and Kay Brune

Mode of action and side effects of cyclooxygenase inhibitors

Biochemical basis

In 1971, Vane showed that the anti-inflammatory action of non-steroidal anti-inflammatory drugs (NSAIDs) rests in their ability to inhibit the activity of the cyclooxygenase (COX) enzyme, which in turn results in a diminished synthesis of proinflammatory prostaglandins.[1] This action is considered a major factor of the mode of action of NSAIDs, although not the only one. The pathway leading to the generation of prostaglandins has been elucidated in detail. Within this process, the COX enzyme (also referred to as prostaglandin H synthase) catalyses the first step of the synthesis of prostanoids by converting arachidonic acid into prostaglandin H_2, which is the common substrate for specific prostaglandin synthases (Figure 77.1). The enzyme is bifunctional, with fatty-acid COX activity (catalysing the conversion of arachidonic acid to prostaglandin G_2) and prostaglandin hydroperoxidase activity (catalysing the conversion of prostaglandin G_2 to prostaglandin H_2). In the early 1990s, COX was demonstrated to exist as two distinct isoforms.[2,3] COX-1 is constitutively expressed as a 'housekeeping' enzyme in nearly all tissues, and mediates physiological responses (e.g. cytoprotection of the stomach, platelet aggregation). COX-2, expressed by cells that are involved in inflammation (e.g. macrophages, monocytes, synoviocytes), has emerged as the isoform that is primarily responsible for the synthesis of prostanoids involved in pathological processes, such as acute and chronic inflammatory states (Figure 77.1). The expression of COX-2 is regulated by a broad spectrum of other mediators involved in inflammation. Accordingly, glucocorticoids have been reported to inhibit the expression of the COX-2 isoenzyme.[2]

Side effects dependent on COX-1 inhibition

All conventional NSAIDs interfere with the enzymatic activity of both COX-1 and COX-2 at therapeutic doses.[4] In fact, many of the side effects of NSAIDs (e.g. gastrointestinal ulceration and bleeding, platelet dysfunctions) are due to a suppression of COX-1-derived prostanoids. Likewise, COX-1 inhibition confers hypersensitivity to aspirin and other chemically unrelated NSAIDs in 5–20% of patients with chronic asthma and in an unknown fraction of patients with chronic urticaria–angioedema. Here, inhibition of COX-1 leads to activation of the lipoxygenase pathway and production of cysteinyl leukotrienes that induce bronchospasm and nasal obstruction. Asthmatic patients who are intolerant to NSAIDs produce low levels of bronchodilatatory prostaglandin E_2 (probably because of a lack of COX-2), and have increased levels of leukotriene C4 synthase and reduced levels of metabolites (lipoxins) released through the transcellular metabolism of arachidonic acid.[5]

Analgesic action dependent on COX-2 inhibition

On the other hand, inhibition of COX-2-derived prostanoids facilitates the anti-inflammatory, analgesic, and antipyretic effects of NSAIDs. Inflammation causes an increased synthesis of COX-2-dependent prostaglandins, which sensitize peripheral nociceptor terminals and produce localized pain hypersensitivity. Prostaglandins regulate the sensitivity of so-called polymodal nociceptors that are present in nearly all tissues. A significant proportion of these nociceptors cannot be easily activated by physiological stimuli such as mild pressure or some increase of temperature.[6] However, following tissue trauma and subsequent release of prostaglandins, 'silent' polymodal nociceptors become excitable to pressure, temperature changes, and tissue acidosis.[7] This process results in a phenomenon called hyperalgesia—in some instances allodynia. Prostaglandin E_2 and other inflammatory mediators facilitate the activation of tetrodotoxin-resistant Na^+ channels in dorsal root ganglion neurons.[8–10] Another important target of protein kinase A-mediated phosphorylation is the capsaicin receptor (transient receptor potential vanilloid 1, TRPV1), a non-selective cation channel of sensory neurons involved in the sensation of temperature and inflammatory pain.[11–13] TRPV1 responds to temperature above 40 °C and to noxious stimuli including capsaicin, the pungent component of chili peppers, and extracellular acidification. On the basis of this mechanism, prostaglandins produced during inflammatory states may significantly increase the excitability of nociceptive nerve fibres, including reactivity to temperatures below 40 °C (i.e., body temperature), thereby contributing to the activation of 'sleeping' nociceptors and the development of burning pain. As such, it appears reasonable that at least a part of the peripheral antinociceptive action of COX inhibitors arises from prevention of this peripheral sensitization. Apart from sensitizing peripheral nociceptors, prostaglandins also act in the central nervous system to produce central hyperalgesia. Experimental data suggest that both acidic and non-acidic COX inhibitors antagonize central

hyperalgesia in the dorsal horn of the spinal cord by modulating the glutamatergic signal transfer from nociceptive C fibres to secondary neurons, which propagate the signals to the higher centres of the central nervous system. Some COX-2 is expressed constitutively in the dorsal horn of the spinal cord, and becomes upregulated briefly after a trauma, such as damage to a limb, in the corresponding sensory segments of the spinal cord.[14] The induction of spinal cord COX-2 expression may facilitate transmission of the nociceptive input. In line with a role of COX-2 in central pain perception, Smith et al.[15] reported that selective COX-2 inhibition suppressed inflammation-induced prostaglandin levels in cerebrospinal fluid, whereas selective inhibition of COX-1 was inactive in this regard. These observations were substantiated by findings showing a widespread induction of COX-2 expression in spinal cord neurons and in other regions of the central nervous system following peripheral inflammation.[16] Several mechanisms have been proposed to underlie the facilitatory action of prostaglandin E_2 on central pain sensation. Baba et al.[17] showed that prostaglandin E_2 at relatively high concentrations directly depolarizes wide dynamic range neurons in the deep dorsal horn. More convincingly, prostaglandin E_2 at significantly lower concentrations reduces the inhibitory tone of the neurotransmitter glycine on to neurons in the superficial layers of the dorsal horn[18] by phosphorylation of the specific glycine receptor subtype GlyRα3,[19] thereby causing a disinhibition of spinal nociceptive transmission. In another study, the same group has identified prostaglandin E_2 receptors of the EP_2 receptor subtype as key signalling elements in spinal inflammatory hyperalgesia,[20] thus opening new avenues for the development of new analgesics.

Side effects dependent on COX-2 inhibition

The hypothesis that selective inhibition of COX-2 might have therapeutic actions similar to those of NSAIDs, but without causing the unwanted side effects elicited by COX-1 inhibition, was the rationale for the development of selective COX-2 inhibitors. However, the simple concept of COX-2 being an exclusively proinflammatory and inducible enzyme cannot be sustained in the light of diverse experimental and clinical findings. Accordingly, COX-2

has also been shown to be expressed under basal conditions in organs including the ovary, uterus, brain, spinal cord, kidney, cartilage, bone, and even the gut, suggesting that this isozyme may play a more complex physiological role than previously recognized (for review see ref. 21).

In line with this view, a permanent blockade of COX-2-dependent prostaglandins, including prostacyclin, is the currently most plausible explanation for the cardiovascular hazard conferred by long-term use of selective and non-selective COX-2 inhibitors. In fact, prostacyclin, which is suppressed by over 60% by both NSAIDs and selective COX-2 inhibitors,[22] is not only a potent inhibitor of platelet aggregation, but also interferes with processes leading to hypertension, atherogenesis, and cardiac dysfunction. In this context changes in arterial blood pressure have been proposed to underlie the long-term cardiovascular side effects of both NSAIDs and COX-2 inhibitors. The involvement of COX-2 in human renal function is supported by numerous clinical studies that showed that COX-2 inhibitors, similar to NSAIDs, can cause peripheral oedema, hypertension, and exacerbation of pre-existing hypertension by inhibiting water and salt excretion by the kidneys.[23–25] These observations are of major importance given that relatively small changes in blood pressure could have a significant impact on cardiovascular events. In patients with osteoarthritis, increases in systolic blood pressure of 1–5 mmHg have been associated with 7100–35 700 additional ischaemic heart disease and stroke events over 1 year.[26]

It has been suggested that both degree and time-course of intravascular COX-2 inhibition might determine the differential profile of cardiovascular side effects associated with NSAIDs and COX-2 inhibitors.[27–29] Claims that NSAIDs inhibit COX-1 thereby conferring cardioprotection proved wrong since platelet COX-1 activity has to be suppressed by more than 95% to translate into inhibition of platelet aggregation.[30] Such a complete COX-1 inhibition over the whole dosing interval is only achieved by low-dose aspirin and in some individuals by high-dose naproxen (500 mg twice daily).[30,31] Other NSAIDs such as ibuprofen and diclofenac suppress COX-1 (>95%) only at peak plasma concentrations. This is

consistent with an increased cardiovascular risk with high-dose diclofenac and ibuprofen, but not with naproxen.[32]

COX inhibition in the whole blood assay as a predictor of analgesic action and side effects

Among the experimental systems developed to study COX-2 selectivity of drugs, the human whole blood assay established by Patrono's group[33] has emerged as the gold standard. Whole blood assays, based on the synthesis of coagulation-induced thromboxane B_2 as an index for COX-1 and on lipopolysaccharide-induced prostaglandin E_2 as an index of COX-2 activity, are currently considered to provide the most meaningful index of COX selectivity. In these assays, the selectivity of COX inhibition is measured in a physiological milieu which takes into account the differential binding of drugs to plasma proteins. According to Huntjens et al.[34] ex-vivo COX-2 inhibition in the whole blood assay by approximately 80% is expected to result in analgesia due to the fact that the analgesic therapeutic plasma concentration of a COX inhibitor correlates with its inhibitory concentration $(IC)_{80}$ (the concentration that leads to 80% inhibition) on COX-2 in the human whole blood assay. By contrast, only in excess of 95% suppression of thromboxane B_2 formation translates into clinically relevant inhibition of platelet aggregation,[30] thus predicting whether a drug might cause cardioprotection (and bleeding) or not. In addition, ex-vivo COX-2 inhibition measurements from whole blood has been suggested as a potential surrogate to estimate cardiovascular risk.[27–29]

Non-steroidal anti-inflammatory drugs (acidic antipyretic analgesics)

Based on the finding that aspirin at high doses (>3 g/day) not only inhibits fever and pain but also interferes with inflammation, Winter developed an assay to search for drugs with a similar profile of anti-inflammatory activity.[35] Amazingly, all substances that survived the test of experimental pharmacology and clinical trials turned out to be acids with a high degree of lipophilic–hydrophilic polarity, similar pK_a values, and a high degree of plasma protein binding (for reviews see refs 36–38).

Later it turned out that high concentrations of these acidic compounds are reached in bloodstream, liver, spleen, and bone marrow (due to high protein binding and an open endothelial layer of the vasculature), but also in body compartments with acidic extracellular pH values.[39] The latter type of compartments includes the inflamed tissue, the wall of the upper gastrointestinal tract, and the collecting ducts of the kidneys. Concerning gastrointestinal toxicity, there are, in fact, at least two major components contributing to the ulcerogenic action of NSAIDs in the stomach: a topical irritant effect on the epithelium and the ability to suppress prostaglandin synthesis.[40–43] Topical irritant properties are confined to acidic NSAIDs which accumulate in gastric epithelial cells because of the phenomenon of 'ion trapping'.[44]

Apart from aspirin, all of these compounds differ in their potency, i.e., the single dose necessary to achieve a certain degree of effect ranges from a few milligrams (e.g. lornoxicam) to about 1 g (e.g. salicylic acid). They also differ in their pharmacokinetic characteristics, i.e. the speed of absorption (time to peak, t_{max};

which may also depend on the galenic formulation used), the maximal plasma concentrations (c_{max}), the elimination half-life $(t_{1/2})$, and the oral bioavailability. Interestingly, all traditional NSAIDs lack a relevant degree of COX-2 selectivity.[4] The key characteristics of the most important NSAIDs are listed in Table 77.1 (most data are from ref. 36). This table also contains the data on aspirin which differs in many respects from the other NSAIDs and is therefore discussed in detail (see 'Compounds of special interest'). Otherwise, the drugs can be categorized in four different groups. Suggestions for indications are listed in Table 77.2.

NSAIDs with low potency and short elimination half-life

The prototype of this type of compounds is ibuprofen. Other drugs of this group are salicylates and mefenamic acid. The latter does not appear to offer major advantages. By contrast, this and other fenamates are rather toxic at overdosage (central nervous system). The drugs of this group are particularly useful for blocking occasional mild inflammatory pain.

In the following the pharmacology of ibuprofen is addressed in more detail. Depending on its galenic formulation, fast or slow absorption of ibuprofen may be achieved. A fast absorption of ibuprofen was observed following administration of the respective lysine salt.[45] The bioavailability of ibuprofen is close to 100% and the elimination is always fast, even in patients suffering from mild or severe impairment of liver or kidney function.[36] Ibuprofen is used as single doses ranging from 200 mg to 1 g. A maximum dose of 3.2 g per day (United States) or 2.4 g (Europe) for rheumatoid arthritis is possible. At low doses ibuprofen appears particularly useful for the treatment of acute occasional inflammatory pain. High doses of ibuprofen may also be administered, although with less benefit, for the treatment of chronic rheumatic diseases. Remarkably, at high doses the otherwise harmless compound has been shown to result in an increased incidence of gastrointestinal side effects.[46] In some countries ibuprofen is also administered as the pure S-enantiomer, which comprises the active entity of the racemic mixture in terms of COX inhibition. On the other hand, a substantial conversion of the less potent COX inhibitor R-ibuprofen (comprises 50% of the usual racemic mixture) into the active S-enantiomer has been observed following administration of the racemic mixture.[47]

NSAIDs with high potency and short elimination half-life

These drugs are predominantly prescribed for the treatment of rheumatic (arthritic) pain. The most widely used compound of this group is diclofenac. Other drugs of this group are lornoxicam, flurbiprofen, and indomethacin (very potent), but also ketoprofen and fenoprofen (less active). All of the latter drugs show a high oral bioavailability and good effectiveness, but also a relatively high risk of unwanted drug effects.[48]

Diclofenac appears to be less active on COX-1 as compared to COX-2.[4,49] This is taken as a reason for the relatively low incidence of gastrointestinal side effects of diclofenac.[48] The limitations of diclofenac result from its usual formulation (monolithic acid-resistant coated dragée or tablet). In fact, retention of such formulations

Table 77.1 Physicochemical and pharmacological data of acidic antipyretic analgesics

Pharmacokinetic/chemical subclasses	pK$_a$	Binding to plasma proteins	Oral bioavailability	t_{max}[a]	$t_{1/2}$[b]	Single dose (maximal daily dose) for adults
Low potency/short elimination half-life						
Salicylates						
Aspirin	3.5	50%–70%	~50% dose-dependent	~15 min	~15 min	0.05–1 g[c] (~6 g)
Salicylic acid	3.0	80%–95% dose-dependent	80%–100%	0.5–2 h	2.5–4.5 h dose-dependent	0.5–1 g(~6 g)
2-Arylpropionic acids						
Ibuprofen	4.4	99%	100%	0.5–2 h	2 h	200–800 mg (2.4 g)
Anthranilic acids						
Mefenamic acid	4.2	90%	70%	2–4 h	1–2 h	250–500 mg (1.5 g)
High potency/short elimination half-life						
2-Arylpropionic acids						
Flurbiprofen	4.2	>99%	No data	1.5–3 h	2.5–4(–8) h	50–100 mg (200 mg)
Ketoprofen	5.3	99%	~90%	1–2 h	2–4 h	25–100 mg (200 mg)
Aryl-/heteroarylacetic acids						
Diclofenac	3.9	99.7%	~50% dose-dependent	1–12 h[e] very variable	1–2 h	25–75 mg (150 mg)
Indometacin	4.5	99%	~100%	0.5–2 h	2–3(–11) h[d] very variable	25–75 mg (200 mg)
Oxicams						
Lornoxicam	4.7	99%	~100%	0.5–2 h	4–10 h	4–12 mg (16 mg)
Intermediate potency/intermediate elimination half-life						
Salicylates						
Diflunisal	3.3	98%–99%	80%–100%	2–3 h	8–12 h dose-dependent	250–500 mg (1 g)
2-Arylpropionic acids						
Naproxen	4.2	99%	90%–100%	2–4 h	12–15 h[d]	250–500 mg (1.25 g)
Arylacetic acids						
6-Methoxy-2-naphthyl-acetic acid (active metabolite of nabumetone)	4.2	99%	20%–50%	3–6 h	20–24 h	0.5–1 g (1.5 g)
High potency/long elimination half-life						
Oxicams						
Piroxicam	5.9	99%	~100%	3–5 h	14–160 h[d]	20–40 mg; initial: 40 mg
Tenoxicam	5.3	99%	~100%	0.5–2 h	25–175 h[d]	20–40 mg; initial: 40 mg
Meloxicam	4.08	99.5%	89%	7–8 h	20 h[e]	7.5–15 mg

[a]Time to reach maximum plasma concentration after oral administration.

[b]Terminal half-life of elimination.

[c]Single dose for inhibition of thrombocyte aggregation, 50–100 mg; single analgesic dose, 0.5–1 g.

[d]Enterohepatic circulation.

[e]Monolithic acid-resistant tablet or similar galenic form.

Table 77.2 Indications for antipyretic analgesics

Acute and chronic pain, produced by inflammation of different etiology	High dose	Middle dose	Low dose
Acidic antipyretic analgesics (anti-inflammatory antipyretic analgesics, NSAIDs)[a]			
Arthritis: chronic polyarthritis (RA, AS (Morbus Bechterew), acute gout (gout attack)	Diclofenac, indometacin, ibuprofen, piroxicam (phenylbutazone)[b]	Diclofenac, indometacin, ibuprofen, piroxicam, (phenylbutazone)[b]	No
Cancer pain (e.g. bone metastasis)	(Indometacin)[c], diclofenac[c], ibuprofen[c], piroxicam[c]	(Indomethacin)[c], diclofenac[c], ibuprofen[c], piroxicam[c]	Aspirin[d], ibuprofen[c]
Active arthrosis (acute pain-inflammatory episodes)	No	Diclofenac, indometacin, ibuprofen, piroxicam	Ibuprofen, ketoprofen
Myofascial pain syndromes (antipyretic analgesics are often prescribed but of limited value)	No	Diclofenac, ibuprofen, piroxicam	Ibuprofen, ketoprofen
Posttraumatic pain, swelling	No	(Indometacin), diclofenac, ibuprofen	Aspirin[d], ibuprofen[c]
Postoperative pain, swelling	No	(Indometacin), diclofenac, ibuprofen	Ibuprofen
Non-acidic antipyretic analgesics			
Acute pain and fever	Pyrazolinones[g] (high dose)	Pyrazolinones[g] (low dose)	Paracetamol (high dose is toxic)
Spastic pain (colics)	Yes	Yes	No
Conditions associated with high fever	Yes	Yes	No
Cancer pain	Yes	Yes	Yes
Headache, migraine	No	Yes	Yes[f]
General disturbances associated with viral infections	No	Yes[e]	Yes

AS, ankylosing spondylitis; RA, rheumatoid arthritis.

[a]Dosage range of NSAIDs and example of monosubstances (but note dosage prescribed for each agent).

[b]Indicated only in gout attacks.

[c]Compare the World Health Organization sequence staged scheme for cancer pain.

[d]Blood coagulation and renal function must be normal.

[e]If other analgesics and antipyretics are contraindicated, e.g. gastroduodenal ulcer, blood coagulation disturbances, or asthma.

[f]In particular patients.

[g]Given the fact that pyrazolinone derivatives (phenazone, propyphenazone, dipyrone) are not available in the United Kingdom, the pharmacology of these drugs is not further addressed in this chapter.

in the stomach for hours or even days may cause retarded absorption of the active ingredient.[36] Moreover, diclofenac has a considerable first-pass metabolism that causes its limited (about 50%) oral bioavailability. Consequently, a lack of therapeutic effect may require adaptation of the dosage or change of the drug. New formulations (microencapsulations, salts, etc.) remedy some of these deficits.[50] The slightly higher incidence of liver toxicity associated with diclofenac may result from the high degree of first-pass metabolism, but other interpretations appear feasible. Previously, it has been demonstrated that pharmacologically relevant concentrations of diclofenac are generated through limited but sustained bioactivation following oral administration of aceclofenac.[49] As aceclofenac per se does not interfere with the COX enzymes, diclofenac seems to confer a major part of the pharmacological action of aceclofenac. Interestingly, metabolic generation of diclofenac after administration of a 100 mg dose of aceclofenac was associated with an apparently improved COX-2 selectivity as compared to a 75 mg dose of a sustained-release diclofenac formulation.[49]

NSAIDs with intermediate potency and intermediate elimination half-life

The third group is intermediate in potency and speed of elimination and comprises drugs such as naproxen and diflunisal. Because of its slow absorption, diflunisal is rarely used anymore.

The use of naproxen has been associated with a potential cardioprotective effect. Indeed, evidence suggests that continuous and regular administration of naproxen 500 mg administered twice daily can affect platelet COX-1 activity and subsequent platelet aggregation throughout the dosing interval in some, but not all, patients.[31] In line with this notion, a meta-analysis of 138 (published and unpublished) randomized trials[32] concluded that the incidence of serious vascular events is similar between a COX-2 inhibitor and any non-naproxen COX inhibitor and that the risk of naproxen is in the placebo range. On the other hand, ulcer bleeds are seen more frequently with naproxen than with ibuprofen, which does not cause lasting platelet inhibition.[51]

NSAIDs with high potency and long elimination half-life

The fourth group consists of the oxicams (meloxicam, piroxicam, and tenoxicam). These compounds are characterized by a high degree of enterohepatic circulation, slow metabolism, and slow elimination.[36] Because of their long half-life (days), oxicams are not drugs of first choice for the treatment of acute pain of short duration. The main indication of the oxicams is inflammatory pain that persists for days, i.e. pain resulting from cancer (bone metastases) or chronic polyarthritis. The high potency and long persistence in the body may be the reason for the somewhat higher incidence of serious adverse drug effects in the gastrointestinal tract and in the kidney observed in the presence of these drugs.[48]

Compounds of special interest

Aspirin, the prototype NSAID, deserves special discussion. This drug irreversibly inactivates both COX-1 (highly effective) and COX-2 (less effective) by acetylating an active-site serine. Consequently, this covalent modification interferes with the binding of arachidonic acid at the COX active site. Most cells compensate the enzyme loss due to acetylation by aspirin via de-novo synthesis of this enzyme. However, as platelets are unable to generate fresh enzyme, a single dose of aspirin may suppress platelet COX-1-dependent thromboxane synthesis for the whole lifetime of thrombocytes (8–11 days) until new platelets are formed.

Following oral administration, aspirin is substantially cleaved before, during, and shortly after absorption, to yield salicylic acid. Consequently, the oral bioavailability is low and the plasma half-life of aspirin is only about 15 min. Aspirin may be used as a solution (effervescent) or as a (lysine) salt, allowing very fast absorption, distribution, and pain relief. Aspirin may cause bleeding from existing ulcers due to its long-lasting anti-platelet effect and topical irritation of the gastrointestinal mucosa.[52] The inevitable irritation of the gastric mucosa may be acceptable in otherwise healthy patients. Aspirin should not be used in pregnant women (premature bleeding, closure of ductus arteriosus) or children before puberty (Reye's syndrome) in addition to the contraindications pertinent to all NSAIDs.

When low doses of aspirin (≤100 mg) are administered, aspirin acetylates the COX-1 isozyme of platelets presystemically in the portal circulation before aspirin is deacetylated to salicylate in the liver. By contrast, COX-2-dependent synthesis of vasodilatory and antithrombotic prostacyclin by vascular endothelial cells outside the gut is not altered by low-dose aspirin. The reason for this phenomenon lies in the rapid cleavage of aspirin leaving little if any unmetabolized aspirin after primary liver passage. Thus, low-dose aspirin has its only indication in the prevention of thrombotic and embolic events.

Another problem concerns the use of low-dose aspirin together with other COX-2-selective or non-selective NSAIDs. In this context, it has been shown that the combination of low-dose aspirin with COX-2-selective inhibitors may abrogate the gastrointestinal-sparing effects of the latter compounds.[46,53] Moreover, ibuprofen and naproxen (the latter at higher than over-the-counter doses) can interfere with the anti-platelet activity of low-dose aspirin when they are coadministered.[54,55] The underlying mechanism might be a competitive inhibition at the acetylation site of platelet COX-1. The clinical implication of this interaction is unclear. It is, however, potentially important because the cardioprotective effect of aspirin, when used for secondary prevention of myocardial infarction, could be decreased or negated if NSAIDs are used too. In this context a small epidemiological study of survivors of myocardial infarction suggested that concurrent ibuprofen but not diclofenac undermined the efficacy of aspirin in preventing a second myocardial infarction.[56] Therefore, current recommendations by the United States Food and Drug Administration (FDA)[57] advise patients who use immediate-release aspirin and require concurrent ibuprofen to take a single dose of 400 mg ibuprofen at least 30 minutes or longer after aspirin ingestion, or more than 8 hours before aspirin ingestion.

Selective COX-2 inhibitors

Selective inhibitors of the COX-2 enzyme, also referred to as coxibs, have been developed as substances with therapeutic actions similar to those of NSAIDs, but without causing gastrointestinal side effects. By definition, a substance may be regarded as a selective COX-2 inhibitor if it causes no clinically meaningful COX-1 inhibition at maximal therapeutic doses. Selective COX-2 inhibitors currently used in rheumatology are the sulfonamide celecoxib and the methylsulfone etoricoxib. Of these, celecoxib is the only COX-2 inhibitor available in the United States. Differences in physicochemical characteristics are reflected in different pharmacokinetic behaviour (Table 77.3; for review see ref. 58). Due to its very poor solubility, the absorption of celecoxib is relatively slow and incomplete; this compound undergoes considerable first-pass metabolism (20%–60% oral bioavailability). Both factors limit celecoxib's utility for treatment of acute pain. In addition, its rate of elimination ($t_{1/2}$ ~6–12 h) appears to be highly variable.[27,59,60] Etoricoxib is eliminated from the body slowly ($t_{1/2}$ ~20–26 h) and is absorbed at a fast rate, which appears to cause its fast onset of action. In fact, peak plasma concentrations of etoricoxib are reached within 1 hour of administration in both healthy volunteers and patients who had undergone hip surgery.[61] In another study addressing the analgesic effect of single oral doses of etoricoxib in the treatment of pain after dental surgery, the median time to onset of analgesia was 24 minutes for etoricoxib 120 mg, 180 mg, and 240 mg, and 30 minutes for etoricoxib 60 mg.[62] Both COX-2 inhibitors undergo oxidative drug metabolism by cytochrome P450 (CYP) enzymes. Celecoxib has been shown to inhibit the metabolism of the CYP2D6 substrate metoprolol, a widely used β-blocker.[60]

The hypothesis that selective COX-2 inhibitors may provide an improved risk-benefit ratio in terms of gastrointestinal safety as compared with conventional NSAIDs was tested in three large phase 3 clinical trials on a total of 35 000 patients. In the Gastrointestinal Outcomes Research (VIGOR) study[63] and the Therapeutic Arthritis Research and Gastrointestinal Event Trial (TARGET)[55] rofecoxib and lumiracoxib (both drugs were subsequently withdrawn due to cardiovascular or hepatotoxic side effects) were found to decrease the risk of confirmed gastrointestinal events (including ulcerations, bleedings, and perforations) associated with traditional NSAIDs by more than 50%. In the Celecoxib Long-term Arthritis Safety Study (CLASS), however, a significant beneficial effect of celecoxib was only evident when the definition of upper gastrointestinal endpoints was expanded to include symptomatic ulcers.[47] Moreover, outcomes of the first 6 months were published instead of the complete 1-year data of this study.

Table 77.3 Physicochemical and pharmacological data of selective COX-2 inhibitors

	COX-1/COX-2 ratio[a]	Binding to plasma proteins	V_d[b]	Oral bioavailability	t_{max}[c]	$t_{1/2}$[d]	Primary metabolism[e] (cytochrome P450 enzymes)	Recommended daily dose for adults
Sulfonamides								
Celecoxib	30	~97%	455 l	20%–60%	2–4 h	6–12 h	Oxidation (CYP2C9, 3A4)[e]	200 mg (1 × 200 mg or 2 × 100 mg) for OA 200 mg (2 × 100 mg)–400 mg (2 × 200 mg) for RA
Methylsulfons								
Etoricoxib	344	~92%	120 l	100%	~1 h	20–26 h	Oxidation to 6-hydroxy-methyletoricoxib (major role, CYP3A4; ancillary role, CYP2C9, 2D6, 1A2)	30–60 mg for OA 90 mg for RA 120 mg for acute gouty arthritis

OA, osteoarthrosis; RA, rheumatoid arthritis.

[e]Compounds may inhibit CYP2D6.

Indeed, the risk of peptic ulcers in high-risk patients taking a COX inhibitor can be significantly reduced by concomitant administration of proton-pump inhibitors.[64,65] This combination, however, does not provide protection against damage caused by COX inhibitors in the lower gastrointestinal tract. Accordingly, a double-blind, placebo-controlled trial using capsule endoscopy revealed celecoxib to be associated with considerably fewer small-bowel mucosal breaks than naproxen plus omeprazole.[66] These data are supported by the recently published CONDOR (Celecoxib versus omeprazole and diclofenac in patients with osteoarthritis and rheumatoid arthritis) trial that was performed on patients with osteoarthritis or rheumatoid arthritis at increased gastrointestinal risk receiving either celecoxib 200 mg twice a day or diclofenac slow release 75 mg twice a day plus omeprazole 20 mg once a day. This study has shown a lower risk of clinical outcomes throughout the gastrointestinal tract in patients treated with celecoxib than in those receiving diclofenac plus omeprazole.[67]

In accordance with a decisive role of COX-1 in aspirin-induced asthma, COX-2 inhibitors are well tolerated by aspirin-sensitive asthmatic patients in several re-exposure studies.[68–71] However, these findings are as yet not seen as proof and the product information of all COX-2 inhibitors still regards aspirin-induced asthma as a contraindication.

COX-2 inhibitors have been associated with an increased incidence of cardiovascular side effects. In fact, in placebo-controlled randomized clinical studies rofecoxib and celecoxib were shown to increase the incidence of myocardial infarctions and other cardiovascular reactions after a prolonged period of treatment.[72,73] With respect to the original purpose of these studies, i.e. adenomatous polyposis prevention study with rofecoxib (APPROVE) and adenoma prevention with celecoxib (APC), both trials demonstrated a significant reduction in new adenoma formation associated with the use of COX-2 inhibitors in patients with a previous history of colorectal carcinomas. Moreover, in high-risk patients short-term treatment with valdecoxib or parecoxib was associated with an increased number of severe thromboembolic events.[74] These observations had various pharmaco-political consequences: rofecoxib (Vioxx) and valdecoxib (Bextra) were withdrawn from the market; and regulatory bodies were prompted to request changes in the labelling of both selective and non-selective COX inhibitors, including those available for over-the-counter use.[75] To minimize this risk, the respective substances should be taken at the lowest effective dose for the shortest possible duration of treatment.[76,77]

In contrast to COX-2 inhibitors, no placebo-controlled randomized trial was designed to define the cardiovascular risk of NSAIDs. However, a recently published meta-analysis of 138 randomized trials[32] concluded that the incidence of serious vascular events is similar between a COX-2 inhibitor and any non-naproxen NSAID, and that the risk of naproxen is in the placebo range. The summary rate ratio for vascular events, compared with placebo, was 0.92 for naproxen, 1.51 for ibuprofen, and 1.63 for diclofenac. Furthermore, population-based nested case-control studies have shown an increased risk of myocardial infarction associated with the current use of both COX-2 inhibitors and traditional NSAIDs.[78,79] Finally, comparable rates of thrombotic cardiovascular events have been reported for the highly selective COX-2 inhibitor etoricoxib and the traditional NSAID diclofenac in the MEDAL study programme,[80] which involved around 35 000 patients with osteoarthritis or rheumatoid arthritis, suggesting that there is presently no rationale for a further differentiation of COX-2 inhibitors and NSAIDs in terms of cardiovascular safety.

Paracetamol

Paracetamol (acetaminophen) possesses weak anti-inflammatory but efficient analgesic and antipyretic activity. It is one of the most widely used over-the-counter antipyretic and analgesic drugs worldwide and is recommended as first-line therapy for pain associated

with osteoarthrosis.[81] Typical further indications of paracetamol are fever and pain occurring in the context of viral infections as well as headache. Paracetamol is also used in children, but despite its somewhat lower toxicity in juvenile patients, fatalities due to involuntary overdosage have been reported.

Despite its improved gastrointestinal safety profile as compared to NSAIDs, paracetamol is unique in causing a dose-dependent hepatotoxic effect: A small proportion of paracetamol is metabolized to the highly toxic nucleophilic N-acetyl-benzoquinoneimine that is usually inactivated by reaction with sulfhydryl groups in glutathione. However, following ingestion of large doses of paracetamol, hepatic glutathione is depleted, resulting in covalent binding of N-acetyl-benzoquinoneimine to DNA and structural proteins in parenchymal cells (e.g. in liver and kidney; for review see ref. 82). Under these circumstances, dose-dependent, potentially fatal hepatic necrosis may occur. When detected early, overdosage can be antagonized within the first 12 h after intake of paracetamol by administration of N-acetylcysteine that regenerates detoxifying mechanisms by replenishing hepatic glutathione stores. Accordingly, paracetamol should not be given to patients with seriously impaired liver function. As a matter of fact, excessive doses of paracetamol are the most common cause of acute liver failure.[83] Remarkably, nearly half of paracetamol-associated cases are caused by unintentional overdose due to taking multiple products containing this drug.[83] In addition, there is increasing evidence that paracetamol may still elicit transient liver enzyme elevations and possibly hepatotoxicity at maximum therapeutic doses (i.e. 4 g daily), particularly in patients with risk factors (e.g., chronic alcohol use, malnutrition, concurrent use of inducers of the cytochrome P450 enzyme).[84–87] Accordingly, too short or insufficient pain relief associated with paracetamol's fast elimination (Table 77.4) or limited potency should be considered as an additional factor leading to overdosages with this drug.

Although paracetamol was discovered over 100 years ago and has been extensively used for over 50 years, its mode of action is still a matter of debate. For more than three decades it was commonly stated that paracetamol acts centrally and is at best a weak inhibitor of prostaglandin synthesis by COX-1 and COX-2.[88] This concept is based on early work by Flower and Vane[89] who showed that prostaglandin production in brain is 10 times more sensitive to inhibition by paracetamol than that in spleen. Instead, several data published during the past few years suggest a tissue-dependent inhibitory effect of paracetamol on the activity of both central and peripheral COX enzymes. Whereas NSAIDs and COX-2 inhibitors inhibit COX by competing with arachidonic acid for entering the COX reaction,[90,91] paracetamol has been suggested to act as a reducing agent within the peroxidase site. In brief, paracetamol quenches a protoporphyrin radical cation. The latter generates the tyrosine radical in the COX site which is responsible for catalysing oxygenation of arachidonic acid.[92,93] In view of the fact that hydroperoxides oxidize the porphyrin within the peroxidase site, COX inhibition by paracetamol is hampered by high peroxide levels. Therefore, high extracellular levels of peroxide in the inflamed tissue may also explain why paracetamol does not suppress inflammation associated with rheumatoid arthritis.[94,95] On the other hand it is noteworthy that paracetamol decreases tissue swelling following oral surgery in humans, with activity very similar to that of ibuprofen.[96,97] Thus, the notion that paracetamol has only weak anti-inflammatory properties rather than it causes no anti-inflammatory action at all appears to be more favourable.

In addition, a recent clinical investigation suggests a preferential COX-2 inhibition by paracetamol in human whole blood. Accordingly, oral administration of 1000 mg paracetamol to human volunteers was shown to inhibit blood monocyte COX-2 by more than 80%, i.e. to a comparable degree as NSAIDs and selective COX-2 inhibitors.[98] In this study paracetamol displayed approximately fourfold selectivity for inhibition of COX-2 both in vitro and in vivo.[98] By contrast, a COX-1 blockade relevant for inhibition of platelet function (>95%) was not achieved.[98] With respect to the above mentioned 'peroxide theory', further experiments revealed that paracetamol elicits the most pronounced COX-2 inhibition in human whole blood when compared to the recombinant enzyme or freshly prepared human monocytes,[98] thus confirming the dependence of its potency as COX-2 inhibitor on the oxidant/anti-oxidant status of the surrounding system. As a matter of fact, human plasma (containing various enzymatic and non-enzymatic anti-oxidant components) may provide favourable conditions in this respect. Collectively, preferential COX-2 inhibition may explain why short-term administration of paracetamol at recommended single doses elicits no measurable toxic effect on the gastrointestinal tract,[99] does not inhibit platelet function,[54,100] and provokes less bronchoconstriction in aspirin-sensitive asthmatics than NSAIDs.[101] On the other hand, these findings raise concerns in particular to the hitherto proposed cardiovascular safety of the drug and the poorly investigated gastrointestinal safety under conditions of long-term treatment.

In contrast to the inflamed tissue, endothelial cells possess low levels of peroxide, making an undisturbed COX-2 inhibition by paracetamol possible.[93] In line with this notion, paracetamol was found to inhibit COX activity in human endothelial cells[102] and to diminish the urinary excretion of a stable prostacyclin metabolite in humans.[102,103] In addition, epidemiological data found that regular consumption of paracetamol is associated with a significantly higher relative risk for development of hypertension compared with no use[104] and that a frequent consumption of paracetamol has nearly the same risk for major cardiovascular events as NSAIDs.[105]

Table 77.4 Physicochemical and pharmacological data of paracetamol

Chemical/pharmacological class	Binding to plasma proteins	Oral bioavailability	t_{max}[a]	$t_{1/2}$[b]	Single dose (maximal daily dose) for adults
Aniline derivatives					
Paracetamol (acetaminophen)	5–50%, dose-dependent	70–100%, dose-dependent	0.5–1.5 h	1.5–2.5 h	0.5–1 g (4 g)

[a]Time to reach maximum plasma concentration after oral administration.

[b]Terminal half-life of elimination.

These epidemiological data are supported by a recently published randomized, double-blind, placebo-controlled, crossover study demonstrating that paracetamol induces a significant increase in ambulatory blood pressure in patients with coronary artery disease.[106] Collectively, these data raise concerns on the hitherto presumed cardiovascular safety of paracetamol, making further randomized trials necessary.

The favourable gastrointestinal tolerability of paracetamol as compared to NSAIDs is often cited with regard to a 7-day randomized trial, where healthy volunteers receiving paracetamol 4 g/day showed no significant difference from the placebo group in terms of gastric mucosal injuries.[107] Unfortunately, no long-term endoscopy study has been performed with paracetamol so far. However, observational studies suggest that higher doses of paracetamol taken for a longer period of time may elicit a gastrointestinal risk. In a first of these studies, Garcia-Rodriguez' group analysed upper gastrointestinal complications in almost one million patients receiving paracetamol and/or NSAIDs during a five-year investigation period. The relative risks for paracetamol showed a clear dose-dependence with an adjusted relative risk (RR) for paracetamol of 3.6 at doses greater than 2 g.[99] In addition, combined administration of NSAID and paracetamol was associated with a synergistic increase of RR.[108] These results were supported by a retrospective cohort study showing an increased risk of hospitalization due to gastrointestinal events (ulcer, perforation, bleeding in upper or lower gastrointestinal tract) among elderly patients requiring analgesic treatment following the use of NSAIDs in combination with paracetamol as compared with use of NSAIDs alone.[109] The authors explained this finding by paracetamol's additional COX-1 inhibition which is plausible in view of data showing paracetamol to augment diclofenac's inhibitory action on platelet aggregation in a synergistic manner,[110] A combined use of NSAID and paracetamol was also addressed in a recently published randomized, active controlled trial on almost 900 participants with chronic knee pain, most of them fulfilling American College of Rheumatology (ACR) criteria for knee osteoarthritis.[111] On the basis of haemoglobin levels measured the authors state that paracetamol 3 g/day may cause similar degrees of blood loss as ibuprofen 1.2 mg/day, and that the combination of the two appears to be additive, or even synergistic in terms of the number of individuals with a greater than 2 g/dL decrease in haemoglobin.[111] Further investigations on paracetamol's long-term gastrointestinal impact are therefore strongly advised.

Future developments

The available traditional antipyretic analgesics and selective COX-2 inhibitors still leave space for additional compounds. In past years, inhibition of the microsomal prostaglandin E synthase I that is coexpressed with COX-2 under diverse inflammatory conditions has been suggested to represent a potential target for treatment of inflammatory pain.[112] From the pharmacological point of view an inhibition of this enzyme would open the opportunity to inhibit the production of COX-2-dependent proinflammatory prostaglandins without a concomitant blockade of COX-2-dependent prostacyclin, which confers various protective actions in the cardiovascular and renal system. Finally, targeting of individual prostaglandin receptor subtypes may permit a separation of desired and unwanted effects of NSAIDs. Recently, blockade of the EP_2 receptor has attracted attention as a possible target for centrally acting anti-hyperalgesic agents.[20] Alternative strategies might interfere with targets beyond prostanoid synthases or prostanoid receptors, such as transient receptor potential channels, tetrodotoxin-resistant sodium channels and inhibitory glycine receptors (for review see ref. 113). Currently, however, therapy of arthritis and arthritic pain has to rely on COX inhibitors whose diverse pharmacokinetics and adverse reaction profiles should be considered in daily practice.

CHAPTER 78

Analgesics

Joanne Foo, Benazir Saleem, and
Philip G. Conaghan

Introduction

Pain is personal and complex in its origins. Pain is the predominant presenting symptom of most musculoskeletal conditions and varies in intensity, character, and duration. Musculoskeletal pain can originate from peripheral sites such as the synovium, tendons, ligaments, enthuses, and muscle, and be modified by spinal cord interactions and the central nervous system (CNS). Inflammation leads to hypersensitivity termed peripheral sensitization, which acts through polymodal recruitment of nociceptors as well as the silent nociceptors for activation.[1] The discordance of perception to pain and actual evidence of damage or inflammation has led to the concept of central pain contributing to chronic pain.[2] The detailed physiology of pain is discussed elsewhere in this textbook (Chapter 59). This chapter provides an overview of current, commonly used analgesics, including paracetamol, opioids, and therapies for neuropathic pain. Non-steroidal anti-inflammatory drugs (NSAIDs) are reviewed in Chapter 77). Some novel therapies are also briefly mentioned.

General principles of pain management

The World Health Organization (WHO) Pain Ladder was developed as a conceptual model to guide the management of cancer pain and provided five simple recommendations for the correct use of analgesics[3]:

- *Oral administration of analgesics.* The oral form of medication should be used whenever possible.
- *Analgesics should be given at regular intervals.* To relieve pain adequately, it is necessary to respect the duration of the medication's efficacy and to prescribe the dosage to be taken at definite intervals in conjunction with the patient's level of pain.
- *Analgesics should be prescribed according to pain intensity as evaluated by a scale of intensity of pain.*
- *Dosing of pain medication should be adapted to the individual.* There is no standardized dosage in the treatment of pain. Every patient will respond differently. The correct dosage is one that will allow adequate relief of pain, without producing intolerable side effects.

- *Analgesics should be prescribed with a constant concern for detail.* For example, the regularity of analgesic administration is crucial for the adequate treatment of pain.

Over the years there have been modifications to the ladder so that it can be used for non-cancer pain, with four steps:

1. Non-opioid analgesics or NSAIDs
2. Weak opioids
3. Strong opioids (oral administration or transdermal patch)
4. Nerve block/epidurals/patient controlled analgesia pump/neurolytic block therapy/spinal stimulators.

Paracetamol

Paracetamol, also known as acetaminophen, is one of the most commonly used non-narcotic analgesics; it is also an anti-pyretic agent. Acetaminophen is *N*-acetylaminophenol, the active metabolite of phenacetin. The antipyretics commonly used in the 1800s consisted of preparations of natural compounds such as cinchona bark, from which quinine is derived, or galenicals based on willow bark, the earliest source of salicylate. Two alternatives were subsequently developed, acetanilide in 1886 and phenacetin in 1887, both of which possessed both antipyretic and analgesic properties. It was established that paracetamol was a major metabolite of both phenacetin and acetanilide and subsequently recommended as a safer option. In the 1950s its use became widespread after evidence of its effectiveness when compared to aspirin was reported.

Mechanism of action

Research indicates that paracetamol inhibits prostaglandin synthesis, in a similar way to aspirin (see Chapter 77). This is through central and peripheral inhibition of both cyclooxygenase (COX) enzymes 1 and 2.[4] Paracetamol is thought to favour COX-2 inhibition. This preferred mode of action is particularly important in the presence of peroxide which is present in higher levels in inflamed tissues. The inhibitory effect of paracetamol on COX-1 becomes paradoxically inhibited in such circumstances. Paracetamol's lack of effect in reducing inflammation in rheumatoid arthritis (RA) can be explained by the levels of arachidonic acid and peroxide in the

RA tissues. Although traditionally known as a pure analgesic, the comparative effects of paracetamol and ibuprofen demonstrated in reducing oral inflammation postoperatively[5] supports the possible anti-inflammatory effects of this drug.[4]

Pharmacokinetics

When taken orally, paracetamol is rapidly and almost completely absorbed, reaching peak levels in 30–60 minutes. The plasma half-life is approximately 2 hours and the duration of action is approximately 4 hours. The drug is widely distributed and is approximately 20–50% plasma bound. Paracetamol is present in breast milk but at low levels (10–15 μg/mL). As paracetamol is metabolized in the liver and eliminated by the renal pathway, the metabolites can be hepatotoxic and nephrotoxic. The therapeutic effects of paracetamol may be decreased when given concomitantly with barbiturates, carbamazepine, isoniazid, rifampicin, and sulfinpyrazone as a result of increased metabolism. Cholestyramine may decrease the absorption of paracetamol.

Side effects

Paracetamol is a common over-the-counter drug used alone and in combination for pain control. In the United Kingdom, an estimate of recent annual consumption was 3500 million 500 mg tablets.[6] Hepatotoxicity is a well-known though uncommon adverse event with paracetamol use, usually in the context of overdosage. This may be deliberate or attributed to the fast clearance of paracetamol leading to risk of overuse. Acute hepatotoxicity may occur when a single dose of 10–15 g or more is taken. Doses of 20–25 g or more can be fatal. The risk of hepatotoxicity when taking paracetamol is increased in the presence of alcohol and NSAIDs.

Paracetamol has recently been associated with a small risk of causing gastrointestinal bleeding at a dose of 2 g daily or higher.[7–9] Doherty et al.[9] performed a randomized controlled trial looking at the use of ibuprofen, paracetamol, and a combination of both in a community population. The use of ibuprofen and paracetamol together was shown to be more effective in pain relief. However decreased haemoglobin levels were observed in all treatment groups. The risk was higher in the elderly, with dosages of 2 g/day or more, and with combination therapy. In their population, paracetamol at 3 g/day caused a similar degree of blood loss as ibuprofen 1200 mg/day. Epidemiological data supports increased upper gastrointestinal complications with use of paracetamol at a dose of 2 g/ day or more; doses below this level did not show an increased risk.[8] Rahme et al.[10] reviewed hospitalization of patients due to gastrointestinal events in patients who used paracetamol alone and in combination with NSAIDS over a 6 year period and showed increased risk with combination therapy. In terms of cardiovascular effects, epidemiological studies also showed regular use of paracetamol increased risk of hypertension and cardiovascular events similarly to traditional NSAIDS.[4] This is further supported by a randomized double-blind placebo controlled trial showing increased ambulatory blood pressure levels in patients with existing coronary artery disease taking paracetamol.[11] This study looked at patients receiving paracetamol 1 g three times a day for 2 weeks, which resulted in increased blood pressure readings.

Clinical indications

Paracetamol is a widely used antipyretic and analgesic. It is not recommended for the primary treatment of inflammatory rheumatic conditions but is commonly used to treat mechanical and degenerative pain. It is recommended as first line therapy by the United Kingdom's National Institute of Clinical Excellence (NICE) for the management of lower back pain[12] and osteoarthritis (OA),[13] and by European League Against Rheumatism (EULAR) for the management of knee, hip, and hand OA.[14–16] However there is concern over its efficacy: the most recent systematic review of OA therapies[17] demonstrated a very low effect size for paracetamol in OA trials. Emerging data on its safety (see above) suggest caution in dosing, especially in combination with NSAIDs.

Opioid analgesics

The opium poppy, *Papaver somniferum*, is the most prevalent source of opioid analgesics, which have been used medicinally since the beginning of recorded history. The most important therapeutically active compounds found in the opium poppy are the alkaloids codeine and morphine.

Mechanism of action

Opioids work by binding to specific receptors of the CNS (mu, kappa, and delta) mounting an inhibitory effect of neurotransmission through G proteins. These receptors are present throughout the nervous system from the brain to the spinal cord. Most of the analgesic effect appears to come from activation of mu receptors. Activation of mu receptors leads to inhibition of neurotransmitters (including noradrenaline, acetylcholine, and the neuropeptide substance P) that would usually activate the pain pathway. Opioids have a central effect on both presynaptic and postsynaptic receptors.[18] Full opioid agonists act by direct stimulation of opioid receptors as outlined above. Most common opioids are full agonists (morphine, diamorphine, pethidine, and fentanyl). Buprenorphine is a partial agonist that binds with very high affinity to receptors but with both agonistic and antagonistic properties; however, no ceiling effect on analgesia has been observed and studies have demonstrated that full analgesic effect occurs with less than 100% receptor occupancy.[19]

Pharmacokinetics

Opioid plasma half-life and duration of action vary between the individual opioid agents. Morphine is a commonly used opioid drug. It has low lipid solubility resulting in longer duration of action but a latent onset of action due to its slow penetration of the blood–brain barrier.[20] Morphine can be administered orally, subcutaneously, intramuscularly, intravenously, rectally, via epidural, and intrathecally. When morphine is taken orally, only approximately 40–50% reaches the CNS after 30 minutes for immediate release and 90 minutes for slow-release preparations.[21] Elimination half-time for morphine is roughly 120 minutes.[20]

Diamorphine is more lipophilic and has more analgesic effect compared to morphine with a rapid onset of action. It is metabolized initially to monoacetylmorphine which crosses the blood–brain barrier rapidly and is therefore more potent than morphine. However, it undergoes extensive hepatic first-pass metabolism leading to low bioavailability. Dosing of diamorphine to morphine is roughly 2 to 1 in ratio and can be given via the same routes. It has a half-life of 2–3 minutes.

Codeine has weak opioid binding affinity for mu receptors, with half the potency of morphine and a half-life of

3 hours. Codeine is usually prescribed orally (doses of 30–60 mg 6 hourly). Smaller doses are used in combination preparations with paracetamol or anti-inflammatories. Codeine has anti-tussive and anti-diarrhoeal properties. There is evidence to show that the analgesic response and anti-diarrhoeal effect of codeine are under the genetic control of CYP2D6 (isozyme).[22] Part of the analgesic effect of codeine is mediated by its *O*-demethylated metabolite, morphine. In poor metabolizers, codeine may not have the desired analgesic effect as they are unable to convert codeine to morphine.[22]

Dihydrocodeine is similar in structure to codeine: it is a semi-synthetic opioid analgesic with mu-receptor binding properties and a half-life of 4 hours. Oxycodone is a semisynthetic derivative of thebaine and similar in chemical structure to natural opioids.[22] Oxycodone has binding capacity for multiple receptors including kappa receptors. When taken orally, it has high bioavailability with a half-life of 3 hours.

Sustained-release analgesics have the advantages in maintaining a stable plasma concentration for a prolonged period of time, with improved patient compliance and satisfaction. Many opioid preparations are available in such formulations, requiring dosing every 8–12 hours. More recently 24 hour sustained-release preparations have been developed,[23] such as a 24 hourly morphine preparation that has been shown to improve sleep quality in chronic pain related to OA.[24] Other preparations of slow-release analgesics are the widely used transdermal patches.

Fentanyl is administered transdermally, parentally, and is also available transbucally; it is a very strong opioid agonist, with highly lipophilic characteristics therefore binds strongly to plasma proteins. It binds mainly to mu receptors. The fentanyl patch has a latent time of 6–12 hours before the onset of action, lasting 3–6 days, and after removal clearance takes up to 24 hours. Fentanyl is metabolized mainly in the liver to an inactive component called norfentanyl and excreted renally. Transdermal fentanyl has a half-life of approximately 17 hours.

A buprenorphine transdermal patch is also available, at a range of strengths (e.g. 5–20 µg/hour) for weekly use. It has a long half-life of approximately 30 hours. As well as an analgesic effect, it also has an anti-hyperalgesic effect, possibly through antagonism of kappa receptors; it may therefore be suitable for neuropathic pain. In the elderly, transdermal buprenorphine is relatively easy to use and is unaffected by renal function, therefore useful in patients with renal impairment.[19]

Tramadol is part of the opioid family, oral preparations being absorbed quickly with reduced first-pass metabolism. Its maximum dose is 400 mg/day. Elimination half-life is 4–6 hours. Sustained-release tramadol given 12 hourly or 24 hourly may improve sleep pattern related to pain, and quality of physical function.[23] Tramadol is also available in combination with paracetamol and has been shown to be efficacious in management of both acute and chronic pain including lower back pain, OA, and fibromyalgia, improving pain, function, and quality of life. The effect is comparable to combination preparations of paracetamol and codeine with some evidence for less constipation.[25]

Some caution should be taken in interpreting equivalent analgesic opioid dosing (often in morphine equivalents, e.g. 200 mg of oral codeine or 150 mg tramadol are equivalent to 10 mg of parenteral morphine), as most of the reported equivalencies are based on acute dosing and not the chronic use as is employed for many musculoskeletal problems. Also, renal impairment must be considered for those agents with metabolites excreted renally.

Side effects

Opioid analgesia, when used short term, can cause nausea through centrally acting chemoreceptors, constipation from delayed gastric emptying, histamine release leading to pruritus, sedation, and respiratory depression. The latter two toxicities are dose related and can lead to coma in high doses. Other effects include meiosis, muscle rigidity, bradycardia, and mood changes. When opioids are used long term, there is recognized tolerance and chemical dependence which can lead to unpleasant withdrawal symptoms. Transdermal opioids can also have local reactions such as erythema and pruritus.

Tolerance refers to reduced effect from a drug after prolonged exposure. Tolerance to opioids is widely recognized; when tolerance occurs, a larger dose may be required to achieve a given effect. Receptor desensitization is thought to play an important role by the functional uncoupling of opioid receptors from G proteins. Tolerance is usually associated with prolonged use of opioids; while some clinicians use opioid rotation to address this, there are no recommendations for best practice.

Dependence can occur after a short period of opioid use and is characterized by a withdrawal response when the drug is stopped. The *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) defines opioid dependence as 'a cluster of behavioural, cognitive, and physiological phenomena that develop after repeated substance use and that typically include a strong desire to take the drug, difficulties in controlling its use, persisting in its use despite harmful consequences, a higher priority given to drug use than to other activities and obligations, increased tolerance, and sometimes a physical withdrawal state.'[26] Generally, problems of dependence are very uncommon in the use of opioids at standard recommended doses for pain management.

Opioid hyperalgesia refers to a paradoxical response to opioids, with an increased perception of pain.[27] It is proposed to occur with chronic opioid use and is characterized by pain persisting or increasing with increased opioid dose. It is difficult to determine clinically if a patient reporting increasing pain is experiencing a change in pathology, tolerance to their opioid, or opioid hyperalgesia. At present small study numbers with varying study designs makes this problem difficult to understand. Opioid-induced endocrinopathy (potentially following suppression of the hypothalamic–pituitary–adrenal axis) is also poorly understood, and while in-vitro and animal studies have suggested opioid-related immunosuppression, this has not been reported as a significant problem in human studies.

Clinical indications

The role of opioids in the management of acute pain, postsurgical pain, and chronic cancer pain is clearly established. However, the role of opioid therapy for chronic non-cancer pain remains an area of debate. There is some evidence that opioids may provide clinically significant pain relief in a proportion of individuals with chronic non-cancer pain.[28] A review from the Cochrane Collaboration in 2009 addressed the use of opioids to treat OA of the knee or hip[29]; the review examined 10 study trials that included transdermal fentanyl and oral morphine, oral codeine, oral oxycodone, and oral oxymorphone, but studies of tramadol were excluded. The review

found that opioid drugs were more effective than control interventions for relieving pain and improving function, but there were no differences in effect according to type or potency of opioid or the duration of treatment. However, given adverse events observed were more frequent compared to controls, the review concluded that 'the small to moderate beneficial effects of non-tramadol opioids are outweighed by the large risks of adverse events.' Clearly this risk/benefit needs to be defined carefully for individual patients, many of whom have no other analgesic options. All modern evidence-based OA guidelines recommend the use of opioids, with the most recent Osteoarthritis Research Society International (OARSI) meta-analysis supporting the benefits of opioid therapy.[30]

Patients with RA perceive pain to be their predominant impairment and report pain management as their highest priority.[31] As the analgesic properties of opioids do not depend on the presence of active inflammation, they are potential analgesic options in RA patients with persistent pain despite the use of disease-modifying anti-rheumatic drugs (DMARDs). The presence of opioid receptors on peripheral afferent nerves within joints also suggests that opioids may have peripheral analgesic effects in addition to their effect on the CNS.[32] Also, intra-articular nociceptive nerve fibres may contribute to joint inflammation via the release of neuropeptides such as substance P and calcitonin gene-related peptide, which raises the possibility that opioids may also act to inhibit joint inflammation.[33,34] A Cochrane review of 11 studies examined the role of opioid therapy in the treatment of RA pain.[35] It was concluded that there was limited evidence that weak oral opioids may be effective analgesics, but adverse effects were common and may offset the benefits of this class of medications.

It has been recommended that patients with chronic musculoskeletal pain avoid the long-term use of opioids unless the benefits outweigh the risks, in which case use should be regularly monitored.[27] The American Colllege of Rheumatology (ACR) Pain Management Task Force advises:

> The prescription of opioids must be done thoughtfully, since patients who may receive the greatest benefit may also be the same as those who are likely to abuse these agents. Better understanding of the risks and benefits of opioids should be mandated for all rheumatologists so that these medications can be safely, albeit selectively, used in patients with certain chronic rheumatologic disorders.[36]

Treatment of neuropathic pain

Neuropathic pain has been defined as 'pain arising as direct consequence of a lesion or disease affecting the somatosensory system'.[37] Neuropathic pain is manifested through a dysfunction of the nervous system at central or peripheral levels characterized by often disabling, constant and diffuse discomfort including hypersensitivity, altered sensitivity and reduced sensitivity. Such pain is often poorly localized and common examples are diabetic neuropathy, trigeminal neuralgia, postherpetic pain, or phantom limb pain.

Antidepressants
Mode of action
Tricyclic antidepressants (TCAs, e.g. amitriptyline, nortriptyline), selective serotonin reuptake inhibitors (SSRIs, e.g. fluoxetine, paroxetine, sertraline), and serotonin noradrenaline reuptake inhibitors (SNRIs, e.g. duloxetine, milnacipran) work to maintain serotonin and noradrenaline levels in the CNS by blocking their reuptake into nerve endings.

Side effects
TCAs can cause anticholinergic side effects of dry mouth, urinary retention, blurring of vision, and constipation. Less common side effects include tremor, palpitations, and somnolence. They can also lower seizure threshold.[38] In elderly people these drugs may result in falls and fainting episodes from postural hypotension. Men may experience erectile dysfunction. In some patients, weight gain has been reported. Venlafaxine, an SNRI, on the other hand can cause hypertension and gastrointestinal side effects as well as adversely effecting sexual function.

Clinical indications
Antidepressants such as TCAs and serotonin uptake inhibitors may be used to treat neuropathic pain. A Cochrane review of 61 randomized control trials showed a minimum to moderate benefit in relief of neuropathic pain. Three studies examined venlafaxine, and a number needed to treat (NNT) of 3 was achieved using TCAs and venlafaxine for at least moderate pain relief.[39] Analgesia was seen to be achieved quicker and at a smaller dose in comparison to the antidepressant effects.

A systematic review of antidepressants in the management of neuropathic pain generally indicated that TCAs and SNRIs are effective in chronic painful states with the strongest evidence being for use in fibromyalgia.[40] In other rheumatic conditions associated with chronic pain, there may be benefit of using antidepressants for managing sleep and fatigue symptoms.

A systematic review of amitryptyline vs placebo use in fibromyalgia[41] showed consistent benefit in patients with fibromyalgia with the use of amitriptyline 25 mg daily (<8 weeks duration) compared to a dose of 50 mg daily or placebo. However, limitations of included studies did not allow definite conclusions to be made. Another systematic review looking at the use of antidepressants in fibromyalgia patients showed that amitriptyline (25–50 mg daily) improved pain, fatigue, depression symptoms, sleep, and overall quality of life. Some domains in fibromyalgia improved with SSRIs (paroxetine, fluoxetine and sertraline) as well as SNRIs (duloxetine and milnacipran).[42]

Neuroleptics
Anticonvulsants are used to treat epilepsy but evidence shows benefit for some of these drugs in treatment of pain, particularly from nerve damage such postherpetic neuralgia, diabetic neuropathy, and neuropathic pain. These agents have also been reported to be effective in fibromyalgia.[43–45]

Mode of action
Some anticonvulsants act by blocking sodium channels leading to membrane stabilization resulting in reduced pain sensitization. Gabapentin acts on an auxillary alpha-2-delta subunit of a calcium channel, inhibiting influx of calcium and neurotransmission.[46] Pregabalin acts similarly to gabapentin in calcium channels, but also affects other neurotransmitters (glutamate, noradrenaline, and substance P) to reduce neuroexcitability.[47]

Side effects
The use of anticonvulsants is largely limited by their side effects which include sedation, cognitive suppression, tremors, and

gastrointestinal side effects. In higher doses, they can also cause hepatotoxicity and haematological problems. Less common effects on metabolism can lead to increased body weight.[48] Commonly used anticonvulsant drugs and their side effects are presented in Table 78.1.

Clinical indications

Carbamazepine has been shown to be effective in trigeminal neuralgia.

A recent review[43] reported efficacy for the use of pregabalin in management of neuropathic pain and in fibromyalgia. A dose between 300 mg and 600 mg daily was found to be effective but a lower dose of 150 mg daily was found to be ineffective, except for pain control in postherpetic neuralgia. NNT for moderate to significant benefit at 600 mg daily doses was also better demonstrated for postherpetic neuralgia and painful diabetic neuropathy in comparison to fibromyalgia.

In 2011, Moore et al.[44] reviewed the use of gabapentin in treating neuropathic pain. Moderate effectiveness of gabapentin (1200 g or more daily) was shown for neuropathic pain from postherpetic neuralgia, painful complications of diabetes, nerve injury pain, phantom limb pain, fibromyalgia, and trigeminal neuralgia.

Novel therapies

In an attempt to reduce bowel dysfunction and constipation due to opioids, a combination preparation of slow-release oxycodone and naloxone (the latter metabolized in the liver and providing opioid antagonism in the gut but not in the CNS) has been developed and licensed in the European Union.[49]

Tapentadol is a novel analgesic now licensed for use in the United States for moderate to severe acute pain. It is a centrally acting drug with dual mechanism in a single molecule acting as an opioid mu-receptor agonist and noradrenaline reuptake inhibitor; the latter action increases transmission in spinal cord inhibitory pathways, resulting in reduced pain sensation. Tapentadol has demonstrated effectiveness in trials of chronic lower back pain, OA knee pain, and diabetic neuropathy. Extended-release formulations are available. Side effects of tapentadol during phase II and phase III trials include nausea, diarrhoea, anxiety, and dizziness.[50,51] Its role compared to traditional opioid analgesics remains to be clarified.

Nerve growth factor (NGF) is a neurotropin which has effects on the nervous system and other non-neuronal cells (mast cells, monocytes, basophils).[52] The release of mediators sensitizing pain nociceptors is triggered partly by tropomyosin-related kinase A (TrkA), which is activated by NGF. TrkA also contributes directly to pain sensation by activating a signalling pathway.[52] A number of antagonists to this neurotropin are in development. Tanezumab is a humanized monoclonal IgG2 antibody against NGF. Lane et al.[53] demonstrated improvement in pain (45–62% from baseline), stiffness, and physical function in patients with moderate to severe knee OA when treated with tanezumab injections given 8 weeks apart. Transient symptoms of abnormal peripheral sensation have been reported in patients receiving tanezumab. The further development of anti-NGF therapies has been complicated by increased rates of joint replacement in patients receiving these agents in clinical trials; work is ongoing to understand if this represents direct drug toxicity or is related to an analgesic effect on already damaged joints.

Conclusion

Most of the traditional analgesic options have been available for many years, with well-defined efficacy and significant toxicity profiles. New formulations or delivery systems may improve their applicability. However, with the growth of genomic and molecular data related to pain pathways and management, it is hoped that new classes of analgesics will soon be forthcoming.

Table 78.1 Common side effects of anticonvulsants

Drug	Adverse effects
Pregabalin	CNS—dizziness, poor concentration, drowsiness, visual disturbances (diplopia, blurred vision, visual field defect), disturbance in muscular function, memory, speech, parasthesias
	Gastrointestinal—dry mouth, nausea, vomiting, weight gain
	Haematological—thrombocytopaenia, neutropaenia, Stevens–Johnson syndrome (rare)
	Other—peripheral oedema, fatigue
Carbamazepine	CNS—headache, ataxia, drowsiness, nausea, vomiting, blurring of vision, dizziness, unsteadiness (dose related, more common in elderly patients)
	Haematological—idiosyncratic blood dyscrasias, aplastic anaemia and agranulocytosis
	Other—Stevens–Johnson syndrome/toxic epidermal necrolysis rare), hyponatraemia.
	Close monitoring of liver dysfunction (induces hepatic enzymes) and blood required
Gabapentin	Gastrointestinal—nausea, vomiting, gingivitis, diarrhoea, abdominal pain, dyspepsia, constipation, dry mouth or throat, flatulence, weight gain, increased appetite, anorexia
	CNS—confusion, emotional lability, depression, vertigo, anxiety, nervousness, abnormal thoughts, drowsiness, dizziness, malaise, ataxia, convulsions, movement and speech disorder, amnesia, tremor, insomnia, headache, paraesthesia
	Haematological—neutropenia (rare)

CHAPTER 79

Glucocorticoids

Johannes W. G. Jacobs, Cornelia M. Spies,
Johannes W. J. Bijlsma, and Frank Buttgereit

Introduction

Glucocorticoids are anchor drugs of therapeutic regimens in most inflammatory and autoimmune rheumatic conditions, because of their effectiveness, versatility and low cost (Box 79.1). Basic mechanisms and effects, indications, adverse advents and monitoring of glucocorticoid therapy in rheumatology and new developments are discussed here with emphasis on clinically relevant implications.

Characteristics of glucocorticoids

Structure and classification

Steroid hormones and cholesterol are characterized by a sterol skeleton; the term 'steroid' refers to this basic sterol nucleus. On the basis of their main functions, steroid hormones can be classified into sex hormones, mineralocorticoids, and glucocorticoids. Mineralocorticoids and glucocorticoids are synthesized in the adrenal cortex, hence the terms 'corticosteroid' and 'corticoid' for

---

Box 79.1 Reasons for the wide usage of glucocorticoids in rheumatology
◆ Low cost
◆ Applicable in many drug combinations, additive effect
◆ Wide spectrum of anti-inflammatory and immunosuppressive actions
◆ Clear dose–effect relationship, wide dosing range, many dose steps
◆ Various routes of administration available
◆ Short lag time of effect
◆ Predictable effect
◆ Relatively mild toxicity, when used cautiously
◆ Inhibitory effect on radiographic progression in early rheumatoid arthritis
◆ Long-term clinical experience
◆ High percentage of responders

---

these hormones. The main natural mineralocorticoid is aldosterone, and the main natural glucocorticoid is cortisol (hydrocortisone). Natural glucocorticoids also have mineralocorticoid effects, but synthetic glucocorticoid drugs have less mineralocorticoid and clearly more glucocorticoid potency (Table 79.1). It is more precise to use the term glucocorticoid than the term corticosteroid when referring to one of the glucocorticoid drugs.[1]

Absorption and protein binding

Most orally administered glucocorticoids are absorbed readily, probably within about 30 minutes. The bioavailability of prednisone and prednisolone is high. The affinity of the individual glucocorticoids to bind to plasma proteins (transcortin, also called corticosteroid-binding globulin, and albumin) varies (Table 79.1). Transcortin binds glucocorticoids more strongly than does albumin; only unbound glucocorticoids are pharmacologically active. Patients with low levels of plasma protein, such as albumin (e.g. because of liver diseases or chronic active inflammatory diseases), are more susceptible to effects and side effects of glucocorticoids. In liver disease, an additional argument for dose adjustment is reduced metabolic clearance of glucocorticoids; see next section.

Conversion into active hormones and vice versa; pharmacology

Glucocorticoids with an 11-keto instead of an 11-hydroxy group, such as cortisone and prednisone, are inactive prohormones, which have negligible glucocorticoid bioactivity because of their very low affinity for the glucocorticoid receptor. They must be reduced in the liver to their biologically active 11-hydroxy configurations, cortisol and prednisolone respectively. Prednisone and prednisolone preparations are considered approximately bioequivalent, but in patients with severe liver disease it is rational to prescribe prednisolone instead of prednisone. The intracellular enzyme 11β-hydroxysteroid dehydrogenase (11β-HSD) type 1 activates the glucocorticoid prohormones. Although this enzyme can also promote the reverse reaction by dehydrogenation, leading to inactivation of active glucocorticoids, its activating activity predominates. In contrast, the isoenzyme 11β-HSD type 2 has only dehydrogenase activity, so converting active glucocorticoids to their inactive forms.

Table 79.1 Pharmacodynamics of glucocorticoids used in rheumatology

	Equivalent glucocorticoid dose (mg)	Relative glucocorticoid activity	Relative mineralocorticoid activity[a]	Protein binding[b]	Half-life (h) in plasma	Biological half-life (h)
Short-acting						
Cortisone	25	0.8	0.8	–	0.5	8–12
Cortisol	20	1	1	++++	1.5–2	8–12
Intermediate-acting						
Methylprednisolone	4	5	0.5	–	>3.5	18–36
Prednisolone	5	4	0.6	++	2.1–3.5	18–36
Prednisone	5	4	0.6	+++	3.4–3.8	18–36
Triamcinolone	4	5	0	++	2–>5	18–36
Long-acting						
Dexamethasone	0.75	20–30	0	++	3–4.5	36–54
Betamethasone	0.6	20–30	0	++	3–5	36–54

[a]Clinical signs: sodium and water retention, leading to oedema and hypertension, and potassium depletion.
[b]–, none; ++, high; +++, high to very high; ++++, very high.

Glucocorticoids have biologic half-lives longer than their plasma half-lives (see Table 79.1); with its biological half-life, prednisolone can be dosed once daily for most diseases. Maximal effects of glucocorticoids lag behind peak serum concentrations. Serum half-life of prednisolone is increased by decreased rates of metabolism in patients with renal disease or liver cirrhosis, and in elderly patients, which means that a given dose may have a greater effect in these individuals. Several other pharmacological mechanisms could be involved in the variability of glucocorticoid sensitivity in patients.[2] Prednisolone can be removed by haemodialysis, but, overall, the amount removed does not require dose adjustment in patients on haemodialysis.

Drug interactions

Cytochrome P450 (CYP) is a family of isozymes responsible for the biotransformation of several drugs. Drug interactions can be based either on induction or on inhibition of these enzymes. An example of induction of CYP isozymes is rifampin-induced non-responsiveness to prednisone in inflammatory diseases, which is clinically relevant.[3] Inhibitors of CYP are, for example, ketoconazole and grapefruit juice; the effect of grapefruit juice intake is likely to be of limited clinical significance.[4] Ketoconazole also interferes with endogenous glucocorticoid synthesis and is therefore used to treat hypercortisolism.[5]

Basic mechanisms of actions

Glucocorticoids influence the transcription of about 1% of the entire genome, which is an exceptionally broad spectrum of effects for a single class of endogenous hormones and hormonal drugs.

Genomic mechanisms

Glucocorticoid receptors are present in almost all tissues; genomic mechanisms constitute most glucocorticoid actions. Genomic mechanisms require passing of glucocorticoid molecules through the cell membrane—glucocorticoids are lipophilic, have a low molecular mass and thus can pass easily—binding, to the cytosolic glucocorticoid receptor, formation of the receptor–glucocorticoid complex, and translocation of this complex into the nucleus and, finally, influencing gene expression via transactivation and transrepression (Figure 79.1).

In the post-transcriptional phase, by decreasing the stability of messenger RNA via induction of ribonucleases, glucocorticoid receptor–glucocorticoid complexes also may inhibit protein synthesis, e.g. of interleukin (IL)-1, IL-6, granulocyte-macrophage colony-stimulating factor (GM-CSF), and inducible cyclooxygenase (COX)-2.[6]

Non-genomic mechanisms

Compared to genomic effects, non-genomic effects are more rapid, occurring within seconds or minutes. Non-genomic effects can involve membrane-bound glucocorticoid receptors. Dexamethasone targets these receptors on T lymphocytes, which rapidly impairs T lymphocyte receptor signalling and immune response.[7] Non-genomic actions without involvement of glucocorticoid receptors occur via physicochemical interactions with biological membranes, altering cell function. For instance, the resulting inhibition of calcium and sodium cycling across the plasma membrane of immune cells contributes to rapid immunosuppression and reduced inflammation.[8] However, for most of the effects of glucocorticoids, the underlying genomic and non-genomic basic mechanisms cannot clinically be discriminated very well.

Pharmacological effects

The spectrum of glucocorticoid effects is summarized in Figure 79.2.

Immunosuppression and immunomodulation

Immune cells, adhesion molecules, and cytokines

Glucocorticoids reduce activation, proliferation, differentiation, and survival of a variety of inflammatory cells, summarized in
Fig. 79.1 Genomic action of glucocorticoids. Of the isoforms α and β of the glucocorticoid receptor, only the α isoform, common in all target tissues, binds to glucocorticoids. The glucocorticoid receptor–glucocorticoid complex rapidly migrates into the nucleus, where a dimer of the complex binds to specific consensus sites of the DNA, glucocorticoid-responsive elements, leading to an upregulated synthesis of certain regulatory proteins (**transactivation**), mainly responsible for unwanted metabolic effects of glucocorticoid therapy. The interaction of glucocorticoid receptor–glucocorticoid complex (as monomer) with transcriptional factors, such as NFκB, inhibits binding of these transcriptional factors to specific consensus sites in the DNA. This results in downregulation of (predominantly proinflammatory) protein synthesis (**transrepression**).[78] Selective glucocorticoid receptor agonists almost selectively exhibiting transrepression could result in less adverse effects than glucocorticoids.[77] Adapted from Jacobs JWG, Bijlsma JWJ. Glucocorticoid therapy. In: Firestein CS, Budd RC, Harris ED et al. (eds) *Kelley's textbook of rheumatology*, 8th edn. Saunders Elsevier, Philadelphia, 2009:863–881.

Fig. 79.3 Glucocorticoid effects (in red type) on the interplay of inflammatory cells and cytokines.[9] The production of proinflammatory cytokines, such as interleukin (IL)-1β and tumour necrosis factor (TNF) is inhibited and the production of anti-inflammatory cytokines, such as IL-10, by macrophages and dendritic cells is stimulated. Glucocorticoids promote apoptosis of macrophages, dendritic cells, and T cells. All these effects result in inhibition of immune responses. Downregulation of adhesion molecules decreases migration of neutrophils and increases the number of circulating neutrophils,[79] increasing the total leucocyte blood count, although there is decreased myelopoiesis and bone marrow release of other leucocyte subsets.

Figure 79.3.[9] The redistribution of leucocytes in the peripheral blood has no clear clinical consequences.

Enzymes

Arachidonic acid metabolism leads to the production of prostaglandins and leukotrienes, most of which are strongly proinflammatory. Via induction of lipocortin (an inhibitor of phospholipase A2), glucocorticoids inhibit the formation of arachidonic acid metabolites. Glucocorticoids also inhibit the cytokine-induced production of COX-2 in monocytes/macrophages, fibroblasts and endothelial cells. In addition, glucocorticoids are potent inhibitors of IL-1 and tumour necrosis factor (TNF)-induced production of metalloproteinases, especially collagenase and stromelysin,[10] which are the main effectors of cartilage degradation in the chronic inflamed joint.

Suppression of hypothalamic–pituitary–adrenal axis

Chronic suppression of the hypothalamic–pituitary–adrenal axis by administration of exogenous glucocorticoids leads by negative feedback loops on corticotropin-releasing hormone (CRH) and adrenocorticotropic hormone (ACTH) to failure in pituitary ACTH release and thus to partial functional adrenal atrophy with loss of cortisol secretory capability: secondary adrenal insufficiency. Patients have low serum cortisol and ACTH levels, in contrast to patients with primary adrenal insufficiency, who have elevated ACTH levels. The outer cortical zone involved in mineralocorticoids (aldosterone) biosynthesis is functionally independent of ACTH and stays intact in secondary adrenal insufficiency; no major electrolyte abnormalities in the blood occur and mineralocorticoid supplementation is not necessary. Certain prediction of secondary, glucocorticoid-induced, adrenal insufficiency is impossible; if in doubt, it seems prudent to treat patients as having it.

Effects on bone

Glucocorticoids and inflammatory diseases are both associated with increased generalized bone loss and risk for osteoporotic fractures, while glucocorticoids by decreasing disease activity also inhibit inflammatory mechanisms inducing bone loss. Glucocorticoids decrease intestinal calcium absorption and increase renal excretion of calcium, but inhibition of osteoblast proliferation leading to a decrease in bone formation seems the most important cause of osteoporosis.[11] This topic is addressed in detail in Chapter 142.

In early rheumatoid arthritis (RA), glucocorticoids also have positive effects of on bone; the joint-sparing effect is probably

based on the inhibition of proinflammatory cytokines such as IL-1 and TNF,[12] which stimulate osteoblasts and T lymphocytes to produce receptor activator of nuclear factor kappa B (RANK) ligand (RANKL). RANKL binding to its receptor RANK on osteoclast precursor cells leads to differentiation and activation of osteoclasts, and subsequently to bone resorption, periarticular osteopenia, and formation of bone erosions in patients with RA.[13]

Applications in rheumatology

In this chapter, systemic glucocorticoid therapy is discussed. Intralesional and intra-articular glucocorticoid injections are discussed in Chapter 87.

Often it is unclear what is exactly meant by semiquantitative terms used for doses, such as 'low' or 'high'. Based on pathophysiologic and pharmacokinetic data, standardization of terminology has been proposed:[1]

- **low**: ≤7.5 mg
- **medium**: >7.5 but ≤30 mg
- **high**: >30 but ≤100 mg
- **very high**: >100 mg prednisone equivalents per day
- **pulse**: ≥250 mg prednisone equivalent per day for one or a few days.

Indications

The aims of glucocorticoid therapy differ for various rheumatic diseases; they range from symptomatic relief and disease-modifying effects to immunosuppressive and immunomodulatory actions. The specific indication determines route of administration, choice of drug (pharmacological properties), and dose. The dose and route of administration are related to clinical efficacy, speed of onset of action, and risk of adverse effects.

Table 79.2 gives an overview of general use of glucocorticoids in rheumatology. Some of the indications could at first glance be considered as questionable. For instance, in systemic sclerosis glucocorticoids, especially in high doses, are contraindicated because of the risk of scleroderma renal crisis, but they may be useful for myositis or interstitial lung disease complicating systemic sclerosis. The table shows that glucocorticoids form part of the primary therapeutic strategy in myositis, polymyalgia rheumatica, and systemic vasculitis. Moreover, they are frequently part of therapeutic

[b]Dose in prednisone equivalents a day: low, ≤ 7.5 mg; medium, >7.5 but ≤ 30 mg; high, >30 but ≤ 100 mg; very high, >100 mg; pulse, ≥250 mg prednisone equivalent per day for one or a few days.[1]

–, rare use; 1, infrequent use, for therapy-resistant disease, complications, severe flare, major exacerbation, and for bridging the lag time of recently started therapy; 2, frequently added to/used as the basic therapeutic strategy; 3, basic part of the therapeutic strategy. Note: there may be considerable variation in uses between countries.

strategies for RA. For the other diseases, glucocorticoids are used as adjunctive therapy or not at all.

Doses and routes of administration

Aspects of systemic glucocorticoid use are discussed here; their use for specific rheumatological diseases is discussed in detail in the relevant chapters.

Oral low to high dose glucocorticoid therapy

Worldwide, glucocorticoids are used in 15–90% of RA patients,[14] given for their symptomatic effect and joint-sparing properties (i.e. disease-modifying effects), which have firmly been proven during the first 2 years of the disease,[15] most recently in the Computer Assisted Management of Early Rheumatoid Arthritis trial 2 (CAMERA-II study).[15a] Data on disease-modifying effects in long-standing RA are lacking, which is not to say these effects cannot be present. The benefit of glucocorticoid use during early disease remains detectable during the following years.[16,17]

Glucocorticoids are always combined with other disease-modifying drugs in early RA. In general, two dosing regimes can be discriminated: (1) starting 5–10 mg of prednisone equivalent per day during the first 2 years of the disease and (2) higher starting doses, e.g. 15–60 mg/day, followed by rapid tapering and continuation of a lower dose or stopping.

Next to RA, collagen disease and vasculitides, oral glucocorticoids are used to treat acute gout, especially in patients with contraindications to non-steroidal anti-inflammatory drugs (NSAIDs) and colchicine. For this use, typically 30–35 mg of prednisone equivalent during 5 days is prescribed.[18] A problem arises when the diagnosis is not proven, because septic arthritis may present similarly; furthermore, coincident septic and gouty arthritis have been described.[19] So this approach is only safe if the risk of septic arthritis is very low. Consequently it is probably safer and more effective to inject glucocorticoid intra-articularly following diagnostic aspiration.

Glucocorticoid pulse therapy

Pulse therapy is used in rheumatology primarily for remission induction, rapid disease suppression, and treatment of flares and severe complications (see Table 79.2). In active RA, pulse therapy is applied to bridge the lag time of recently initiated second-line anti-rheumatic treatment; although the duration of the effects varies, the beneficial effects—which are similar to effects of long-term methotrexate in patients with early RA[20]—generally last for about 6 weeks.[21] In systemic lupus erythematosus (SLE), osteonecrosis and psychosis seem to be more frequent side effects of pulse therapy compared to patients with RA, but these may also be complications of active SLE itself.

Alternate-day dosing

Alternate-day therapy uses a single dose administered every other morning, which is usually equivalent to, or higher than, twice the usual or pre-established daily dose. The rationale of this regimen is that the body, including the hypothalamic–pituitary–adrenal axis, is exposed to exogenous glucocorticoid only on alternate days. Alternate-day therapy is unsuccessful in most patients with a rheumatic disease; they often experience exacerbation of symptoms on the second day. This is in line with the clinical impression that a single dose of glucocorticoids daily is less effective in RA than half that

dose given twice daily. In giant cell arteritis, alternate-day glucocorticoid therapy also is less effective than daily administration.[22] Alternate-day regimens are rarely used in rheumatology today except in patients with juvenile idiopathic arthritis, in whom this regimen results in less inhibition of body growth than does daily usage.[23]

Glucocorticoid-sparing drugs

For most inflammatory rheumatic diseases, other immunomodulatory drugs, including biologicals, are often added to therapy with glucocorticoids to improve efficacy. If this is done to decrease the glucocorticoid dose or the duration of this therapy, the added immunomodulatory drug is often referred to as a glucocorticoid-sparing agent. In polymyalgia rheumatica and giant cell arteritis, anti-malarials, ciclosporin, azathioprine, and more frequently methotrexate have been tried as glucocorticoid-sparing agents; half of the six randomized trials on methotrexate support its use in this situation.[24–26]

Stress regimes

Patients on long-term glucocorticoid medication should be instructed to double their daily glucocorticoid dose, or increase the dose to at least 15 mg prednisolone daily or equivalent, if they develop fever attributed to infection, and to seek medical help. In case of major surgery, given the unreliable prediction of adrenal suppression, many physicians recommend 'stress doses' of glucocorticoids, even for patients with a low risk of adrenal suppression. However, the scheme of 100 mg of hydrocortisone intravenously just before surgery, followed by an additional 100 mg every 6 hours for 3 days, is based on anecdotal information and is not always necessary.[27] Although conclusive evidence is scarce, other regimes with lower doses are used.[27,28] These include infusion continuously of 100 mg of hydrocortisone intravenously the first day of surgery, followed by 25–50 mg of hydrocortisone every 8 hours for 2 or 3 days. Another option is to administer the usual dose of oral glucocorticoid orally (or the equivalent) parenterally on the day of surgery, followed by 25–50 mg of hydrocortisone every 8 hours for 2 or 3 days. In cases of minor surgery, it is probably sufficient to double the oral dose or to increase the dose to 15 mg of prednisolone or equivalent daily for 1–3 days.

Tapering

Because of their potential adverse effects, glucocorticoids usually are tapered as soon as the disease being treated is under control. Tapering must be done carefully to avoid disease flares, and cortisol deficiency. Gradual tapering permits recovery of adrenal function. There is no standard scheme for tapering; it depends on the individual's disease, the disease activity, doses and duration of therapy, and clinical response. In general the lower the dose, the smaller the taper steps and the longer the period between steps. To taper high-dose prednisone, decrements of 10–5 mg every 1–2 weeks can be used to 30 mg; then 2.5 mg/day decrements every 2–4 weeks until 15 mg/day; thereafter, tapering steps of 1 mg each month or 2.5 mg every 7 weeks.

Glucocorticoids during pregnancy and lactation

The fetus is protected from exogenous (i.e. maternal) glucocorticoids via two mechanisms. First, glucocorticoids bound to transport

proteins cannot pass the placenta. Second, the enzyme 11β-HSD in the placenta catalyses the conversion of active cortisol, corticosterone, and prednisolone into their inactive 11-dehydro-prohormones. As a result of these mechanisms, the maternal-to-fetal prednisolone blood concentration ratio is about 10:1. In contrast, dexamethasone has little or no affinity for transport proteins and is poorly metabolized by 11β-HSD in the placenta; its maternal-to-fetal blood concentration ratio is about 1:1. So if a pregnant woman has to be treated with glucocorticoids, prednisone, prednisolone, and methylprednisolone would be good choices to protect the unborn child. If the unborn child has to be treated, e.g. to induce lung maturation in a fetus at risk of preterm delivery or to treat congenital heart block associated with maternal Sjögren's syndrome, fluorinated glucocorticoids, such as betamethasone or dexamethasone, are indicated. The fear of physical and neurocognitive adverse effects has not been substantiated in children exposed to antenatal repeat doses of 12 mg betamethasone,[29] in contrast to adverse effects of early postnatal glucocorticoid exposure.[30] However, because of a small but increased risk of an oral cleft, it is advised to avoid high doses in the first trimester of pregnancy[31]; low to moderate doses of prednisone seem to be safe.[32]

Prednisolone and prednisone are excreted in small quantities in breast milk, but breastfeeding is generally considered safe for an infant whose mother on these drugs. Because curves of milk and serum concentrations for prednisolone are virtually parallel in time, the exposure of the infant seems minimized if breastfeeding is avoided during the first 4 hours after prednisolone dosing.[32]

Adverse effects and events

Often patents and physicians do not fully realize that the adverse effect spectrum of high-dose glucocorticoids differs from that of low-dose glucocorticoids.[33] This likely decreases adherence to treatment. In an investigation into patients' and physicians' perspectives on glucocorticoid therapy, osteoporosis, diabetes, and cardiovascular disease were ranked both by patients and rheumatologists within the top five of most worrisome adverse events; however, rheumatologists showed more concern about infections.[34]

There is lack of robust data on incidence of adverse effects of glucocorticoids; most data are derived from observational studies, which tend to overestimate adverse effects. First, in these studies there is bias by indication, i.e. that patients with the more severe disease are more frequently prescribed glucocorticoids. In these patients the risk of adverse effects is higher, based on their higher disease activity and their often more frequent comorbidities. Second, not all negative events are adverse effects of glucocorticoids; they could be manifestations of the disease,[35] and several negative effects on bone mass, lipids, endothelium, glucose metabolism, and infection risk are associated both with the disease treated and with glucocorticoids, especially at medium and high doses.[36–39] The adverse effects, at least of low-dose chronic glucocorticoid therapy, seem to be mild[33]; in fact glucocorticoid in lower doses, by inhibiting the inflammatory process, might counteract the negative effects of the disease mentioned above.

Infections

Epidemiological studies show that treatment with a daily dose of less than 10 mg of prednisone or equivalent leads to only a slightly increased risk of infection. An explanation might be that higher disease activity—adjusted for demographics, medications, and clinical factors—is associated with a higher risk of infections,[36] and that by lowering disease activity, the effect of the low-dose glucocorticoid on infection risk could be neutral. However, at doses of 20–40 mg daily, an increased infection risk is found (relative risk 1.3 to 3.6).[40] This risk increases with higher doses and longer duration of treatment.[41]

Glucocorticoid-treated patients with RA undergoing hand and wrist surgery while continuing this therapy appear to have no increased risk of wound infection or disturbed wound healing.[42]

Gastrointestinal adverse effects

Data from literature on the risk of peptic ulcer associated with oral glucocorticoids are inconclusive. The inhibition by glucocorticoids of the production of COX-2 without hampering the production of COX-1 is in line with studies that found no increased risk. In other studies, a relative risk of serious upper gastrointestinal peptic complications of about 2 was found.[43] When glucocorticoids are used in combination with NSAIDs, the relative risk of peptic ulcer disease and associated complications is estimated at about 4,[44] although this risk has been questioned.[45] Inflammatory disease and higher age are also risk factors for peptic ulcer disease.

Although glucocorticoids are usually listed as one of the many potential causes of pancreatitis, evidence for such an association is weak and difficult to separate from the underlying disease, such as vasculitis or SLE.[46] The risk of asymptomatic or symptomatic colonization of the upper gastrointestinal tract with *Candida albicans* is increased in patients treated with inhalation glucocorticoids and in those on systemic glucocorticoids, especially if combination immunosuppressive therapy is applied.[47]

Negative effects on bone

Osteoporosis

Fractures, especially of vertebral bodies, ribs, hips, and wrists, occur in 30–50% of patients on long-term glucocorticoid therapy. Many of the vertebral fractures are asymptomatic. Glucocorticoid-induced vertebral fractures occur at a higher bone mineral density (BMD) compared to postmenopausal vertebral fractures: BMD underestimates the risk of glucocorticoid-induced fractures. A negative effect of glucocorticoids also on bone structure seems important.[48] The topic of osteoporosis is comprehensively discussed in Chapter 142.

Osteonecrosis

Osteonecrosis has been attributed to fat emboli, microvascular obstruction of the blood vessels of the femoral head by marrow fat or oedema, and defective mending of stress fractures, depending on underlying diseases and risk factors. The mechanism of glucocorticoid-associated osteonecrosis may be osteocyte apoptosis as many apoptotic osteocytes were identified in femoral heads obtained at total hip replacement for glucocorticoid-associated osteonecrosis, which were absent in femoral heads with traumatic or sickle-cell osteonecrosis.[48]

Glucocorticoid-induced myopathy

Weakness in proximal muscles, especially of the lower extremities, may indicate glucocorticoid-induced myopathy. It is often suspected, but infrequently found; it occurs almost exclusively in patients treated with high doses (>30 mg/day prednisone or

equivalent). Diagnosis is clinical and can be confirmed by a muscle biopsy specimen that reveals atrophy of type II fibres and lack of inflammation; there is no elevation of serum muscle enzymes. Treatment is withdrawal of the glucocorticoid if possible.

Metabolic and cardiovascular adverse effects and events

The risk of adverse cardiovascular events is twice as high in patients with RA as it is in the general population, similar to that in patients with type 2 diabetes mellitus.[49] This increased risk is probably caused by negative effects of chronic inflammation; by effects of treatment on conventional risk factors such as hypertension (secondary to use of NSAIDs, ciclosporin, and leflunomide), lipids, obesity, and glucose metabolism[50]; and by specific and unknown RA-related mechanisms. Consequently, guidelines published in 2010 recommend that a multiplication factor of 1.5 should be applied to cardiovascular risk scores for patients with severe or longstanding RA.[51] Increased cardiovascular risk has also been found in other inflammatory rheumatic diseases such as SLE and ankylosing spondylitis.[51] However, negative effects on conventional risk factors seem not to be adverse effects of low-dose glucocorticoids. Furthermore, atherosclerosis itself has been recognized as an inflammatory disease of arterial walls, for which glucocorticoids may be beneficial; glucocorticoids have been found to inhibit macrophage accumulation in injured arterial wall in vitro, possibly resulting in attenuation of the local inflammatory response.[52]

Glucose intolerance and type 2 diabetes mellitus

Glucocorticoids increase hepatic glucose production, induce insulin resistance, and probably also have a direct effect on the beta cells of the pancreas, resulting in enhanced insulin secretion. It may take only a few weeks before glucocorticoid-induced hyperglycaemia occurs on medium glucocorticoid doses, but in pulse therapy this effect is present within hours. In previously non-diabetic subjects, an odds ratio of 1.8 for the need to initiate antihyperglycaemic drugs during glucocorticoid therapy in doses of 10 mg or more of prednisone or equivalent per day was seen; the odds ratio was 3 for 10–20 mg, 5.8 for 20–30 mg, and 10.3 for 30 mg or more of prednisone or equivalent per day.[53] It is likely that the risk is higher in patients with other risk factors for diabetes mellitus, such as a family history of the disease, advanced age, obesity, and previous gestational diabetes. Controlling inflammation by disease-modifying anti-rheumatic drugs (DMARDs) including low-dose chronic glucocorticoid therapy may improve insulin sensitivity and subsequently reduce the risk of developing type 2 diabetes in RA patients.[37] Worsening of glucose control in patients with established diabetes mellitus is to be expected on medium to high glucocorticoid doses. Usually, glucocorticoid-induced diabetes is reversible when the drug is discontinued, unless there was pre-existing glucose intolerance.

Body fat and body weight

One of the most notable effects of long-term endogenous or exogenous glucocorticoid excess is the gain in total body and trunk fat.[54] Increased appetite occurs during glucocorticoid therapy leading to higher body weight; also, patients with active inflammatory diseases tend to lose weight, which is prevented with disease control by drugs, including glucocorticoids.[54a] A centripetal fat accumulation with thin extremities with atrophic skin and bruising is a characteristic feature of patients exposed to long-term high-dose glucocorticoids. Potential mechanisms include increased conversion of cortisone to cortisol in visceral adipocytes, hyperinsulinaemia, and a change in expression and activity of adipocyte-derived hormones and cytokines, such as leptin and TNF.[55] Protein loss resulting in muscle atrophy may also contribute to the change in body appearance, although protein loss or redistribution of fat is not always found.[54] Trials in patients with RA on low-dose glucocorticoids for a prolonged period showed only minor effects in fat distribution and body weight.[56,57]

Atherosclerosis and lipids

The effects on lipids and other cardiovascular risk factors of low-dose glucocorticoids in inflammatory diseases probably are different from those of medium and high doses,[50] or those of glucocorticoid therapy in non-inflammatory diseases. Low-dose glucocorticoids might improve dyslipidaemia associated with inflammatory disease[51,58]; in patients with RA using a glucocorticoid, a more favourable atherogenic index was found compared to that of patients without glucocorticoid therapy.[39] The interplay of disease activity, glucocorticoids, and adverse effects makes it difficult to judge the net adverse effects of glucocorticoids on cardiovascular risk and lipids.[59]

Hypertension and other mineralocorticoid effects

Cortisol in particular also has mineralocorticoid actions (Table 79.1), including reduced excretion of sodium and water and increased excretion of calcium and potassium, leading to hypokalaemia, especially when administered concomitantly with amphotericin B or potassium-depleting diuretics. Frequent clinical signs are oedema, weight gain, and increased blood pressure. However, low doses of synthetic glucocorticoids are not a cause of hypertension, in contrast to higher doses.[60] No formal studies addressing the effects of glucocorticoids in previously hypertensive patients have been performed. Glucocorticoids exerted no negative effects on myocarditis and idiopathic cardiomyopathy.[61,62]

Adverse effects on the eye

Cataract

Glucocorticoids stimulate the formation of especially posterior subcapsular cataract,[63] but the risk of cortical cataract is also increased, with an odds ratio of 2.6.[64] The likelihood and severity of this adverse effect depend on dose and duration of treatment. In patients treated with prednisone at a dose of 15 mg or more daily for at least 1 year, cataract is observed frequently, but cataract may also develop with long-term, low-dose therapy.[65] These cataracts are usually bilateral and progress slowly.

Glaucoma

Glucocorticoids may cause or aggravate glaucoma, especially in patients with a family history of open-angle glaucoma and patients receiving high doses; checks of intraocular pressure are then warranted. If intraocular pressure is found to be increased, patients need to be treated with medications that reduce pressure, often for a prolonged period after stopping the glucocorticoid.[66] Topical application of a glucocorticoid in the eye has a more pronounced effect on intraocular pressure than does systemic therapy.[67]

Adverse effects on skin and hair

Clinically relevant adverse effects of high-dose and long-term glucocorticoids on skin include cushingoid appearance, easy

bruising, ecchymoses, skin atrophy, striae, disturbed healing, acne, perioral dermatitis, hyperpigmentation, facial redness, mild hirsutism, and thinning of scalp hair. The physician often considers these changes to be of minor clinical importance, but they may be disturbing to the patient.[68] No reliable data on the exact frequency of these adverse effects are available, but they are dependent on duration of therapy and dose.[65]

Psychological adverse effects

Glucocorticoid treatment is associated with a variety of behavioural symptoms.[69] Although most attention is drawn toward infrequent overt psychiatric disturbances, e.g. depression and mania, less florid psychological manifestations more frequently occur, which may cause distress to patients.[68] These include depressed or elated mood (euphoria), insomnia, irritability, emotional instability, anxiety, memory failure, and other cognition impairments; they may also occur on withdrawal of glucocorticoids. The exact incidence is unknown and probably dependent on dose. A history of psychiatric illness does not predict occurrence, nor do previous glucocorticoid-induced psychiatric disturbances or previous treatment(s) free of such disturbances.[69]

Prophylactic measures and monitoring

Some prophylactic measures during glucocorticoid therapy are evidence based. If comedication with an NSAID is needed, consider cotreatment with a proton pump inhibitor or misoprostol, and/or prescribe a COX-1 sparing NSAID,[33] dependent on the individual patient's risk of peptic ulcer and cardiovascular disease. Adequate use of calcium, vitamin D, and bisphosphonates according to national or international guidelines minimizes the risk of osteoporosis.

Recommendations have been formulated on the management of systemic glucocorticoid therapy in rheumatic diseases (Table 79.3),[70] as well on monitoring of patients receiving low-dose glucocorticoid therapy.[34] Overall, additions to standard monitoring of patients with an inflammatory disease should include screening for osteoporosis, and pretreatment assessments of fasting blood glucose levels, risk factors for glaucoma, and a check for ankle oedema.[34] For patients receiving medium or high doses of glucocorticoids monitoring should be intensified, but specific guidelines for use of these doses do not yet exist. In future clinical trials of glucocorticoid-based therapies for RA, comprehensive monitoring and reporting of treatment-related adverse effects is advised, to obtain more reliable data on the spectrum, incidence, and severity of adverse effects.[34]

New developments

Increased knowledge about modes of action of glucocorticoids and pathophysiological backgrounds of rheumatic diseases creates opportunities for new developments to optimize the effects

Table 79.3 The 10 EULAR recommendations on systemic glucocorticoid therapy in rheumatic diseases[70]

1a	The adverse effects of glucocorticoid therapy should be considered and discussed with the patient before glucocorticoid therapy is started
1b	This advice should be reinforced by giving information regarding glucocorticoid management
1c	If glucocorticoids are to be used for a more prolonged period of time, a 'glucocorticoid card' should be issued to every patient, with the date of commencement of treatment, the initial dosage, and the subsequent reductions and maintenance regimens
2a	Initial dose, dose reduction, and long-term dosing depend on the underlying rheumatic disease, disease activity, risk factors, and individual responsiveness of the patient
2b	Timing may be important, with respect to the circadian rhythm of both the disease and the natural secretion of glucocorticoids
3	When it is decided to start glucocorticoid treatment, comorbidities and risk factors for adverse effects should be evaluated and treated where indicated. These include hypertension, diabetes, peptic ulcer, recent fractures, presence of cataract or glaucoma, presence of (chronic) infections, dyslipidaemia, and comedication with NSAIDs
4	For prolonged treatment, the glucocorticoid dosage should be kept to a minimum and a glucocorticoid taper should be attempted in case of remission or low disease activity. The reasons to continue glucocorticoid therapy should be regularly checked
5	During treatment, patients should be monitored for body weight, blood pressure, peripheral oedema, cardiac insufficiency, serum lipids, blood and/or urine glucose and ocular pressure depending on individual patient's risk, glucocorticoid dose, and duration
6a	If a patient is started on prednisone >7.5 mg daily and continues on prednisone for more than 3 months, calcium and vitamin D supplementation should be prescribed
6b	Antiresorptive therapy with bisphosphonates to reduce the risk of glucocorticoid-induced osteoporosis should be based on risk factors, including BMD measurement
7	Patients treated with glucocorticoids and concomitant NSAIDs should be given appropriate gastroprotective medication, such as proton pump inhibitors or misoprostol, or alternatively could switch to a COX-2 selective inhibitor
8	All patients on glucocorticoid therapy for longer than 1 month, who will undergo surgery, need perioperative management with adequate glucocorticoid replacement to overcome potential adrenal insufficiency
9	Glucocorticoids during pregnancy have no additional risk for mother and child
10	Children receiving glucocorticoids should be checked regularly for linear growth and considered for growth hormone replacement in case of growth impairment

BMD, bone mineral density; COX, cyclooxygenase; NSAID, non-steroidal anti-inflammatory drug.

and to decrease adverse effects of these agents.[71] For instance, a modified-release prednisone tablet is now available. When taken in the evening, the delayed prednisone release mimics the natural circadian rhythm of cortisol and effectively targets the nocturnal release of proinflammatory cytokines, especially IL-6. This results in more reduction of morning stiffness in RA compared to taking prednisone early in the morning.[72] Further research is needed and is under way.[73] Combining glucocorticoids with agents that selectively amplify their anti-inflammatory activity, e.g. the platelet-activation blocking agent dipyridamole, could improve the risk–benefit ratio by reducing the effective dose.[74] Another such compound under development is nitric oxide.[75] Glucocorticoid-containing liposomes, which accumulate at sites of inflammation, enabling less-frequent dosing, are also being studied.[76] Selective glucocorticoid receptor agonists causing less DNA transactivation than conventional glucocorticoids could be associated with fewer metabolic and endocrine adverse effects.[77]

Conclusion

◆ Glucocorticoids are still the most effective, broadly applicable and cheapest immunosuppressive drugs.

◆ The risk of adverse effects of a glucocorticoid is patient, dose, and time dependent and is generally overestimated.

◆ Glucocorticoids have disease-modifying properties in early RA.

◆ For low-dose glucocorticoid therapy, monitoring as part of good clinical care in rheumatic patients in daily practice needs only to be extended with screening for osteoporosis, and pretreatment assessments of fasting blood glucose levels, risk factors for glaucoma, and a check for ankle oedema.

CHAPTER 80

Immunosuppressants

Joanna Ledingham and Sarah Westlake

Methotrexate

Methotrexate (MTX) is used with therapeutic benefit, to treat a wide range of rheumatological disorders. In the United Kingdom its only rheumatic licence is for rheumatoid arthritis (RA).[1]

The use of MTX progressively rose during the 1980s and it is now considered the gold standard DMARD.[2] It also has efficacy in other inflammatory arthritides, connective tissue diseases (CTDs), and vasculitides.[2–4]

Pharmacology

MTX is a structural analogue of folic acid. Its exact mechanism of action is unknown. In high doses, used to treat malignancy, it inhibits DNA synthesis by inhibiting the reduction of dihydrofolate to tetrahydrofolate. In lower rheumatological doses it probably acts on multiple pathways including cytokine production, adenosine and arachidonic acid metabolism, and cell apoptosis.

For rheumatic diseases doses of 7.5–30 mg once weekly (licensed dose up to 25 mg) are used. MTX can be given orally, intramuscularly, or subcutaneously. At higher doses (>17.5 mg), parenteral absorption and bioavailability may be better than oral. The onset of action is usually 6–12 weeks.

Toxicity

MTX is contraindicated in pregnancy and breastfeeding. It should be stopped, in men and women, 3 months prior to conception. Effective contraception is essential for all couples with a woman of childbearing age.

MTX should not be started in patients with current sepsis or bone marrow failure.

Important MTX drug interactions are with other folate inhibitors, particularly trimethoprim and septrin; these should not be used with MTX. Theoretically, non-steroidal anti-inflammatory drugs (NSAIDs) may interact with MTX by impairing renal function, thereby reducing renal excretion and leading to haematological toxicity; in practice, with appropriate monitoring, this combination is safe and effective. MTX dose reduction should be considered in patients with renal impairment.

Rheumatological MTX doses are usually well tolerated. Most adverse effects are mild and do not require discontinuation. Some deaths have, however, been reported.

Nausea and oral ulceration are the most common adverse events(1–10%). These usually respond to symptomatic treatment. Coprescription of folic acid reduces their incidence. Parenteral administration may reduce gastrointestinal side effects.

Elevated liver function tests (LFTs) occur in approximately 10% of patients; most changes are mild, sporadic, and not linked to the rarer complication of cirrhosis. Risk factors for hepatotoxicity are as for non-MTX-linked liver disease (increasing age, obesity, heavy alcohol consumption, and diabetes) and should be minimized wherever possible. Persistently raised LFTs (>3× upper limit of normal) despite MTX dose reduction/discontinuation requires further investigation.

Cirrhotic complications are very rare (0.01%), more common with psoriatic arthritis (PsA) and can occur despite normal LFTs and hepatic imaging. Routine liver biopsy or serum procollagen III monitoring is not currently recommended in the United Kingdom.

Pulmonary complications are uncommon (0.1–1%) but potentially fatal pneumonitis, an idiosyncratic hypersensitivity reaction, is well recognized.[5] Symptoms (breathlessness and dry cough typically developing over several days) usually develop early in treatment (most within 1 year). Prompt recognition, discontinuation of MTX and investigation (high-resolution CT and possibly biopsy) is recommended. High-dose oral or intravenous steroids may hasten recovery and rechallenge is not recommended. Underlying lung disease has been linked with pneumonitis mortality so MTX should be used with caution in patients with established lung disease. Routine chest radiography (CXR) or pulmonary function test monitoring is not helpful.

Infections, including opportunistic infections such as disseminated herpes zoster, are common with MTX. Other factors (e.g. chronic disease, steroids, diabetes) contribute to this risk. Patients and clinicians should be vigilant for infection. MTX can be continued during minor infections but should be stopped with severe or opportunistic infections requiring antibiotics.

Leucopenia, thrombocytopenia, and anaemia are uncommon with MTX (0.1–1%). Most episodes respond to temporary dose reduction or MTX cessation. Severe pancytopenia is uncommon but is linked with renal impairment, hypoalbuminaemia, accidental overdose, and coprescription of other anti-folate drugs.[6] Fatal cases are reported. Severe leucopenia requires MTX cessation and may

respond to folinic acid rescue.[7] Macrocytosis commonly occurs but does not require MTX withdrawal.

Rheumatoid nodules can develop or increase with MTX and regress with MTX dose reduction or cessation.[8]

There is no conclusive evidence for an increased risk of malignancy with MTX.[9,10]

Other information

MTX-treated patients should not receive live vaccines. Pneumovax and annual flu vaccination are recommended. Varicella zoster immune globulin (VZIG) can be considered for patients exposed to chickenpox or shingles.[7]

MTX may be associated with a decreased risk of cardiovascular disease in RA patients.[11]

Sulphasalazine

Sulphasalazine (SSP) has been used to treat RA since the 1940s.[12] Following 30 years of limited use, SSP was confirmed as an effective DMARD.[13] SSP is licensed for use in RA; it is unlicensed but commonly used for seronegative spondyloarthropathies (SPA).[1] It has no other rheumatic uses.

Pharmacology

SSP consists of sulphapyridine (SP) and 5-aminosalicylic acid (5-ASA). The majority of SSP is converted to SP and 5-ASA following enzymatic breakdown in the large intestine.[14] Studies suggest that SP has the main DMARD effect.[14] SP has immunomodulatory actions, to date not fully established, in addition to potential antibiotic effects. 5-ASA may have anti-inflammatory effects only.[14]

SSP is available as a tablet (500 mg) or syrup.[1] The dose is incrementally increased to a standard maintenance dose of 1 g twice daily (maximum 3 g daily or 40 mg/kg per day). Clinical effect should be achieved within 6–12 weeks.[7]

Toxicity

The main contraindication to SSP is sulphonamide allergy.[1,7]

SSP should be used with caution while breastfeeding.[7,15]

SSP has no cumulative toxicity. Most serious side effects occur early (within 3–6 months) and reverse promptly on SSP withdrawal.[9,16,17]

Nausea and rarely vomiting, are the most common side effects, causing estimated withdrawal rates of 10–15%. Nausea usually occurs early, generally eases with time and can be reduced by use of the enteric-coated tablet, taking SSP with food and increasing the dose more gradually.[9,16,17] Centrally acting anti-emetics can be beneficial, suggesting a central, not local, effect.[9]

Mucocutaneous reactions are common.[9,16,17] Dose reduction or temporary SSP withdrawal may allow milder symptoms to settle; severe rashes require SSP withdrawal and rechallenge is not advised.[9]

Diarrhoea and abdominal pain causes withdrawal in up to 5%; these do not result from structural change within the bowel, small-bowel bacterial overgrowth, or pseudomembranous colitis.[9]

Neuropsychiatric complications (headaches, irritability, anxiety) occur in up to 19% and may necessitate SSP withdrawal.[9,16,18]

Haematological complications occur in 1–3%.[9,16,17,19]

Mild neutropenia, lymphopenia, and thrombocytopenia may correct with no action or temporary dose reduction/drug holiday.

Severe neutropenia is reversible, can be life threatening, and necessitates SSP withdrawal; rechallenge is not recommended [9] Very rarely aplastic anaemia is reported.[17,19,20]

Megaloblastic anaemia and significant haemolysis are rare but a rise in mean corpuscular volume is relatively common (70%) and the cause for this is not fully understood.[9,19] SSP, despite competitively antagonizing folic acid, does not directly affect folic acid levels.[21] Macrocytosis does not usually require SSP withdrawal.

Minor LFT abnormalities occur in up to 3%, do not require SSP withdrawal, and do not predict the rarer severe acute hepatic complications that do require SSP withdrawal.[9,22]

Pneumonitis is extremely rare (<0.1%), usually occurs early, and requires SSP withdrawal; eosinophilia and pulmonary infiltrates are often found in conjunction with rash and fever.[23]

Azoospermia occurs in some males but rapidly reverses on stopping treatment.[15,24]

Persistent reduced immunoglobulin levels occur in up to 10% but do not link with increased infection risk.[9]

Other information

SSP can cause orange discolouration of body fluids—this can stain soft contact lenses and discolour urine.

SSP can be continued if required during pregnancy provided adequate folic acid intake is ensured.[7,25]

Monitoring requirements

See Table 80.1.

Leflunomide

Leflunomide is the newest DMARD licensed for treatment of RA and PsA.[1] It is not commonly used for other rheumatic conditions.

Pharmacology

Leflunomide, *N*-(3-trifluromethylphenyl)-5-methylisoaazole-4-carboxamide, inhibits pyrimidine synthesis, resulting in blockage of T-cell proliferation. It is a prodrug that is rapidly converted to its active metabolite. It has a long half-life (1–4 weeks).[26] At a dose of 20 mg daily (licensed maintenance dose 10–20 mg) it reaches a steady state in 7 weeks. This period can be shortened by using a loading dose of 100 mg daily for 3 days. Time to onset of action is 3–12 weeks.[7]

Toxicity

Pregnancy is contraindicated with leflunomide. Couples with a woman of childbearing age must use reliable contraception. Women planning pregnancy should stop leflunomide 2 years before conception or undergo a washout (see 'Other information'). Men should use reliable contraception for 3 months after stopping leflunomide.[1,7]

Leflunomide should not be started in the presence of active sepsis, severely impaired bone marrow function, immunodeficiency, or liver disease.

Leflunomide interacts with warfarin.[1]

Leflunomide has a similar side-effect profile to MTX and SSP.[26] because of its long half-life side effects typically persist for longer. Minimal data are available on long-term toxicity.

Gastrointestinal side effects (nausea, dyspepsia, abdominal pain, and diarrhoea) are common (1–10%).[27] Diarrhoea is more

Table 80.1 Guidelines for monitoring DMARD therapy

Drug	Pretreatment	FBC	U&E, Creat 1	LFT	BP	Urine dipstick protein	Frequency/comment
Azathioprine	FBC, U&E, LFT, creatinine, **TPMT assay**	√	√	√	–	–	*FBC and LFT*—**weekly for 6 weeks**; then **2 weekly** until dose stable for **6 weeks**; then **monthly** After dose increase: FBC and LFTs after **2 weeks**, then **monthly** If dose and results stable for **6 months** consider reducing to **3 monthly** In **heterozygote** TPMT patients, **monthly** monitoring should continue *U&E, creatinine*—**6 monthly**
Ciclosporin	FBC, U&E, LFT, Creatinine: twice 2 weeks apart to obtain mean value creatinine clearance or equivalent Fasting lipids BP: <140/90 twice, 2 weeks apart	√	√	√	√	–	*U&E*—**every 2 weeks** until dose and results stable for **3 months;** then **monthly** *FBC and LFT*—**monthly** until dose and results stable for **3 months; thereafter 3 monthly** *BP*—at each attendance. BP >140/90 twice, 2 weeks apart—treat hypertension. If BP cannot be controlled, stop ciclosporin. Once BP controlled can restart ciclosporin *Fasting lipids*—check periodically
IM Gold	FBC, U & E, LFT & creatinine, urinalysis	√	–	–	–	√	Prior to each injection *FBC and urinalysis* Enquire about *skin rashes or mouth ulcers*
Hydroxychloroquine	FBC, U&E, LFT Identify visual impairment not corrected by glasses Record near visual acuity of each eye (with glasses if worn) using a test type or reading chart If abnormality, refer first to optometrist	–	–	–	–	–	*Annual review* either by an optometrist or enquiring about visual symptoms, rechecking visual acuity and assessing for blurred vision using the reading chart. Discuss with ophthalmologist if on treatment for >5 years **Patients should also be advised to report any visual disturbance**
Leflunomide	FBC, U&E, LFT, creatinine. BP twice, 2 weeks apart. If >140/90 treat before starting leflunomide Body weight	√		√	√	–	*FBC, LFT*—**every month** for 6 months; once if stable, **2 monthly thereafter** If other immunnosuppressant or hepatotoxic agent are coprescribed **monthly tests long term** *BP*—at each visit *Weigh*—at each visit
Methotrexate (oral/IM or SC)	FBC, U&E, LFT CXR (within the last 6 months) Pulmonary function test in selected patients	√	√	√	–	–	*FBC, U&E, LFT* **every 2 weeks** until dose and monitoring **stable for 6 weeks**; thereafter **monthly**, until the dose and disease is stable for a year. Thereafter consider reducing monitoring **to every 2–3 months**

(Continued)

Table 80.1 (*Continued*)

Drug	Pretreatment	FBC	U&E, Creat 1	LFT	BP	Urine dipstick protein	Frequency/comment
Folic acid							*Dyspnoea or dry cough*—assess at each visit
Mycophenolate mofetil	FBC, U&E, LFT, CXR (within the last 6 months)	√	–	–	–	–	*FBC*—**weekly** until dose **stable for 4 weeks** then **fortnightly for 2 months; monthly thereafter**
D-Penicillamine	FBC, U&E, creatinine, urinary protein	√	–	–	–	√	*FBC and urinalysis*—**every 2 weeks** until dose and monitoring stable for **3 months; monthly thereafter**
Sulfasalazine	FBC, U&E, LFT, creatinine	√	–	√	–	–	*FBC, LFT*—**monthly for 3 months**. If dose and results **stable for 3 months**, then **3 monthly**. If dose increase, repeat **bloods after 1 month**; if stable revert to usual monitoring regime If **after first year** dose and results are stable, frequency of **6 monthly** tests for second year **After 2 years** of stable dose and results, no monitoring required

The BSR/BHPR guidelines on DMARD therapy provides further information on actions to take in the light of monitoring test results.[7] Note that in addition to absolute values a rapid fall or rise and a consistent upward or downward trend in any value should prompt caution and extra vigilance.

From the BSR guidelines for DMARD monitoring.[95]

common with use of the loading dose, typically occurs within the first 3 months, and often settles with symptomatic treatment or with dose reduction.[9] Significant weight loss has been reported.[28]

Raised LFTs occur in 10% and usually improve with dose reduction/treatment cessation.[9] Cirrhosis and fatal liver disease can occur and caution is recommended particularly with concomitant use of other hepatotoxic drugs (e.g. MTX and NSAIDs) and in patients with other risk factors for liver disease.[29] Alcohol intake should be limited.[7]

An increase in blood pressure (BP), usually mild, is commonly seen (1–10%). BP should be controlled prior to and during treatment. Severe, uncontrolled hypertension may require leflunomide withdrawal.[7]

Rashes and alopecia occur in 1–10%. Both respond to dose reduction or cessation if severe.[9]

Leucopoenia, anaemia, and thrombocytopenia are uncommon (0.1–1%) [9]; severe cases may require leflunomide cessation and washout (see 'Other information').

Rare cases of pneumonitis are reported.[30]

Cases of peripheral neuropathy have been reported, typically after 6 months of treatment.[31] Drug cessation is associated with the best outcome and most cases improve.

Other information

In the event of severe complications, or before conception, a washout procedure can be considered to expedite drug elimination. Leflunomide should be stopped and either cholestyramine or activated charcoal given for 11 days. Confirmation of active metabolite concentrations below 20 μg/litre is recommended before conception.[1,7]

Advice on immunization is as for MTX.

Monitoring

See Table 80.1.

Hydroxychloroquine and other anti-malarials

Anti-malarials have been used to treat rheumatic diseases since the 1950s.[32] Hydroxychloroquine (HCQ) is licensed to treat RA and CTDs.[1] Chloroquine is also licensed to treat inflammatory conditions but is rarely used.[1] Mepracrine and dapsone are sometimes used off license to treat discoid lupus and cutaneous vasculitides respectively.

Pharmacology

HCQ is administered orally.[7] Its DMARD actions are not well understood, but it is known to impair phago/lysosomal function and inhibit Toll-like receptors.[33] HCQ has a long half-life (approximately 40 days)[9], reaches a steady state concentration after about 6 months, and takes longer than other DMARDs to take effect (3–6 months).[9,34]

A typical dose of HCQ is 200–400 mg daily.[7] The dose should not exceed 6.5 mg/kg per day.[1]

Toxicity

Pre-existent maculopathy is a contra-indication.[7]

HCQ may reduce seizure thresholds and exacerbate psoriasis so should be used with caution in patients with epilepsy or psoriasis [7]

HCQ is relatively safe in pregnancy and can be continued if breast feeding.[15]

Anti-malarials generally have better toxicity profiles than other DMARDs. In particular, there is no significant increased risk of infection.

Gastrointestinal (nausea, vomiting, abdominal pain) and neurological (headache, dizziness and tinnitus) side effects are uncommon (0.1–1%) and usually respond to dose reduction.

Skin rashes are rare (0.01–0.1%); if severe, drug cessation is recommended.

Ocular toxicity is the major concern with HCQ. 'Bullseye' retinopathy can progress to blindness even with drug withdrawal but is rare with rheumatological doses (<6.5 mg/kg per day).[35] Blurring of vision is more common (0.1–1%) but resolves on stopping treatment.[9] The role of retinopathy screening is much debated.

Monitoring

See Table 80.1.

Gold (sodium aurothiomalate)

Gold therapy was first investigated for RA in the 1920s, having been used for tuberculosis in the preceding 30 years.[36] It became the most commonly prescribed DMARD before losing popularity to newer treatments with better efficacy:toxicity profiles.[9] Gold only has a licence for RA but has been used to treat seronegative arthritis; it has no well-established role in treating other rheumatic diseases.[1]

Pharmacology

Therapeutic gold is a water-soluble compound of sodium aurothiomalate (a sulphur moiety attached to gold). It localizes to synovium (larger amounts in inflamed synovium), in synovial fluid[37] and up to 60% can remain in the body for up to 25 years.[9,37] Gold is concentrated in the liver, bone marrow, lymph nodes, skin, and muscle as it binds highly to protein.[9,38]

Gold's mode of action is not fully understood. It has effects on B-cell and macrophage function, osteoclastic bone resorption, interleukin production, and signal transduction.[9] Interaction with thiol groups on cell membranes and proteins is postulated to be key in its actions.[39]

Gold is given as an intramuscular injection. A test dose (10 mg) precedes doses ranging from 20–50 mg weekly; once response is achieved (usually with a cumulative dose of 500 mg) injection frequency is reduced to monthly.[1] Clinical benefit should be seen within 3–6 months.[1,7]

Toxicity

The main contraindications to gold are pregnancy and breastfeeding.[1,7]

Gold should only be used with caution in patients with severe renal or hepatic impairment and in those with systemic lupus erythematosus (SLE), porphyria, previous exfoliative dermatitis, significant pulmonary fibrosis, necrotizing enterocolitis, or a history of blood dyscrasias.[1,7,37]

Tolerance is less good than many DMARDs, with 30% withdrawal rates over the first year of treatment.[9,40]

Mucocutaneous reactions account for up to 60% of adverse reactions.[41] Mild reactions may settle with topical treatments and/or reduced injection dose or frequency; more severe rashes require gold withdrawal.[41] Pruritus accompanies most rashes (85%), can occur alone, and may settle with anti-histamines. Rising eosinophilia can herald a rash.[38] Exfoliative dermatitis is rare but requires gold withdrawal with no rechallenge; rechallenge can be considered for other rashes.[41]

Renal toxicity (most commonly membranous glomerulonephritis) presents with proteinura in approximately 8%.[9,40,42,43] Renal complications are immune mediated and generally reverse with gold withdrawal; reversal may take months or years.[43] Proteinuria with no glomerular abnormality can occur and will often reverse with dose reduction. Gold-induced nephrotic syndrome usually occurs within the first year (75%) and requires gold withdrawal.[43]

Acute facial flushing (nitritoid reaction) occurs in 5%; other symptoms include sweating, nausea, vomiting, dizziness, fainting, and rarely acute coronary and/or cerebral ischaemia.[9,44] Reactions generally reduce with ongoing treatment but are more common in those on angiotensin converting enzyme (ACE) inhibitors.[45] Patients should be observed for half an hour after their initial doses.

Haematological abnormalities develop in up to 3%. Thrombocytopenia occurs most commonly (up to 18 months after treatment has stopped) and slow-onset changes will often reverse on reducing dose or frequency.[9] All acute haematological changes, including aplastic anaemia and thrombocytopenia, require gold withdrawal with no rechallenge.[9] Eosinophilia can occur in up to 40%.[46] Hypogammaglobulinaemia that may reverse on stopping treatment is also reported.[47]

Gold-induced colitis is a rare (<1%) but serious complication.[48] It usually occurs within 3 months and after just small doses of gold but can also present late in treatment.[47,48] It is slow to settle with gold withdrawal and supportive treatment and has a high linked mortality (26%).[47,48]

Chrysiasis (blue discolouration) reflects gold deposition in the cornea and skin; it develops after long-term treatment and does not usually require gold withdrawal.[9,49]

Rarer complications include 'gold lung', hepatotoxicity, pancreatitis, and neurological complications (peripheral neuropathy, Guillain–Barré type syndrome, encephalopathy, cranial nerve palsies).[9,38,50,51]

Other information

Advice on immunization is as for MTX.

Monitoring requirements

See Table 80.1.

D-Penicillamine

D-Penicillamine (DPA) was originally used to treat Wilson's disease. It was used for RA when it was found to dissociate rheumatoid factor in the 1960s.[52] DPA has a licence for RA and has particularly been used to treat extra-articular features such as nodulosis.[1,53]

DPA has been used in scleroderma due to its inhibition of collagen cross-linking.[54,55] It has no significant role in the management of other rheumatic diseases and its use has progressively declined with the introduction of more effective, less toxic therapies.[56,57]

Pharmacology

DPA is an amino acid with a thiol side chain that can be formed synthetically or through acid hydrolysis of penicillin.[9,38,57] Its mode of action is not fully understood although the thiol side chain is thought to be important.[57] DPA has no effect on B-cell function but inhibits T helper-cell function (CD4).[57] It reduces rheumatoid factor titres and, by reducing proliferation of fibroblasts, may have an impact on RA pannus formation.[57,58]

DPA is given orally. The starting dose is 125 mg daily with monthly 125 mg increases in dose as required to 500 mg.[1] Beneficial effects take 12–24 weeks to achieve.[7]

DPA should be taken on an empty stomach. Absorption is reduced by iron, calcium, vitamin supplements. and indigestion medication.[9,57]. Through unknown mechanisms, indomethacin and chloroquine have been linked with raised blood levels of DPA.[57]

Toxicity

DPA is contraindicated in SLE and should only be used with caution with pregnancy and lactation.[1,7,37,59]

DPA toxicity limits its use and is linked with higher doses, but there is no clear cumulative dose effect.[9]

Mucocutaneous reactions are common (10–20%) and can occur both early and late in treatment.[9,38] Milder reactions (mouth ulcers, stomatitis, pruritus) may respond to symptomatic treatments and/or DPA dose reduction or temporary withdrawal. DPA-induced pemphigus requires urgent DPA withdrawal and pemphigus treatment.[9]

Hypogeusia or dysgeusia (altered or lost sense of taste) occur in 10–20%,[9] usually occur early (within 6 weeks) and settle after 2–3 months. Early-onset anorexia and nausea will also usually settle with time.

Renal and bone marrow toxicity are the major concerns with DPA, occurring in 10–15% and 5–10% respectively.[9] Isolated haematuria often reflects non-drug-related pathology but significant haematuria and proteinuria require further investigation for potential glomerulonephritis (usually membranous; rarely crescentic).[60–62]

DPA-associated pancytopenia, neutropenia, and thrombocytopenia usually respond to dose reductions or drug withdrawal.[9,38]

DPA can trigger several clinical conditions.[9,38] DPA-induced lupus differs from non-drug-induced lupus with the production of single-stranded (ss) DNA but not double-stranded (ds) DNA antibodies. DPA-induced myasthaenia gravis, polymyositis, and dermatomyositis all reverse with time on DPA withdrawal. Rarely a syndrome resembling Goodpasture's (without the anti-glomerular basement membranes antibodies) and an obliterative bronchiolitis can develop.

Mammary hyperplasia is also a rare side effect.[9,37,38]

Other information

Advice on immunization is as for MTX.

Monitoring requirements

See Table 80.1.

Azathioprine

Azathioprine was originally developed for transplant medicine. In the United Kingdom its only rheumatic disease license is for RA.[1] Its use in RA has declined. Off-licence efficacy has been shown for seronegative arthritides and CTDs.[63]

Pharmacology

Oral azathioprine is metabolized to 6-mercaptopurine and thereafter 6-thioquanine, the main active metabolite. Azathioprine reduces circulating B and T lymphocytes.[64] Thiopurine methyltransferase (TPMT) is the key inactivation enzyme. TPMT activity is autosomal dominantly inherited.[7,65]

Azathioprine is typically started at a dose of 1 mg/kg per day, increasing after 4–6 weeks up to 2–3 mg/kg.[1] The onset of action is 6–12 weeks.[7]

Toxicity

TPMT levels should be measured prior to treatment.[7] Low TPMT activity is linked with myelosuppression (up to 86%) and azathioprine is contraindicated in these patients.[64] With intermediate TPMT activity the risk of myelosuppression is increased (approximately fourfold); azathioprine can be prescribed with caution using lower initial doses if clinically indicated. Patients with high TPMT activity may require larger doses for clinical effects.[7]

Azathioprine is not recommended during pregnancy.[15] Effective contraception is recommended for all couples with a woman of childbearing age. For some women the potential risks of stopping treatment may outweigh those of continued treatment and, with informed consent, azathioprine may be continued during pregnancy.[7]

Breastfeeding is not recommended during treatment.[1]

Azathioprine has multiple drug interactions.[1] The most important are:

◆ allopurinol: reduce azathioprine dose to 25%

◆ ACE inhibitors: an alternative DMARD/anti-hypertensive should be considered due to risk of anaemia

◆ warfarin: higher warfarin doses may be required

◆ SSP and co-trimazole: avoid if possible as increased risk of bone marrow toxicity.

Nausea and vomiting are the commonest adverse events (10%).[7] They can be treated symptomatically, but often lead to drug withdrawal. Diarrhoea and oral ulceration are less common (<5%). Hepatitis is rare and usually responds to drug cessation. Pancreatitis is an uncommon (<1%) idiosyncratic reaction that requires azathioprine withdrawal without rechallenge.[9]

Rashes are relatively common (<5%), typically occur early and respond to drug cessation.[9]

Significant neutropenia requires azathioprine withdrawal and cautious reintroduction at a lower dose on resolution.[9]

Macrocytosis is common, occurs early[9] and does not require azathioprine withdrawal.[7]

Infection risk is probably increased with azathoiprine (2%).[9] Therapy should be stopped during severe infections but can usually be restarted on resolution.

With rheumatological doses there is probably a small increased risk of lymphoproliferative and skin malignancies.[64] The situation is complicated by the increased risk associated with inflammatory disease.

Other information

Advice on immunization is as for MTX.

Effective sun protection is advised.[1]

Monitoring

See Table 80.1.

Mycophenolate mofetil

Mycophenolate mofetil (MMF) was first used in transplant medicine.[66] It has no rheumatic disease licenses but is increasingly used to treat CTDs and vasculitis.[1,7,67] MMF has no significant role in treating inflammatory arthropathies.[64]

Pharmacology

MMF is a prodrug that is activated to mycophenolic acid (MPA).[68] MPA suppresses T- and B-cell proliferation and affects cellular endothelial adhesion, reducing lymphocyte accumulation at sites of inflammation.[64]

For rheumatic diseases oral doses of 1–2 g daily are used. The daily dose is usually increased weekly from 500 mg to a tolerated maintenance dose. The onset of action is typically 6–12 weeks.[7]

Toxicity

MMF should not be started in the presence of sepsis or bone marrow failure.

MMF is not recommended during pregnancy or breastfeeding.[7]

Most MMF toxicity data comes from the higher doses (2–3g daily) used in transplant medicine; the toxicity profile of MMF is similar to azathioprine.[66]

Diarrhoea, nausea, vomiting and abdominal pain are the commonest side effects (20–36%).[66]

Leucopenia occurs in up to 35% and severe neutropenia in 0.5%. These usually occur in the first 6 months of treatment. Neutropenia often responds to temporary drug cessation.[7] Upon resolution MMF can be cautiously reintroduced at half the previous dose. Anaemia and thrombocytopenia are also common (8–13%).[7]

The incidence of viral infections is increased with MMF.[66]

The incidence of malignancies, particularly non-Hodgkin's lymphoma, is increased.[69]

Other information

Advice on immunization is as for MTX.

Monitoring

See Table 80.1.

Ciclosporin

Ciclosporin was initially used in transplant medicine.[70] It was first used to treat RA in the 1970s.[9] Its only rheumatic license is for RA[1] but it has efficacy in PsA and some CTDs.[71] Poor tolerability limits its use.[2]

Pharmacology

Ciclosporin targets calcineurin, inhibiting the production of inter-leukin (IL)-2 by T lymphocytes. It predominantly inhibits T helper cells and T-cell-dependent B-cell responses.[72]

Ciclosporin is orally administered and metabolized in the liver by the cytochrome P450 isoenzyme CYP 3A4. Drugs may alter ciclosporin levels by inducing or inhibiting this enzyme.[73]

For RA a starting dose of 2.5 mg/kg per day in two divided doses is given.[1,7] This can be increased gradually after 6 weeks to a maxi-mum dose of 4 mg/kg per day. The lowest effective dose should be used as toxicity is dose dependent.[7] The time to response is typi-cally 3 months.

Toxicity

Ciclosporin is contraindicated in pregnancy and breastfeeding.[74]

Ciclosporin should not be started in patients with renal or hepatic failure, uncontrolled hypertension, sepsis, or electrolyte imbalance.[7]

Ciclosporin has multiple drug interactions; use of a data sheet is recommended before initiating or adding other drugs.[1] The most notable interactions are:

- other nephrotoxic drugs, including NSAIDS
- colchicine
- potassium-sparing diuretics
- some calcium channel blockers
- grapefruit juice.

Adverse events with the low doses used rheumatologically are generally mild and reversible. However, toxicity causes drug with-drawal within the first year in up to 15%.[9]

A dose-related decrease in glomerular filtration rate (GFR) is common (1–10%),[75] is usually reversible, and responds to dose reduction or cessation.[75] The risk is greatest in elderly patients and with comcomitant use of nephrotoxic drugs.[9] Irreversible renal damage can occur with long-term use of more than 5 mg/kg per day.[9]

Increases in BP are common (up to 33%), dose related,[64] and should be treated (note drug interactions) before ciclosporin is reduced or stopped.[7]

Headaches, parasthesiae, and tremor are common (1–10%), dose related,[9] and typically respond to dose reduction or cessation.

The risk of viral infections (e.g. herpes simplex and zoster) is increased.[9] Ciclosporin can be continued with minor infections but should be suspended with more severe infections.

Hirsutism and hypertrichosis are common (1–10%).[9] In severe cases drug cessation should be considered.

Nausea, vomiting, and diarrhoea are common and often respond to symptomatic measures.[75]

Gum hyperplasia can be severe, necessitating drug cessation; resolution can take months.[9]

Leucopenia, anaemia, and thrombocytopenia are relatively rare (0.01–0.1%) compared to other DMARDs.[9] In severe cases dose reduction or cessation should be considered.

The risk of skin malignancies and lymphoma may be increased, particularly with long-term immunosuppression (data from trans-plant patients).[9,76] This is of particular importance for PUVA-treated PsA patients.[76]

Hepatotoxicity is very rare but is seen in overdose.[9] Raised transaminases should prompt investigation of other causes.[7] Dose reduction or cessation may be needed.

Other information

Advice on immunization is as for MTX.

Monitoring

See Table 80.1.

Cyclophosphamide

Cyclophosphamide (CP) was initially developed as a more selec-tive cytotoxic agent for malignant cells.[77] Rheumatologically it is used to treat severe disease or major organ involvement with many inflammatory, vasculitic, and CTDs.[1,78,79] The availability of less toxic drugs limits its use in RA to severe disease and extra-articular features such as RA vasculitis.[1,79]

Pharmacology

CP is well absorbed orally (over 90% bioavailability) and is acti-vated in the liver by cytochrome P450; phosphoramide mustard is the main active metabolite.[38,77,80] CP and its metabolites are renally excreted. Acrolein is one renally excreted metabolite that is linked with bladder toxicity.[9,81]

CP is an alkylating agent that prevents DNA replication and has an effect on both B- and T-cell function and the production of immunoglobulins.[77,82] Maximal effects are seen on rapidly divid-ing cells, but all cells are affected.[82]

CP can be given orally or intravenously.[1] Oral doses are usu-ally 50–150 mg per day (maximum 2 mg/kg per day or 200 mg).[78] 'Pulsed' oral CP can also be prescribed.[83]

Intravenous (IV) doses usually range from 0.5–1 g (maximum 1500 mg) per infusion with infusions repeated at variable frequen-cies dependent on the clinical condition; most commonly every 2–4 weeks.[1,78] IV CP is ideally given in the morning to reduce blad-der stasis overnight; IV fluids and high oral water intake during and after treatment encourage diuresis.[1,78] Mesna (2-mercaptothane sulphonate) and anti-emetics are recommended coprescriptions to reduce side effects.[78,83] Treatment duration should be minimized given the cumulative toxicity. CP usually takes effect over 2–3 weeks but oral CP can take up to 6–12 weeks.

Toxicity

Pregnancy and breastfeeding are contraindicated while on treat-ment and for 3 months and 36 hours after treatment respectively.[1]

Toxicity limits CP use and is generally dose dependent. Many side effects are reduced with IV CP regimes.[84]

Infection risk is increased and CP should be used with caution in those with high infection risk.[1,78] Infection risk is independent of haematological complications of CP and is more common with oral regimes.[84] Neutropenic sepsis can be fatal but most haemato-logical changes are reversible; their peak incidence is at days 8–14 after IV CP.[38]

Prophylactic treatment against *Pneumocystis jirovecii* and consid-eration of anti-fungal and anti-staphylococcal treatment is recom-mended for many treatment regimes.[78] Pretreatment tuberculosis (TB) screening is recommended.[78]

Serious bladder toxicity is more common with oral regimes and links with cumulative dose and duration of treatment.[84] Dysuria can occur in up to 45%.[9] Haemorrhagic cystitis occurs in 10–43%, can range in severity and persist for up to 3 months.[9] CP rechallenge is not recommended after haemorrhagic cystitis due to the linked risks of bladder fibrosis and cancer.[9] Bladder malignancy is a dose-dependent complication and can occur up to 15 years after treatment has stopped; the risk is increased 31-fold compared to the general population.[85] Bladder complications can be reduced with mesna.[1]

Malignancies are more common with oral CP and are significant, dose-dependent, long-term complications.[85,86] Malignancy can develop many years after stopping CP and occurs more frequently in smokers.[86] No significant increase in mortality is reported and this probably reflects the high incidence of non-fatal bladder and skin malignancies.

Infertility is a major concern with CP—the risks are lower with pulsed IV CP and increase with increasing age, higher doses, and longer duration of treatment.[87]

Alopecia occurs in up to 63% of patients on oral CP; this again is dose dependent and usually reverses with CP dose reduction or withdrawal.[9]

Nausea and vomiting are also common (up to 64% with oral CP).[9]

Reversible reductions in immunoglobulins occur in up to 20% and patients have an impaired response to immunizations.[9]

Other information

As dialysis removes CP, administration should occur after dialysis in dialysed patients.[77]

As active metabolites are renally excreted, doses need to be reduced with renal impairment.[1,78]

Effective skin sun protection is advised

Advice on immunization is as for MTX.

Pretreatment sperm and oocyte cryopreservation should be considered.[78]

Monitoring requirements

For IV CP—pre- and 10 day post-treatment full blood count (FBC) and urea and electrolytes (U&E); urine dipstick prior to each treatment.[78]

For oral CP—FBC and U&E pretreatment, weekly for month 1, 2 weekly for months 2–3, then monthly. Regular urine dipstick.[78]

Vigilance for skin and other malignancies and annual cervical screening.

Minocycline and antibiotic regimes

Although not licensed for RA use, antibiotic regimes (tetracyclines, particularly minocycline used alone or in combination with other antibiotics) have been used to treat RA, having been found to have immunomodulatory effects. These treatments are tolerated well and a meta-analysis has shown benefit of tetracyclines with equivalent effects of minocycline to HCQ.[88,89]

Chlorambucil

Toxicity limits chlorambucil use in RA to the management of severe DMARD-resistant disease.[9,90,91] With proven reduction in mortality chlorambucil is mainly used to treat secondary AA amyloid. Given its cumulative dose toxicity, the smallest dose for the shortest duration is recommended.

Thalidomide

Thalidomide is a potent immunosuppressant[92] that can successfully (off-licence) treat resistant Behçet's syndrome or skin manifestations of SLE.[92,93] Teratogenicity and irreversible neuropathy limit its use.[93,94]

CHAPTER 81

Signalling pathway inhibitors

Roy Fleischmann

Introduction

The treatment of rheumatoid arthritis (RA) has evolved significantly over the past 50 years with the realization that the disease is most likely to respond to early aggressive therapy with the lowest disease activity obtainable as the goal of therapy.[1] Methotrexate (MTX) has been the cornerstone of therapy for the last 25 years.[2,3] With the advent of biological agents having multiple mechanisms of action, including molecules that inhibit tumour necrosis factor alpha (TNFα) interleukin (IL)-1, IL-6, costimulation, or depletion of B cells, especially in combination with MTX, more patients are reaching lower disease activity with the hope that this will lead to less future disability. These biological agents, however, are all injectable and expensive; along with their safety profile, this limits the numbers of patients who have access to them. In addition, not all patients respond to these medications, and a number who do respond still have moderate or severe disease activity.

For years there has been an effort to develop orally administered small molecules targeting intracellular signalling pathways, which would be safe and efficacious in the treatment of RA. Among the first compounds investigated were ones that inhibit p38 MAP kinases (MAPK). These are intracellular enzymes in signalling pathways activated by inflammatory cytokines, pathogens, and growth factors. They ultimately regulate the transcriptional activation of several genes, including those encoding TNFα, IL-1, and IL-6. Activated p38 MAPK is found in the synovial lining and endothelium of vessels in RA synovium and studies have shown that inhibition of p38 MAPK suppresses production of inflammatory cytokines. Animal arthritis models have demonstrated reduction in paw swelling and joint damage with these compounds. A number of molecules (SCIO 469, Pamapimod, VX-702, BMS-582949, ARRY-797, and ARRY-162) have been evaluated in phase 1 and phase 2 trials but their development was discontinued as either clinical efficacy was not observed or dose-related toxicity was seen.[4,5]

Oral inhibitors that target the more upstream protein tyrosine kinases, such as spleen tyrosine kinase (SyK) and the JAK family of kinases have been investigated in phase 3 clinical studies; at least one JAK inhibitor, tofacitinib, has demonstrated efficacy in a variety of clinical situations in RA. The efficacy and safety profile of these small molecule drugs shares many similarities with that of the biological agents approved for use, with some differences from these agents and from each other. Because these compounds are oral small molecules but have clinical efficacy similar to approved biologics, they have the potential to be utilized after MTX, before a biologic, or, after failure of one or more biological agents.

SyK is a non-receptor protein tyrosine kinase; it is a modulator of immune signalling in cells bearing Fcγ-activating receptors including B cells, mast cells, macrophages, neutrophils, and synoviocytes. SyK binds to the cytoplasmic region of receptors that contain the immune-receptor tyrosine-based activation motif (ITAM) and receptor binding results in ITAM phosphorylation activating SyK. SyK activation activates downstream MAPKs, Pi3K, and phospholipase C with resultant increase in IL-6 and matrix metalloproteinase (MMP) production.[6] An oral agent that inhibits SyK, R788 (fostamatinib disodium), a prodrug of the active metabolite R406, was studied in phase 3 clinical trials.

Janus kinases (JAKs) bind the cytoplasmic region of transmembrane-cytokine receptors. After receptor–ligand interaction, various JAKs are activated, resulting in tyrosine phosphorylation of the receptor and subsequent activation of STATs (signal transducer and activators of transcription), which act as transcription factors.[7] JAKs consist of four types: JAK1, JAK2, JAK3, and tyrosine kinase (TyK). JAKs work in pairs as homo- or heterodimers. The combination of JAK3/1 is primarily expressed in haematopoietic cells and is critical for signal transduction from the common gamma chain of the receptors for IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 on the plasma membrane to the nuclei of immune cells while the combination of JAK1/2 is important for the signalling of interferon (IFN)γ, G-CSF, IL-6, and IL-23.[7–9] Baricitinib (INCB028050) is a selective orally bioavailable JAK1/JAK2 inhibitor in development in RA which is currently in phase 3 trials; the results of phase 2 studies in methotrexate (MTX) incomplete responders (IR) designed to show efficacy have been reported in abstract form only at the time of writing. Tofacitinib is an orally available JAK 3/1/2 antagonist that has now been approved by the FDA for the treatment of RA.

SyK inhibitor

Fostamatinib has been investigated in several phase 2 and phase 3 clinical trials. The proof-of-concept trial was a randomized, double-blind, placebo-controlled study in 189 patients who had active RA despite receiving MTX.[10] Patients were treated with fostamatinib 50, 100, or 150 mg or placebo twice a day The twice-daily 100 and 150 mg doses were statistically superior to placebo in achieving the primary endpoint of an American College of Rheumatology (ACR) 20 response at month 3 (65%, 72% vs 38%, p <0.01; the 100 and 150 mg twice-daily doses were also statistically superior to placebo for ACR 50 and 70 response rate. 26% of patients receiving 100 mg twice daily and 49% receiving 150 mg achieved a DAS28 score less than 2.6 compared to 8% in the placebo group, which was also statistically significant. Responses were seen as early as week 1. The most common adverse events are summarized in Table 81.1 and included abdominal complaints (diarrhoea, nausea, gastritis, dyspepsia, and abdominal pain), hypertension, neutropenia, oedema, and increased alanine transaminase (ALT).

The second phase 2 study[11] was a similar design in 457 RA patients who were also MTX incomplete responders (MTX IR). The primary endpoint was the ACR 20 response at month 6; fostamatinib 100 mg twice daily and 150 mg once daily were compared to placebo. Both doses were statistically superior to placebo in achieving an ACR 20 response at month 6 (ACR 20: 67%, 57%, 35% in the 100 mg twice daily, 150 mg four times daily, and placebo groups, respectively (p < 0.001)). Statistically significant differences were seen for both doses compared to placebo for an ACR

50 response but only for the 100 mg twice daily dose for an ACR 70 response. A DAS28 score of less than 2.6 was observed in 31% of the 100 mg twice daily and 21% of the 150 mg daily groups vs 7% in the placebo group (p = 0.003). Improvement in function, as measured by a change in Health Assessment Questionnaire—Disability Index (HAQ-DI) and Short Form 36 (SF-36) scores, was recently reported.[12] Diarrhoea was seen in 19%, 12% and 3% of patients in the 100 mg twice daily, 150 mg daily, and placebo groups, respectively; 7%, 5%, and 1% respectively developed neutropenia; hypertension was seen in 29% of combined fostamatinib treated patients vs 17% in the placebo group (mean 3 mm increase in systolic blood pressure by month 1 in the fostamatinib group vs a 2 mm decline in the placebo group); 23% of the patients taking fostamatinib required initiation or change of anti-hypertensive medication vs 7% in the placebo group. Fostamatinib was reduced to 100 mg daily in 5% of patients for gastrointestinal symptoms, in 4% for elevation of aminotransferase, and in 3% for hypertension (Table 81.1) [13]

Fostamatinib 100 mg twice daily vs placebo has been investigated in a 3 month study in 219 patients with active RA who had failed TNFα inhibitors.[14] Fostamatinib failed to achieve the primary endpoint of a statistically significant difference in the ACR 20 response at month 3 vs placebo (38% vs 37%). A secondary endpoint, decrease in synovitis score on MRI, was achieved. Based on the results of the phase 2 studies, fostamatinib advanced to phase 3 trials both in patients with an incomplete response to DMARDs, including MTX, and in those who have failed TNFα inhibitors. In these trials, fostamatinib 100 mg twice daily was being compared to fostamatinib 100 mg twice daily for 4 weeks followed by 150 mg daily vs placebo. However, a phase 2b study comparing fostamatinib monotherapy to placebo at week 6 and to adalimumab monotherapy at week 24 was reported at EULAR 2013 (OP0048), prior to the conclusion of phase 3 studies. Multiple doses of fostamatinib were superior to placebo in reduction of DAS28 (CRP) at week 6 but adalimumab monotherapy was more effective than all doses of fostamatinib at week 24. Furthermore the previously noted adverse events of diarrhea and hypertension were again evident and the development of fostamatinib in RA was subsequently halted. The failure of this compound may be compound- rather than target- specific and other inhibitors of Syk are currently in development.

Table 81.1 Fostamatinib: important adverse events with incidence rate 2/100 per year or more[12]

Adverse events	All placebo PY 109 (n = 273)	All fostamatinib PY 1038 (n = 803)

JAK3/1/2 inhibitor

Tofacitinib is an orally administered inhibitor of JAK 3, 1, and 2. Three multinational phase 2 trials have been reported.[15–17] These trials demonstrated efficacy of tofacitinib, both as monotherapy and in combination with MTX, with respect to ACR responses, HAQ improvement,[18] and achievement of DAS28 score less than 2.6. With respect to safety, tofacitinib was associated with dose-dependent development of neutropenia and lipid elevation, and an increase in mean serum creatinine. A clinically significant increase in ALT or aspartate aminotransferase (AST) was not seen with tofacitinib monotherapy but was seen in combination with MTX. Serious infectious episodes (SIE) occurred more frequently in patients treated with tofacitinib than those treated with placebo.

Based on the results of the three phase 2 trials, a large phase 3 programme was initiated to investigate tofacitinib as

monotherapy[19]; in combination with DMARDs in patients who had an incomplete response to DMARDs[20]; in combination with MTX in patients who had an incomplete response to MTX (in which radiographic progression was assessed)[21]; compared to adalimumab in patients who had an incomplete response to MTX, who were TNF inhibitor (TNFI) naive and who were eligible for treatment with a TNFI[22]; in patients who had failed TNF inhibitors and were taking background MTX[23]; and compared to MTX in patients who were MTX naive.[24] Based on the results of the phase 2 studies, tofacitinib 5 and 10 mg twice daily were chosen as the optimal doses for the phase 3 trials, considering efficacy and safety.

Study design in the phase 3 studies

The study plans of the six reported phase 3 studies were similar (Figure 81.1). In five trials, patients with active disease who had failed one or more DMARDs were studied; in the sixth trial, patients who were naive to MTX were treated with tofacitinib 5 or 10 mg twice daily or MTX as monotherapy. In the comparator to adalimumab study, the patients could not have been treated with a TNF inhibitor (TNFI) previously; in the TNFI failure study, all patients had failed at least one TNFI. The MTX incomplete responder study required the patient to have been treated with MTX, with an incomplete response; the DMARD incomplete responder study included patients with an incomplete response to DMARDs, which included MTX; stable background non-steroidal anti-inflammatory drugs (NSAIDs) and prednisone up to 10 mg a day were allowed in all studies. Patients who were initially treated with placebo and who did not have a decrease in tender and swollen joints of 20% or more at month 3 were advanced to treatment with tofacitinib at a preassigned dose of 5 mg or 10 mg twice daily. At month 6, all patients in the placebo group were switched to tofacitinib, again at preassigned doses. In the TNFI failure study, although there was a similar rescue at month 3 for patients treated with placebo, the study ended at month 6. In all studies other than the TNFI failure study, approximately 75% of patients were not from the United States or western Europe.

Phase 3 monotherapy study in DMARD incomplete responders

This study was conducted in 610 RA patients with active disease who had failed one or more DMARDs, which could have been a biological agent.[19] They received either 5 or 10 mg of tofacitinib twice daily orally as monotherapy (no concomitant DMARD) or placebo. The coprimary endpoints at month 3 were ACR 20 response, change from baseline in HAQ-DI, and percentage of patients achieving disease activity score 28—erythrocyte sedimentation rate (DAS28-ESR) less than 2.6. Both doses of tofacitinib were statistically superior to placebo in achieving an ACR 20/50/70 response and improvement in HAQ-DI, with benefit maintained to month 6. Patients switching to tofacitinib at month 3 showed a response similar to patients originally treated with tofacitinib. There were no statistical differences among the placebo, tofacitinib 5 mg or 10 mg groups with respect to achieving DAS28-ESR less than 2.6 (Table 81.2).

In this study, the placebo group had a higher incidence of serious adverse events (SAE), 4.9% vs less than 1%, and the incidence of liver test abnormalities was similar between the monotherapy and placebo groups.

Phase 3 DMARD incomplete responders study

In a study in DMARD incomplete responders continuing DMARDs, 792 RA patients who had failed one or more DMARDs, which could have been a biologic agent, were treated with either 5 or 10 mg of tofacitinib twice daily or placebo orally in combination with a continued background DMARD.[20] The coprimary endpoints at month 3 were the HAQ-DI change from baseline and at month 6, the ACR 20, response and the percentage of patients achieving DAS28-ESR less than 2.6. All three primary endpoints were met (Table 81.2).

Phase 3 MTX incomplete responders with radiographic outcomes study

A study in 800 MTX incomplete responders also assessed radiographic outcomes.[20] The coprimary endpoints were the HAQ-DI change from baseline at month 3 and the ACR 20 response, the change in the van der Heijde modified Sharp score (vdHmTSS)
Fig. 81.1 Example of the plan for MTX IR assessing radiologic progression. Placebo patients were predetermined as to whether they would advance to 5 or 10 mg tofacitinib twice daily. Placebo patients were advanced to tofacitinib at month 3 if tender and swollen joints did not improve at least 20%; all placebo patients were advanced to tofacitinib at month 6. Patients on tofacitinib who did not improve by 20% or more at month 3 remained on their dose of tofacitinib.

5, tofacitinib 5 mg po BID; 10, tofacitinib 10 mg po BID; ADA, adalimumab; DMARD IR, tofacitinib in DMARD incomplete responder study; Mono, tofacitinib monotherapy study; MTX, methotrexate; MTX IR, tofacitinib in MTX incomplete responders; ND, not done; NR, not reported; P, placebo; TNF IR, tofacitinib in TNFI incomplete responder study; Tofa/ADA vs Pbo, comparator trial of tofacitinib and adalimumab compared to placebo.

All studies 3 month endpoint, non-responder imputation, except Tofa/ADA vs Pbo = 6 months, DMARD IR DAS28 <2.6 and MTX IR = 6 months ACR50/70 without advancement penalty.

All statistically significant at p ≤ 0.05 except DAS < 2.6 in the monotherapy study; TSS progression in the 5 mg tofacitinib group (and thus p values not computed for change in HAQ-DI or DAS28 <2.6 per protocol).

from baseline, and the percentage of patients achieving DAS28-ESR less than 2.6 at month 6. Statistically significant improvements were seen in the ACR 20 response and in achievement of DAS28-ESR less than 2.6 versus placebo at month 6, and improvement of the HAQ-DI at month 3. At month 6, the change from baseline in the vdHmTSS, compared to placebo, was statistically significant for the 10 mg twice daily dose but not for the 5 mg twice daily dose (Table 81.2).

Phase 3 MTX incomplete responders comparing tofacitinib to adalimumab

A study of tofacitinib or adalimumab (as active comparator) in 717 patients on background MTX again used coprimary endpoints at month 3 of HAQ-DI change from baseline and at month 6, the ACR20 response, and the percentage of patients achieving DAS28-ESR less than 2.6.[22] Statistically significant changes were seen in both tofacitinib groups and adalimumab compared to placebo for each of these primary endpoints (Table 81.2).

Phase 3 TNFI incomplete responders study

A 6 month study was conducted in 399 RA patients with active disease despite concurrent MTX therapy who had failed one or more TNF inhibitor.[23] Subjects were treated with either 5 or 10 mg of tofacitinib twice daily or placebo in combination with background MTX. The majority of patients were from Europe and North America. The coprimary endpoints at month 3 were the HAQ-DI change from baseline, the ACR20 response, and the percentage of patients achieving DAS28-ESR less than 2.6; there was a statistically significant difference between both doses of tofacitinib and placebo for all three endpoints (Table 81.2).

Phase 3 monotherapy in patients naive to MTX study

A 24 month study was conducted in 952 RA patients with active disease who were naive to MTX.[24] Subjects were treated with either 5 or 10 mg of tofacitinib twice daily or MTX, titrated to 20 mg a week, as monotherapy. The coprimary endpoints at

Table 81.3 Important safety data from pooled phase 2, 3, and long-term extension studies of tofacitinib[26]

Event	% of patients

month 6 were the change in the modified Sharp score and the ACR 70 response; there was a statistically significant difference between both doses of tofacitinib and MTX for both endpoints (Table 81.2).

JAK1/2 inhibitor

A 12 week phase 2A study was conducted in 302 patients who were MTX IR. Subjects continued MTX and were treated with placebo or baricitinib 1, 2, 4 or 8 mg orally once a day.[25] The primary endpoint was the combined ACR 20 response at week 12 of the combined 4 mg and 8 mg groups; there was a statistically significant difference between the combined groups (ACR 20 76% vs 41%, p <0.001) for the combined groups Both 4 mg and 8 mg once daily achieved statistically significant differences from placebo in ACR 20, ACR 50 and ACR 70 responses, DAS28 remission and improvement in HAQ and had an adverse event profile similar to

Table 81.4 Tofacitinib 5/10 mg BID: deaths and serious infections: phase 3 and long-term extension studies[27]

	Tofa (phase 3) n=3030	Pbo n=681	ADA n=204	Tofa (LTE) n=3227

Herpes zoster >5% in LTE

tofacitinib.[25] The 4 mg dose was found to have significantly less adverse effects than 8 mg, and 4 mg is the dose being explored in phase 3 trials.

Safety

The safety profile of tofacitinib was similar in phase 2 and 3 trials and open-label extensions (Tables 81.3 and 81.4).[26,27]

Summary and clinical impact

The oral kinase inhibitors appear to be clinically effective. Fostamatinib was shown to be efficacious in MTX IR in two phase 2 studies but further development has been halted due to a combination of insufficient efficacy (as monotherapy compared to adalimumab) and adverse events. There is one report of baricitinib in MTX IR which showed that 4 mg and 8 mg orally once daily is clinically effective with a safety profile similar to tofacitinib; the 4 mg dose is the dose being explored in phase 3 trials, which should define it's clinical efficacy and safety.

Tofacitinib has been shown to be effective in multiple studies including use as monotherapy, in DMARD IR, in MTX IR, and in TNF inhibitor failures; it was comparable to adalimumab in patients with an IR to MTX. In MTX naive patients, both 5 mg and 10 mg orally twice daily were superior to MTX clinically, functionally and inhibiting radiographic progression. Both 5 mg and 10 mg twice daily are effective in improving patient-reported outcomes such as improvement in the HAQ-DI and SF-36.

Fostamatinib is associated with adverse effects of diarrhoea, hypertension, and liver test abnormalities. Tofacitinib is associated with neutropenia; elevation of lipids, liver tests, and creatinine; and anaemia in some patients. Similar adverse events were seen with baricitinib. With all three medications it appears that there is an increase in serious infections similar to the biological therapies currently approved; opportunistic infections have been described with tofacitinib as well, especially herpes zoster.

Clearly, regulatory authorities, as well as payers, will have a significant voice as to where these agents are used in the treatment paradigm; their decisions will be based on cost, cost-effectiveness, and safety. As the agents are oral, they should be more convenient, and one would hope cheaper, than biological agents. This could affect their uptake significantly.

Preliminary data have been reported with another molecule that inhibits JAK3[28]; this compound was found to be effective as monotherapy in a phase 2A study. Too few patients were studied to determine if this compound will have a distinct efficacy and safety profile to tofacitinib.

Rheumatologists are comfortable with biological agents, and know what to expect with respect to efficacy and safety. It will take time for them to become equally comfortable with these oral agents. Nonetheless, they should provide an attractive alternative for patients with active RA who cannot tolerate or do not respond to traditional oral DMARDs or biological agents.

CHAPTER 82

Anti-cytokine biologics

Andrew J. K. Östör

Introduction

Produced in living systems, biologics comprise a group of recombinant proteins including antibodies and cytokine inhibitors. Following their introduction a seismic shift has occurred in the management of rheumatoid arthritis (RA) and a therapeutic landscape without them now seems inconceivable. The ascent of biologics occurred as a consequence of greater understanding of the proinflammatory mediators involved in the disease. At the vanguard has been tumour necrosis factor alpha (TNFα) antagonism and we now have five such agents at our disposal (infliximab, etanercept, adalimumab, certolizumab, golimumab)[1] as well as the interleukin (IL)-6 antagonist tocilizumab (Elliott et al.[1] is a key reference: the first randomized controlled trial (RCT) to show benefit of anti-TNF therapy in RA). These biologics are beneficial in a variety of clinical settings, including early and late disease, and have an acceptable safety profile. Not all anti-cytokine therapies have been successful, however, with the cost–benefit ratio of IL-1 antagonism with anakinra being deemed less favourable. A number of novel anti-cytokine biologics are in clinical trials which will increase the options to achieve individualized treatment and disease remission.

Aetiopathogenesis of rheumatoid arthritis

It is clear that cytokines are critical in the pathogenesis of RA, with the best-characterized being TNFα and IL-6. Their upregulation leads to the pathological manifestations of the condition including synovitis, and cartilage and bone destruction. Although the CD4+ T cell holds primacy as the orchestrator of the cell-mediated immune response in RA, it largely acts by stimulating other cells to produce cytokines including TNFα, IL-1, and IL-6.[2] Blocking cytokines therefore became a tantalizing prospect for treatment.

The pathogenesis of RA is discussed in detail in Chapter 109.

Properties of anti-cytokine biologics

A number of anti-TNF biologics exist, including monoclonal antibodies and a receptor fusion protein. Tocilizumab is an anti-IL-6 receptor monoclonal antibody and anakinra a recombinant IL-1 receptor antagonist. The agents currently available are listed in (Table 82.1).

Efficacy
Evidence base

Multiple RCTs using anti-cytokine biologics, usually in combination with methotrexate (MTX), have shown benefit, including signs and symptoms of disease, radiographic progression, function, and quality of life. In general these drugs work rapidly, with many patients experiencing improvement within weeks. Furthermore, a dramatic slowing of radiographic damage has resulted in an unprecedented alteration in the natural history of RA. Interestingly, an uncoupling of radiographic and clinical response was observed in some patients following TNF blockade, with slowing of bony damage even without a clear symptomatic response.[3] Tocilizumab has also been found to slow radiographic progression.[4]

Anti-cytokine biologics have led to significant benefits in patient-reported outcomes, with multiple trials showing improvement in function and quality of life indicators such as the Health Assessment Questionnaire (HAQ) and Sort Form 36 (SF-36). A systematic review of the efficacy of TNF antagonists calculated a number needed to treat of 5–6 for at least an acceptable response (ACR 20).[5] A recent Cochrane review found that the overall efficacy of biologic agents was similar, with the exception of anakinra which resulted in poorer responses.[6]

Anti-TNFα agents and productivity in rheumatoid arthritis

Several studies have shown that TNF inhibition increases the likelihood of remaining employed and reduces both presenteeism (reduced productivity) and absenteeism. This occurs in early and longstanding disease and in both 'real world' practice and clinical trials.[7–9] In the PROWD study, for example, job loss was significantly lower in patients receiving combination therapy with adalimumab than in those treated with MTX monotherapy.[10] Improvement in this area clearly has enormous health economic implications.

Window of opportunity

One of the most important lessons to emerge from research into RA treatment has been the need to treat patients as early in the disease process as possible and to adopt a tight control paradigm (see Chapter 112). Investigation continues to determine the optimal point to introduce anti-cytokine agents, but the benefits of targeting early disease have been clearly demonstrated.[9,11,12] (Goekoop-Ruiterman et al.[11] is a key reference, demonstrating

Table 82.1 Properties of anti-cytokine biological agents

Generic drug name	Chemical structure	Year of first approval	Brand name	Half-life	Dosage
Etanercept	Recombinant human soluble p75 TNFα receptor fusion protein	1998	Enbrel	70–132 h	25 mg twice weekly or 50 mg weekly SC
Infliximab	Recombinant chimeric monoclonal antibody to TNFα	1999	Remicade	9.5 days	3 mg/kg IV repeated 2 weeks and 6 weeks after the first infusion, then every 8 weeks
Adalimumab	Recombinant fully human monoclonal antibody to TNFα	2002	Humira	10–20 days	40 mg SC fortnightly
Golimumab	Recombinant fully human monoclonal antibody to TNFα	Apr 2009	Simponi	7–20 days	50 mg SC monthly
Certolizumab Pegol	Pegylated recombinant humanized anti-TNFα antibody Fab fragment	May 2009	Cimzia	14 days	400 mg SC at 0, 2 & 4 weeks then 200 mg fortnightly
Tocilizumab	Recombinant humanized monoclonal antibody to the IL-6 receptor	January 2009	Actemra (also RoActemra)	8–14 days	8 mg/kg IV monthly
Anakinra	Recombinant IL-1 receptor antagonist	November 2001	Kinaret	4–6 h	100 mg SC daily

that early intervention with combination therapy results in optimal outcomes.)

Further management issues

Anti-cytokine biologics are not always successful and failure of these drugs may occur due to:

- non-response (primary inefficacy)
- inefficacy following initial response (secondary inefficacy)
- incomplete response (patient remains in an unacceptably high disease state)
- toxicity

Failure of biologic agents has been most characterized for TNF antagonists, because they were first to market. Significant observational data has confirmed the benefit of switching to an alternative anti-TNF following loss of response with a first. However, only one RCT, using golimumab, has confirmed these observational data.[13] Other biologics found to be effective following failure of TNF antagonism include tocilizumab, rituximab, and abatacept.[14] A potentially important cause for a loss of response is immunogenicity, which can occur with any biologic.[15] Infliximab appears the most immunogenic of the anti-TNF drugs, with anti-infliximab antibodies also associated with infusion reactions.

Coprescription of MTX improves the efficacy of TNF blockade efficacy but many patients do not tolerate this disease-modifying anti-rheumatic drug (DMARD). Adalimumab, etanercept, and certolizumab are licensed for monotherapy when MTX is contraindicated or is not tolerated, as is tocilizumab. However tocilizumab is the only agent to show superiority to MTX when compared head-to-head as monotherapy and it appears that maximal response to tocilizumab is independent of background MTX.[16,17] (Jones et al.[16] is a key reference: the first study to show superiority of a biological agent when given as monotherapy when compared with MTX

monotherapy). Tocilizumab may also be used with non-MTX DMARDs with significant benefit.[18]

IL-1 antagonism

Despite positive evidence from animal models, blockade of IL-1 in humans has been less successful.[6] Apart from the reduced efficacy compared with other anti-cytokine biologics, the daily subcutaneous injections were less well tolerated by patients.

Safety of anti-cytokine biologics

As cytokines are critical for homeostasis, it may be anticipated that blockade of these molecules would result in a number of deleterious effects. In general, however, the major side-effect profile of anti-cytokine biologics has been favourable.[6] As more than 2 million patients worldwide have received infliximab, adalimumab, and/or etanercept for a variety of conditions, there is substantial real world experience. In addition, national biologic registries have been developed to monitor long-term safety (see Chapter 34). The British Society for Rheumatology Biologics Register (BSRBR) was formulated to detect an increased risk of lymphoma with TNF blockade, but a wealth of further safety data has been forthcoming.

No increased risk of lymphoma has been seen to date. However, the register has demonstrated that anti-TNF therapy is associated with an increased risk of serious infection. This occurs particularly in the first 3–6 months of the treatment where the risk almost doubled compared to controls taking non-biologic DMARDs.[19] A recent report has also confirmed an increased hospitalization rate for varicella infections compared with the general population, although the absolute risk remains low.[20]

Rarer side effects may be missed because of their short-term nature and the homogeneous group of patients used in clinical trials. A case in point was the reactivation of latent tuberculosis (TB) infection with anti-TNF agents observed in postmarketing surveillance. The risk appears less with etanercept, possibly due

to its construct and mechanism of action.[21] Consequently, screening is now mandatory for latent TB infection prior to starting TNF antagonists. A substantial reduction in TB cases has been seen as a result. Other serious opportunistic infections reported following TNFα antagonism include reactivated histoplasmosis, listeriosis, pulmonary aspergillosis, and pneumocystis pneumonia, although these are all rare.

Other safety issues with TNF antagonism

Demyelination

One unexpected adverse event was demyelinating disease. Although the number of cases was no greater than would be expected in the general population, the results of two clinical trials found a worsening of multiple sclerosis in patients with known disease.[22,23] The precise role of anti-TNF agents in triggering demyelination is unclear, but they are contraindicated in patients with a known history, or family history, of such disorders.

Autoantibodies

Autoantibody production has been documented in patients receiving TNF antagonists, especially infliximab, with up to 60% of patients developing new anti-nuclear antibodies (ANA).[24] Lupus like syndromes have rarely been reported but the symptoms are usually mild and respond to stopping the medication. However, occasional patients have developed anti-dsDNA antibodies associated with renal or cerebral lupus.

Heart failure

As TNFα is upregulated in heart failure, trials were undertaken to determine whether blocking this cytokine would be beneficial. However, a worsening of heart failure was seen in these studies including some deaths.[25,26] Despite this observation a review of TNF antagonist use in RA found no worsening of heart failure relative to controls.[27] As RA increases cardiovascular risk per se, the true role that TNF antagonism plays in relation to cardiac disease remains unclear. Nonetheless, TNF antagonists remain contraindicated in patients with severe heart failure.

Malignancy

Given the immunosuppressive effects of the TNF antagonists, concerns exist regarding the development of malignancy, especially after prolonged use. For solid tumours, data from the United States National Cancer Institute and the Swedish register is reassuring, with no evident increased risk.[28,29] The data overall regarding the development of lymphoproliferative malignancies is reassuring. TNFα antagonists have been implicated in the development of bone marrow suppression although all reported cases were in patients with chronic RA receiving multiple medications.

Interstitial lung disease

Uncontrolled reports exist of a worsening of interstitial lung disease in patients treated with biologics, especially anti-TNF agents.[30] At the same time, observational data from the BSRBR are reassuring.[31] Vigilance must be employed, however, in any patient treated with biologics with pre-existing lung disease.

Tocilizumab

Like the anti-TNF agents, tocilizumab has been found to have an acceptable safety and tolerability profile. The experience is less than with anti-TNF agents as tocilizumab has only recently been licensed. The most common side effects in clinical trials were infections such as nasopharyngitis; however, a small but significant increase in serious infection was also seen, consistent with the rate with other biologic agents.[32]

Lower gastrointestinal complications have been described with tocilizumab, such as diverticular perforation, at a rate of 1.9 per 1000 patient years.[33] This is slightly higher than with traditional DMARDs and anti-TNF agents but less than with corticosteroids or NSAIDs.

A reduction in neutrophil count below 1×10^9/litre occurred in 3.4% of patients receiving tocilizumab 8 mg/kg plus DMARDs in controlled trials, approximately one-half of these occurring within 8 weeks of starting therapy. Despite this, no increase in infections was seen. Transient elevations in alanine/aspartate transaminases (ALT/AST) have also been observed particularly in patients who received tocilizumab plus DMARDs, especially MTX.

As the lipid profile represents a 'negative' acute-phase response, reduction of inflammation leads to an elevation in lipids. This has been seen with anti-TNF agents and tocilizumab. Approximately 24% of patients receiving tocilizumab experienced sustained elevations in total cholesterol to 6.2 mmol/litre or more, with 15% experiencing a sustained increase in low-density lipoprotein (LDL) to 4.1 mmol/litre or more. No increase in cardiovascular events was seen in patients with a rise in lipid parameters, although longer-term data are required. As inflammation itself leads to an increase in cardiovascular disease, attempts to block this should be beneficial with respect to cardiovascular risk.

Tocilizumab does not appear to reactivate TB or lead to the emergence of ANAs. There is also no evidence at present that tocilizumab increases the risk of malignancy.

Biological combination therapy

Trials using combinations of biological agents have not been successful, including etanercept with anakinra and abatacept with etanercept.[34,35] An increased risk of adverse events, including serious infections, was seen without an improvement in efficacy. Therefore combining biologics is not currently recommended.

Precautions and contraindications

Anti-TNF

Contraindications to use include active TB or other active infection as well as moderate to severe heart failure and demyelination. Their use is also cautioned in patients with a history of malignancy, blood dyscrasias, and chronic obstructive pulmonary disease as well as certain viral infections, including hepatitis B and C, and alcoholic hepatitis.

Anti-IL-6

Similar precautions exist as for anti-TNF agents. Inhibition of C-reactive protein (CRP), and neutropenia in some patients, requires vigilance as signs and symptoms of sepsis may be masked. Tocilizumab should also be used with particular caution in patients with a history of diverticulitis. Monitoring of lipids, hepatic enzymes, neutrophils, and platelets is required.

Use in pregnancy/breast feeding

The use of anti-cytokine drugs in pregnancy and breast feeding is currently contraindicated. This is in part because generally these

agents are coprescribed with MTX. Data from spontaneous reports and registries has been encouraging, however, with reports of normal pregnancies in patients receiving anti-cytokine biologics.[36] Further data are required in this area, and with regard to their use during breastfeeding.

Monitoring

Prior to treatment routine screening should include full blood count (FBC), U&E, and liver function tests (LFT), as well as chest radiograph (CXR), followed by FBC and LFTs every 3 months (many patients will be receiving concurrent MTX therefore monitoring for this will suffice).

In relation to anti-IL-6 therapy lipids should be checked prior to treatment and then following 3 months of treatment. FBC and LFTs should be monitored monthly in the first 3 months of treatment then at 2–3 monthly intervals.

Vigilance for possible exacerbation of interstitial lung disease (ILD) is required, but serial CXRs are not recommended.

Guidelines and recommendations for anti-TNF agents

The licences for TNF antagonists and tocilizumab require the failure of at least one conventional DMARD prior to their prescription. In addition a number of guidelines have been developed for the use of anti-cytokine therapies in RA. The European League Against Rheumatism (EULAR) guidelines provide robust recommendations for the management of RA. They state that if the treatment target, such as disease remission, is not achieved following the first DMARD strategy in the presence of poor prognostic factors, or in patients responding insufficiently to DMARDs, then biological therapy should be considered. These individuals may be considered for combination DMARDs plus a biologic at the outset if poor prognostic features are present.[37] The ACR 2008 guidelines largely concur with the EULAR recommendations.

In the United Kingdom the role of the National Institute for Health and Clinical Excellence (NICE) is principally to determine the health economic implications of therapeutic interventions. The threshold for obtaining a biologic in the United Kingdom is currently high. However, due to the emerging evidence base the British Society for Rheumatology (BSR) has revised their guidelines regarding eligibility for biologic treatment.[38]

Pharmaco-economics

Although biologic therapy is expensive, in the region of £10 000 per patient per year, this should be set against the enormous societal impact of RA. Up to 50% of patients become work disabled within 10 years of disease onset and the total cost of RA in Europe has been estimated as €45.3 billion annually.[39] The cost of biologics will fall once patents expire, biosimilars arrive, and further agents are developed.

Future

Anti-cytokine therapy is well embedded in the management of moderate to severe RA but not all patients respond to the current agents. Research continues to identify biomarkers of response and prognostic factors to individualize treatment. A number of novel anti-cytokine therapies are being trialled, such as anti-IL-17 and anti-IL12/23. However, it remains to be seen whether these will have an advantage over the currently available drugs. In addition, the pre-eminence of anti-cytokine therapy for RA may be challenged if the promise of intracellular small molecule therapies (e.g. JAK/STAT inhibitors) is realized (see Chapter 81).

Over the next few years, treat-to-target strategies will ensure early review of patients with brisk escalation of treatment to switch off the aberrant immune-inflammatory process. The future is consequently bright for patients with RA, especially when biologics are used at the appropriate time in order to maximize the chance of remission.

Conclusion

Perhaps in no area of medicine have the recent therapeutic advances been as great as in RA. This has largely been due to biologic therapies, of which we have the greatest experience with anti-cytokine agents. TNFα antagonists currently rule supreme in the hierarchy of biologics due to their efficacy and safety in the long term; however, IL-6 receptor blockade is developing a solid track record. Thankfully for patients we now have the ability to profoundly alter the natural history of RA resulting in outcomes unimaginable even a decade ago.

Case history

A 63 year old woman with a 3 year history of seropositive, non-erosive RA presented with a flare of disease over 2 months. She had previously been well controlled on MTX 25 mg/week, folic acid 5 mg/week, and hydroxychloroquine 200 mg twice daily. Her erythrocyte sedimentation rate (ESR) was 47 mm/h and her DAS28 was 5.6. She was finding it increasing difficult to work and was considering early retirement although she loved her job as the manager of a care home for elderly people. It was decided to commence anti-TNF therapy and after 6 weeks she had responded well with a DAS28 of 3.1. After 6 months of the biologic her disease was in remission (DAS28 2.4), she was working, and playing golf in her spare time.

CHAPTER 83

Rituximab and abatacept

John D. Isaacs and Philip M. Brown

Introduction

In contrast to cytokine blockade, which targets downstream mediators of joint inflammation, anti-cellular biologics target cells that are proposed to coordinate the immunopathology of rheumatoid arthritis (RA) (Figure 83.1). Currently available agents target two key players in RA pathogenesis: B cells and T cells. B cells are targeted and killed by rituximab, whereas T cells are modulated by abatacept, which interferes with their activation without killing them.

Rituximab

Rituximab is a chimeric human IgG1 monoclonal antibody (mAb) that targets the four-transmembrane phosphoprotein CD20. The function of CD20 is not fully elucidated, but involves calcium signalling and the formation of lipid rafts. Rituximab binds to CD20 and induces cell lysis by antibody-mediated cellular cytotoxicity, complement mediated cell lysis, and promotion of apoptosis. CD20 is expressed on pre-B cells and mature B cells, but not plasma cells or pluripotent B-cell precursors. Consequently, rituximab results in rapid B-cell depletion with subsequent recovery and minimal impairment of pre-existing humoral immunity. CD20 is also expressed on a minor proportion of mature T cells. These produce interleukin (IL)-1β and tumour necrosis factor alpha (TNFα) although the relevance of their depletion to rituximab efficacy is unclear.[1]

Efficacy

Six randomized controlled trials (RCTs) have investigated rituximab in RA (Table 83.1). In each study rituximab was administered as two infusions given 14 days apart. The first compared rituximab monotherapy, rituximab plus cyclophosphamide, and rituximab plus methotrexate (MTX) vs MTX monotherapy in MTX inadequate responders.[2] At 24 weeks, all active treatment groups demonstrated superiority over MTX monotherapy. By 48 weeks, however, only the combination groups retained superiority and responses were more robust with MTX cotherapy. The second phase 2 study (DANCER) compared 500 mg and 1000 mg infusions of rituximab.[3] Both were effective but 1000 mg led to more American College of Rheumatology70 (ACR70) and European League Against Rheumatism (EULAR) good responses. This trial also compared regimes for minimizing cytokine release reactions (see 'Adverse effects'). Earlier trials had combined premedication with intravenous methylprednisolone (days 1 and 15) with oral prednisolone on days 2–14 but DANCER concluded that the latter was unnecessary.

The phase 3 REFLEX study confirmed rituximab's efficacy, in combination with MTX, in patients who had failed at least one anti-TNF agent (current licensed indication).[4] The primary outcome (ACR 20 at 24 weeks) was achieved by 51% of rituximab recipients and only 18% in the placebo group, who continued MTX and received placebo infusions. ACR 50 and 70 responses were achieved in 27 and 12% (rituximab) vs 5 and 1% (placebo). EULAR moderate and good responses were seen in 50% and 15% respectively (rituximab), vs 20% and 2% (placebo). There were also improvements in fatigue, function, and quality of life outcomes. In addition, radiographic joint damage was reduced by active treatment at 52 and 104 weeks.[5] The benefits of rituximab have subsequently been confirmed in MTX inadequate responders, in the SERENE and MIRROR studies, as well as in MTX-naive patients in the IMAGE study, but neither of these is a licensed indication.[6–8] While rituximab's licence requires cotherapy with MTX, postmarketing data suggest that leflunomide may also provide effective background therapy.[9] Table 83.1 summarizes phase 2 and 3 trials with rituximab.

Although B-cell depletion occurs rapidly following rituximab infusions, the maximum therapeutic effect may not be seen for 12–16 weeks. The duration of benefit following a course of treatment is variable but is usually at least 6 months. There is some evidence that more robust responses are experienced by patients who are seropositive for rheumatoid factor (RF), anti-citrullinated peptide autoantibodies (ACPA), or both. Most clinical trials contain too few seronegative patients to robustly address this question, but pooled trial data and registry data support this observation.[10,11] Other response predictors are being actively sought, but none has been validated. However, emerging evidence suggests that response may relate to the depth of B-cell depletion.[12] Patients with higher circulating memory B-cell and plasmablast counts at baseline may also respond less well.[13–15] However, these observations require validation and currently have minimal utility in the clinic.

Mode of action

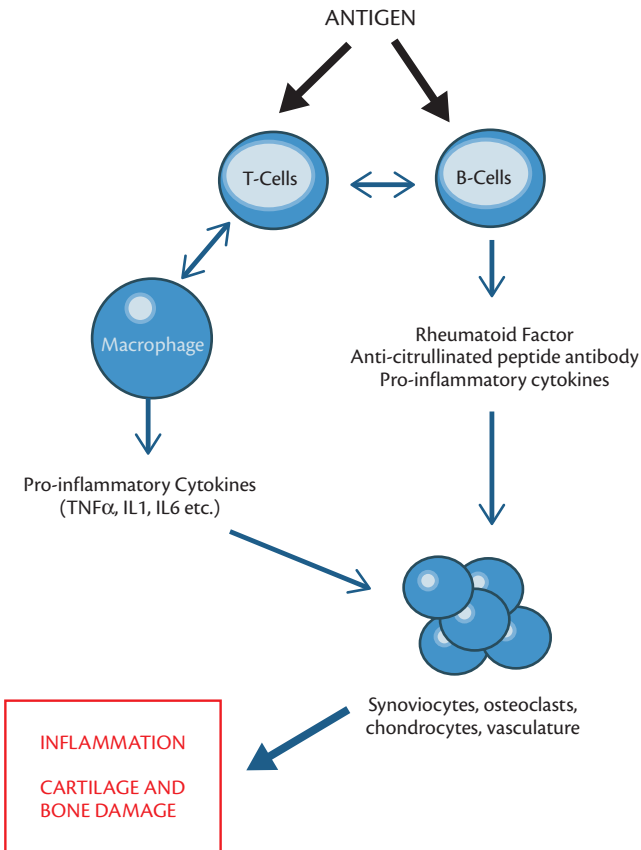
There are three potential mechanisms by which B-cell depletion could improve RA symptoms. The first is via an effect on circulating


Fig. 83.1 A simplifed model of RA pathogenesis. T and B cells respond to autoantigen by releasing proinflammatory cytokines and autoantibodies (B cells only). These two lymphocyte classes also interact with one another directly, as well as with other cell types such as macrophages. Ultimately, via soluble mediators and by direct interaction, they activate joint resident cells such as synoviocytes, osteoclasts. and chondrocytes and also generate an acute inflammatory reaction within the joint, ultimately leading to joint damage and destruction. By targeting B cells and T cells respectively, rituximab and abatacept act 'upstream' in RA pathogenesis compared to biologics that target proinflammatory cytokines.

autoantibody levels, although treatment leads to a variable reduction and rarely results in their complete disappearance from serum.[16] Furthermore, there is no clear evidence for a direct pathogenic role for either RF or ACPA in RA. A second possibility relates to loss of cytokine production by depleted B cells, but the relatively slow onset of action argues against this. Thirdly, B-cell presentation of antigen to autoreactive T cells could provide an explanation, consistent with rituximab's slow onset of action. Direct evidence in humans is lacking but there are supportive preclinical data.[17] Biomarker studies have not so far demonstrated a clear association between synovial B-cell depletion and rituximab efficacy, although a small, uncontrolled study suggested that synovial plasma cell depletion could be of importance.[18]

Safety

The safety of rituximab in RA has been investigated using a pooled analysis of 8 randomized trials and 2 long-term, open-label extensions, incorporating 3194 patients and 11 962 patient-years of experience.[19] Follow-up was from 1 to 9.5 years and number of rituximab courses between 1 and 17.

Infusion reactions

The commonest adverse reactions, affecting approximately one-third of patients receiving rituximab for the first time, are infusion reactions. These coincide with B-cell lysis and are generally mild in patients receiving premedication with methylprednisolone, an analgesic/anti-pyretic, and an anti-histamine. Common symptoms include headache, pruritus, throat irritation, flushing, rash, and pyrexia. Severe reactions occur in less than 1% of patients, and include chest and throat tightness, and hypotension; resuscitation facilities should therefore always be available during infusions. The incidence and severity of infusion reactions is lower with the second infusion of the first course and with subsequent courses.

Infections

The incidence of serious infections with rituximab is similar to other biologic therapies at 3.94 (confidence interval 3.60–4.31) per 100 patient-years in the aforementioned pooled analysis. The risk does not apparently increase with multiple courses. Commonest infections are bacterial affecting the respiratory tract, skin, urinary tract, and bowel. Unlike TNF blockade, opportunistic infections are rare and reactivation of tuberculosis (TB) has not been reported. Although most RA patients will have previously received TNF blockade and therefore been screened for TB, the incidence of reactivation is also low in patients receiving rituximab for non-Hodgkin's lymphoma. Rare cases of progressive multifocal leucoencephalopathy have been reported in RA patients receiving rituximab, although in almost all cases there was another potential contributing factor.[20] Nonetheless patients must receive a patient alert card with each infusion and be monitored for new neurological symptoms or signs. There are also rare reports of hepatitis B reactivation, occasionally resulting in fulminant hepatitis. Hepatitis B status should therefore be ascertained before therapy in relevant populations and local monitoring guidelines followed.[21]

Repeated courses of rituximab result in reduced levels of circulating IgM (incidence of 22% in the pooled analysis referred to above), although this is not associated with heightened infection risk. IgG levels below the normal range are less common, affecting 3.5% in the pooled analysis. Patients with a low IgG level have a higher serious infection risk than those who never develop a low IgG. The enhanced infection risk predates the fall in IgG levels, however, implying a common predisposing factor such as age or glucocorticoid use.[19] Other risk factors for serious infection include comorbidities such as diabetes, chronic lung or heart disease, and extra-articular disease.[22]

Vaccination

Live or attenuated vaccines are not recommended in patients receiving immunosuppressive drugs (see Chapter 94). Several studies report a reduced response to killed vaccines following rituximab.[23,24] RA patients should therefore receive necessary vaccines at least 4 weeks before a course of treatment.

Pregnancy and breastfeeding

Rituximab crosses the placenta and can deplete B cells in the fetus. It should not be administered during pregnancy and contraception is recommended for 12 months following treatment. Rituximab should also not be given to breastfeeding women.

Malignancy

There has been no statistically significant increase in the rate of malignancies following the use of rituximab for RA.[19]

Place in therapeutic algorithm

Rituximab, with concomitant MTX, is licensed in the United Kingdom for the treatment of RA in patients who have failed to have an adequate response to other disease-modifying anti-rheumatic drugs (DMARDs), including at least one TNF inhibitor. NICE guidelines are broadly in line with the licence. In practice rituximab is sometimes used as first biologic therapy where there is a (relative) contraindication to TNF blockade, such as interstitial lung disease, prior history of malignancy, or demyelinating illness.

Treatment and retreatment with rituximab

In RA, rituximab is administered as two infusions of 1000 mg, given 15 days apart, in combination with MTX. Retreatment should be considered only if there is a significant response, measured at 12–16 weeks, and should not be offered any more frequently than every 6 months. Critically (and unfortunately), neither serial B-cell measurements nor any other blood biomarker predict symptomatic relapse, which therefore must be based on clinical measures. There is continued debate on the optimal retreatment regime: treatment on disease flare vs regular retreatment (e.g. every 6 months) vs treatment-to-target. However, current expert opinion suggests treatment-to-target provides the optimal strategy, combining better disease control while minimizing the risk of overtreatment.[21] Uncontrolled data suggest that the response to rituximab may improve with subsequent treatment courses.[25] Furthermore, occasional patients who fail to benefit from an initial course may respond to a second course.

Use in other diseases

Two RCTs have studied rituximab for the treatment of Sjögren's syndrome.[26,27] Although small, both found statistically significant improvements in disease symptom scores and objective measures of disease activity compared to placebo.

EXPLORER was a phase 2/3 study comparing rituximab with placebo in 257 patients with moderate to severely active extrarenal systemic lupus erythematosus (SLE).[28] Patients continued on background therapy and also received tapered prednisone. There was no difference in primary or secondary outcome measures between the groups over 52 weeks of observation. In the phase 3 LUNAR study, 144 patients with lupus nephritis were randomized to rituximab or placebo in addition to starting mycophenylate mofetil, pulsed methylprednisolone, and tapered prednisone.[29] Again, rituximab failed to show superiority over placebo at 52 weeks. SLE is a complex disease, rendering clinical trial design problematic. In both EXPLORER and LUNAR there were biomarker (dsDNA, complement) improvements with rituximab and clinical benefits could still be seen in future studies with distinct designs.

Rituximab was non-inferior to daily oral cyclophosphamide at achieving prednisone-free remission at 6 months in newly diagnosed or relapsing ANCA-associated vasculitis. In this double-blind randomized trial, the 197 participants also received pulsed methylprednisolone plus tapered prednisone.[30] In a small study (n = 44) in ANCA-associated renal vasculitis, sustained remission at 12 months was high in patients receiving either rituximab or pulsed intravenous cyclophosphamide as induction therapy, in addition to standard glucocorticoids. There was also no difference in adverse events.[31] Thus rituximab may provide an alternative to cyclophosphamide in ANCA-associated vasculitis. Confirmatory and longer-term studies are now required.

Abatacept

Abatacept (CTLA4-Ig) is a genetically engineered fusion protein, comprising the extracellular domain of cytotoxic T-lymphocyte-associated antigen-4 (CTLA-4) linked to a modified Fc segment of human IgG1. T cells require two key signals for activation to occur. The first is an antigen-specific signal, triggered when the T-cell receptor recognizes its cognate MHC/peptide combination on an antigen-presenting cell (APC). The second, costimulatory, signal is triggered when T-cell CD28 binds either CD80 or CD86 on the APC. Following activation, the T cell upregulates CTLA-4. This molecule outcompetes CD28 for binding to CD80 and CD86, providing negative feedback and switching off T-cell activation (Figure 83.2). Abatacept is a soluble form of CTL-4 and similarly competes with CD28, depriving T cells of costimulation. This prevents activation of naive, and potentially memory, T cells. The mutation in the abatacept Fc reduces binding to complement and Fc-γ receptors, minimizing cytotoxicity to APC.

Efficacy

Phase 3 trials studied abatacept in patients with an inadequate response to MTX (AIM) and in patients failing TNF blockade (ATTAIN).[32,33] In AIM, patients were randomized to abatacept (approximately 10 mg/kg monthly) or placebo. ACR 20/50/70 responses for abatacept and placebo groups were 67.9 vs 39.7%, 39.9 vs 16.8%, and 19.8 vs 6.5% respectively at 6 months and DAS28 remission was achieved in 14.8% and 2.8% respectively. Clinically significant improvements in HAQ-DI were achieved in 63.7 vs 39.9% of patients at 12 months. Mental and physical domains of the SF-36, as well as fatigue, improved with abatacept, and radiographic progression was also retarded.[32] In ATTAIN patients received abatacept or placebo, following a washout of anti-TNF for current users. Background DMARDs (mostly MTX) were continued. The primary endpoint was at 6 months, when response rates in abatacept and placebo groups were 54 and 19% (ACR 20), 20 and 4% (ACR 50), and 10 and 1% (ACR 70). A HAQ-DI improvement of 0.3 or more was achieved by 47.3 vs 23.3% of patients in each group, and DAS28 remission was achieved in 10.0 vs 0.8% of patients.

An indirect head-to-head trial randomized patients to abatacept, infliximab, or placebo.[34] The primary outcome compared abatacept and placebo for Disease Activity Score (DAS) reduction at 6 months but the study design allowed an indirect comparison between abatacept and infliximab. There was no difference at 6 months but at 12 months ACR 20 was achieved by 72.4 of patients receiving abatacept vs 55.8% receiving infliximab, ACR 50 by 45.5 vs 36.4%, and ACR 70 by 26.3 vs 20.6%. DAS low disease activity was achieved by 35.3 vs 22.4% and DAS remission by 18.7 vs 12.2%. Table 83.2 summarizes phase 2 and 3 trials with abatacept.

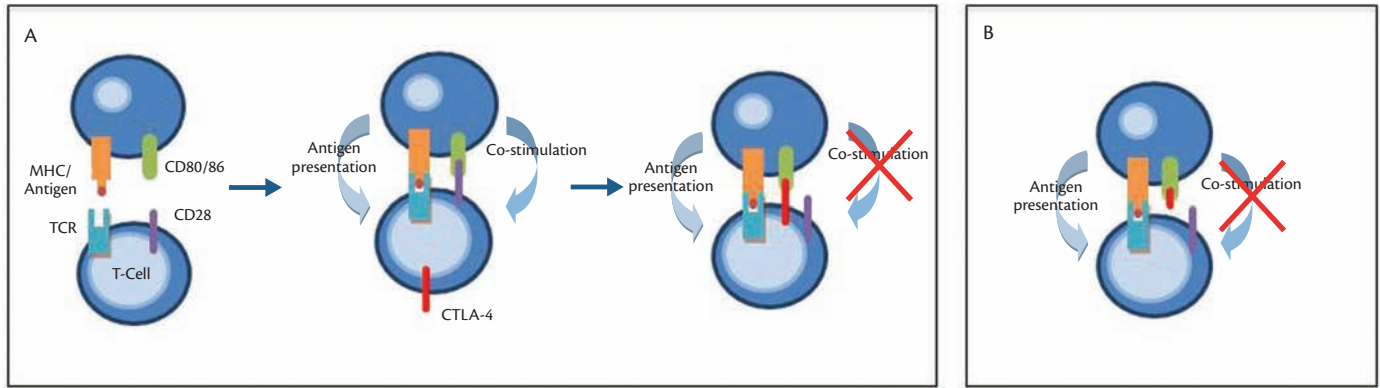
Abatacept has also been investigated in MTX-naive as well as in undifferentiated arthritis patients.[35,36] Although data from both trials were encouraging, neither group of patients is included in abatacept's licence.


Fig. 83.2 T-lymphocyte activation and the effect of abatacept. (A) Activation of T lymphocytes (T cells) involves interaction of an MHC–antigen complex on an antigen-presenting cell (APC) with the T-cell receptor (TCR)—signal 1. This then allows interaction of CD80 or CD86 on the APC with CD28 on the T cell, providing costimulation—signal 2—and resulting in activation of the T cell. Subsequently there is upregulation of CTLA-4 on the T cell which competes with CD28 for CD80/86, antagonizing the costimulatory signal and simultaneously providing an inhibitory signal to the T cell. (B) Abatacept is a soluble form of CTLA-4 and therefore reduces T-cell costimulation by competing with CD80/86.

Mode of action

Abatacept deprives T cells of their key costimulatory signal. Immune dogma suggests that the dominant downstream effect is to inhibit activation of naive T cells. However, heterogeneity is increasingly recognized amongst memory T cells, with at least some requiring costimulation for their continued activity.[37] Furthermore, under some circumstances lack of costimulation can result in an anergic T cell, which cannot subsequently respond to antigen.[38] In this regard, the dynamics of the clinical response to abatacept are intriguing. Compared to cytokine blockade the onset of response to abatacept may be slower, although in both AIM and ATTAIN ACR 20 improvements were statistically superior to placebo by day 15. However, patient retention appears high with abatacept, with some evidence that the quality of response improves with time. Caution is required when interpreting 'as observed' data because only responders continue on therapy. However in a modified intention-to-treat analysis of ATTAIN, for example, DAS (CRP) low disease activity and remission were achieved by 18.3 (95% CI 13.0–23.5%) and 11.1 (6.8–15.3%) of patients at 6 months, increasing to 32 (24.6–39.4%) and 20.3 (13.9–26.6%) at 2 years.[39] Radiographic studies are also consistent with further slowing of joint damage with prolonged therapy. A possible interpretation of these data is that costimulation blockade leads to a gradual 'switching off' of T-cell responses, although direct evidence is lacking.

A small (n = 15) synovial biopsy study revealed minimal depletion of B cells (which express CD80 and CD86), and a reduction in levels of interferon (IFN)-γ, interleukin (IL)-1β, IL-6, matrix metalloprotein (MMP)-1 and MMP-3 in responders, suggesting a 'downstream' effect of costimulation blockade on other cell populations.[40] A preclinical study demonstrated an inhibition of T-cell activation with abatacept and secondary effects on B-cell function and antibody production, consistent with reductions in autoantibody titres documented in clinical trials.[41]

Safety

Infusion reactions were more common with abatacept than with placebo in AIM (9% vs 4%) and ATTAIN (5% vs 3%). Infections and serious infections were either numerically higher with abatacept (AIM) or similar to placebo (ATTAIN). Opportunistic infections were rarely reported and most serious infections were bacterial. A recent integrated safety review, incorporating more than 1000 patient-years of observation, reported slightly more serious infections with abatacept compared to placebo over 12 months of observation (3.47 vs 2.41 events/100 patient-years respectively) but no further increase in risk with long-term therapy.[42] Furthermore, a recent Cochrane review of biological therapies (not limited to RA) suggested that, using indirect comparisons, short-term abatacept use was associated with fewer serious adverse events and serious infections than other biological drugs.[43] During the first 12 months of the ATTEST study, serious adverse events (SAEs; 9.6 vs 18.2%) and serious infections (1.9 vs 8.5%) were fewer with abatacept than with infliximab, and all five reported opportunistic infections (herpes encephalitis, pseudomonas pneumonia, peritoneal TB, pneumocysitis pneumonia, and pulmonary TB) occurred with infliximab.[34] There was no signal relating to malignancy or autoimmune adverse events in the integrated safety review. Nonetheless when abatacept was combined with other biological drugs, an increase in both serious adverse events and serious infections was documented, without additional clinical benefit.[44,45]

Pregnancy and breastfeeding

Very limited information is available around the safety of abatacept during pregnancy or breastfeeding. Consequently, abatacept should not be administered during pregnancy and contraception is recommended for 14 weeks after the last dose.

Place in therapeutic algorithm

In the United Kingdom abatacept is licensed for use in combination with MTX, in patients who have failed treatment with one or more DMARDs. Unlike rituximab, its licence permits use before a TNF inhibitor. However, NICE guidelines restrict its use to third-line biological therapy when a patient develops side effects with rituximab, or second-line when rituximab is contraindicated. Abatacept is also licensed for the treatment of moderate to severe juvenile idiopathic

Table 83.2 Abatacept clinical trials

arthritis (JIA) in patients who have failed at least one TNF inhibitor (patients aged ≥6; see Chapter 84). Abatacept is administered as infusions of approximately 10 mg/kg, fortnightly for the first three doses and then monthly. A subcutaneous formulation is currently in late-phase clinical development and is non-inferior to intravenous abatacept.[46]

Conclusion

Improved understanding of RA pathogenesis has allowed anti-cytokine biologics to be complemented by direct targeting of lymphocytes. Both rituximab and abatacept, targeting B and T cells respectively, are currently licensed for the treatment of RA. Their safety is broadly comparable to the anti-TNF biologics, and to one another, although the risk of TB reactivation is much less. Rituximab has very rarely been associated with the development of Progressive Multifocal Leucoencephalopathy, but may be safer than TNF blockade in patients with a history of malignancy. Between them, rituximab and abatacept provide additional options for patients in whom TNF blockade has failed or is contraindicated. Abatacept's licence permits its use as a first-line biologic but several guidelines, e.g. NICE, reserve its use for more refractory disease.

Biologics in paediatric rheumatic diseases

Daniel J. Lovell, Nicolino Ruperto, Hermine I. Brunner, and Alberto Martini

Introduction

In the last 15 years the treatment approaches for children with rheumatic diseases have been dramatically changed as a result of the introduction of an ever-enlarging number of biological therapies. These biological therapies target a vast number of proteins and receptors central to the pathogenesis of the disease. In paediatric rheumatology, these biological therapies have been focused primarily on juvenile idiopathic arthritis (JIA) and to a lesser extent, on children with systemic lupus erythematosus (SLE). The treatment for JIA, including the expectations for treatment efficacy, has been revolutionized by the introduction of biologics. In this chapter the results of key efficacy and safety studies in JIA and SLE are described.

Biologics in juvenile idiopathic arthritis

Systemic juvenile idiopathic arthritis

Systemic JIA is characterized by prominent systemic features, such as fever, rash, and serositis. Anti-tumour necrosis factor (TNF) agents have been shown to be less effective in systemic JIA.[1] Findings from previous studies have suggested a major pathogenic role for interleukin (IL)-6[2–4] and for IL-1.[5] Indeed, a controlled withdrawal trial and several uncontrolled studies have shown the efficacy of tocilizumab[5] and anakinra.[6,7] In a double-blind controlled trial of tocilizumab against placebo in systemic JIA with or without systemic features, at the end of the 12 week double-blind phase 85% of those on tocilizumab and 24% of those on placebo (p <0.001) demonstrated an ACR Paediatric 30 level of response plus absence of fever. At week 52, 80% of those on tocilizumab were demonstrating an ACR Paediatric 70 level of response with no fever and 59% an ACR Paediatric 90 level of response without fever.[8] Two double-blind placebo-controlled trials of canakinumab (a new monoclonal antibody against IL-1) in children with systemic JIA with active systemic features have also been completed. In the first trial patients were randomly assigned to a single injection of canakinumab or placebo and assessed at day 15. Eighty-four per cent of those receiving canakinumab compared to only 10% of

those receiving placebo demonstrated an ACR Paediatric 30 level of response and no fever (p <0.001). In the second trial, which used a randomized withdrawal design, at the end of the open-label phase of the study (median 113 days), 73% of the patients demonstrated at least an ACR Paediatric 50 level of response and no fever and 31% had inactive disease. In the randomized withdrawal phase the median time to flare was 236 days in the placebo group; the median was not observable in the canakinumab group, since less than 50% of the patients had a flare (p = 0.003 by the log-rank test).[9,10]It has been hypothesized that the early introduction of treatment with anakinra could be associated with a substantial prevention of refractory arthritis.[11] This hypothesis needs to be substantiated by prospective randomized trials. Another anti-IL-1 agent is rilonacept, for which very little information has been reported.[12]

According to the pattern of response to anti-IL-1 therapy, two subpopulations can be identified[13]: one with a pronounced, complete response to IL-1 blockade and another that is resistant to treatment or has an intermediate response. These two subpopulations do not differ in IL-1 in-vitro production or in serum cytokine concentrations, but only in the number of joints affected and in neutrophil counts. Patients with fewer joints affected or with a higher neutrophil count have an increased probability of responding to anti-IL-1 treatment. Thus, systemic JIA can be stratified into at least two subgroups on the basis of the response to IL-1 blocking agents and therefore on the possible pathogenic relevance of this cytokine.[14]

Polyarticular juvenile idiopathic arthritis

Currently JIA is classified, according to the International League Against Rheumatism (ILAR)[15,16] classification, criteria, into seven distinct clinical phenotypes, some of which appear to be rather definite disease entities, while others still appear to include heterogeneous conditions.[14,17] Since there are several JIA categories to be studied, most of the clinical trials described in the following paragraphs employed the concept of polyarticular-course JIA. This functional category groups patients with extended oligoarthritis, polyarthritis rheumatoid factor (RF) positive or negative,

and systemic arthritis without active systemic features. Other than the studies in polyarticular forms of JIA, specific studies have been implemented so far only for systemic JIA while evidence for other JIA categories is scarce.[18] In the following sections the current evidence about the most widely used drugs, for children with polyarticular-course JIA, is summarized. In most of the trials a randomized withdrawal design has been used,[19] in which eligible children are treated in an open-label fashion with the experimental therapy for a few months, after which responders are randomized in a double-blind fashion either to continue the experimental therapy or to switch to placebo to look for disease flare.

Anti-tumour necrosis factor agents

TNF is a proinflammatory cytokine that plays a central role in the pathogenesis of JIA.[14] Three anti-TNF agents have so far been tested in randomized clinical trials (RCTs) in polyarticular-course JIA and have shown comparable efficacy and safety.

Etanercept

A controlled trial with a withdrawal design has shown the efficacy of etanercept, at a dose of 0.4 mg/kg subcutaneously twice a week (it can also be administered at 0.8 mg/kg once per week), in patients with JIA who were resistant or intolerant to methotrexate.[20] A total of 76 patients enrolled in the original trial have received the drug for at least 8 years with 28 of them reaching at least an American College of Rheumatology (ACR) 70 level of improvement,[21] at the last available observation. In the registry run by the Pediatric Rheumatology Collaborative Study Group (PRCSG) in North America of the 397 patients treated with etanercept alone or in combination with methotrexate for 3 years, a total of 218 (55%) discontinued, with the most frequent reasons being insufficient therapeutic effect, remission, or other[22]; patients treated with etanercept were generally with longer disease duration (40.7–58.1 months) when compared to the group newly treated with methotrexate (20.2 months). Etanercept was the first biological agent registered for use in JIA. Other studies have confirmed the remarkable and rapid efficacy of etanercept in JIA,[23–25] including restoration of normal growth in children with JIA,[22] and improved quality of life.[25]

Infliximab

A controlled trial with methotrexate (MTX) plus either infliximab or placebo failed to demonstrate a statistically significant difference in its primary outcome at 3 months.[26] However, by week 52, response to infliximab was similar to that observed with etanercept. Of note, although the two dosages used (3 and 6 mg/kg per infusion) were of comparable efficacy, patients receiving 3 mg/kg had a more frequent occurrences of serious adverse events, infusion reactions, antibodies to infliximab, and newly induced antinuclear and anti-double-stranded DNA antibodies. Therefore, 6 mg/kg is the dose recommended in paediatric rheumatology practice. Infliximab is not registered for use in JIA.

Adalimumab

A controlled trial with a withdrawal design has also shown the efficacy of adalimumab[27] for patients who were either methotrexate naive or methotrexate resistant or intolerant. Seventy-four per cent of patients not receiving methotrexate and 94% of those receiving methotrexate responded by week 16 with sustained response after 104 weeks of treatment. Overall, safety and efficacy were comparable to those observed with the other anti-TNF agents. Adalimumab is registered for JIA both in the United States (at a fixed dose of 20 mg every 2 weeks for children <30 kg and 40 mg/every 2 weeks for children ≥30 kg) and in Europe (24 mg/m^2/every 2 weeks, maximum dose 40 mg).

Other anti-TNF agents

Other agents such as golimumab are undergoing phase 3 trials while for others, such as certolizumab, there is no public information available concerning future JIA trials.

Combined therapy

Although no specific studies exist in children, the results of the adalimumab trial as well as a retrospective analysis of the German registry[28] suggest that, in children, anti-TNF agents are more effective if combined with methotrexate. Similarly, no studies have been performed to assess the disease-modifying potential of biological agents on disease progression in JIA although a retrospective analysis has suggested that etanercept may reduce radiographic progression.[29] More recently, some evidence suggested early aggressive therapy with methotrexate and infliximab seems to be more effective than therapy with methotrexate alone or in combination with another disease-modifying anti-rheumatic drug (DMARD).[30]

Abatacept

Abatacept is a soluble, fully human fusion protein that consists of the extracellular domain of CTLA-4, linked to a modified Fc portion of human immunoglobin G1, which does not activate complement. Abatacept competitively binds to CD80 or CD86, where it selectively inhibits T-cell activation, and potentially affects many downstream cytokines and cell types involved in the immunopathogenesis of autoimmune disease. Its efficacy has been shown in a double-blind randomized controlled withdrawal trial in 190 patients with polyarticular-course JIA and inadequate response or intolerance to at least one DMARD, including anti-TNF drugs.[31] After 4 months of treatment an ACR Pediatric 50 was reached by 50% of the patients (and 25% of the patients who previously failed an anti-TNF). Durable efficacy was confirmed also in the long-term open-label extension phase also in patients who did not initially respond.[32] Treatment was also accompanied by a significant improvement in health-related quality of life.[33] Abatacept is registered for use in JIA in both the United States and Europe at a dose of 10 mg/kg of abatacept intravenously every 28 days in JIA patients at least 6 years old.

Tocilizumab

Tocilizumab was evaluated in polyarticular JIA patients using a double-blind, randomized, controlled withdrawal study design. After 16 weeks of open-label treatment with tocilizumab, ACR Pediatric 30, 50, 70, and 90 levels of response were seen in 89%, 83%, 62%, and 26%, respectively. In the withdrawal phase, 48% of those randomized to placebo flared compared to 26% of those continuing tocilizumab (p = 0.0035).[48]

Other JIA subtypes

The evidence for the treatment of other JIA subtypes such as enthesitis related arthritis (ERA) or psoriatic arthritis is scanty and comes mainly from retrospective case series. The largest body of evidence is from the Dutch registry,[18] where 22 JIA patients with ERA were treated with etanercept or adalimumab suggesting that treatment with anti-TNF seem effective also in this ILAR category. No information is available for the treatment with biologics of psoriatic arthritis patients.

Biologics in systemic lupus erythematosus

The pathogenesis of SLE involves a complex interplay between genetic and environmental factors and the adaptive and innate immune systems.[34] B-cell abnormalities leading to autoantibody production play a central role in SLE pathogenesis. Biological agents targeting specific pathways (i.e. T–B lymphocyte interaction, cytokines, and complement) have been proposed as new treatment tools for SLE.[35] B-cell targeted therapies, including anti-B lymphocyte stimulator (BLyS) and anti-CD20 monoclonal antibodies (mABs), are at the forefront of new SLE treatments.[36] Belimumab, a human mAb that binds to BLyS and thereby prevents it from activating various receptors and slows B-cell proliferation, was recently the first biological medication approved for the treatment of SLE in adults. Conversely, data on the safety and effectiveness of belimumab when used in children and adolescents with SLE are not available at present, but a paediatric trial is active at the time of writing.

Whereas belimumab only blocks soluble BLyS, the mAb LY2127399 also blocks membrane-bound BLyS and is in phase 3 trials in adults with SLE that are due to report results in 2013. The fusion protein atacicept combines immunoglobulin with a segment of the TNF receptor superfamily member TACI is also in phase 2/3 study. Because TACI binds both BLyS and the related TNF superfamily cytokine APRIL (a proliferation inducing ligand), it promises an advantage over belimumab.[37]

By lowering the number of circulating B cells and thereby decreasing autoantibody levels, anti-CD20 mABs like rituximab have been tested in SLE. Yet despite several clinical trials of the drug in SLE and regular off-label use, conclusive evidence of its efficacy has remained elusive. Compared to anti-CD20 blockage by 30%, the anti-CD22 mAB epratuzumab leads to a decrease in the number of B cells by 90% in early studies. There are at least 20 other biologic agents in clinical trials of SLE. Among others, there are phase 2/3 studies in adults with SLE that are testing biologic agents that block APRIL together with BLyS, T lymphocytes, T-lymphocyte activation antigens, interferon-α, or the interferon receptors. In phase 1 study are biologics blocking phosphdiesterase 4 and TNFα, IL-6, ICOSLG (inducible T-cell costimulator ligand), and JNK (Jun N-terminal kinase).

Targeted biological therapies show great promise in SLE treatment but additional studies are needed to define their role in SLE treatment.[34] Studies on the pathogenesis of SLE will open a new era of tailored patient-specific therapy.

Safety of biologics

With over a decade of international widespread use, the safety profile of the anti-TNF biologics is rather well characterized in children with JIA. To date, the safety signal with anti-TNF biological therapy in children with JIA is for the most part similar to that seen with use in adults with rheumatoid arthritis (RA). Safety data with the newer biological therapies in JIA are less extensive and limited primarily to the RCTs and open-label extension studies of the JIA patients in the trials. Safety data with biological agents in other rheumatic diseases are even more limited. Unique childhood safety issues are described below. An excellent review of safety of biological therapies in JIA patients was published in 2010.[38]

Anti-TNF agents

The safety of etanercept has been described in a randomized placebo-controlled trial,[20] up to 8 years of open-label follow-up of children in the randomized trial,[39] a drug-specific registry,[40] and as part of several national biologics registries.[23,24,28] In the controlled trial there were three cases of primary varicella infection that followed a complicated course. Those three cases had been treated as one would varicella infection in healthy children—observation only. Subsequently, there was an adoption in the remainder of that trial and other studies of anti-TNF therapies in JIA patients of the recommendation to evaluate and treat varicella infections in JIA patients on anti-TNF therapies as one would for infection in other moderately immunocompromised children and subsequently very few complicated varicella infections have been seen in JIA patients on anti-TNF agents.[23,24,28] In the drug-specific etanercept registry, the rates of adverse events (AEs), serious AEs (SAEs), medically important infections, and autoimmune events were similar in those treated with methotrexate alone, etanercept alone, and the combination of etanercept and methotrexate. No cases of demyelinating disease, tuberculosis, malignancy, or death were reported in the 594 patients in this registry, of whom 397 received etanercept therapy either alone or in combination with methotrexate.[40] However, the experience has not been so positive in other studies. There are several ongoing national registries of all JIA patients treated with etanercept in Germany, the Netherlands, and England. In the German registry, in 322 JIA patients treated with etanercept (592 patient-years of exposure), there were 12 SAEs; treatment was permanently stopped due to AE in 11 patients including 1 cancer (thyroid carcinoma) and 1 cerebral demyelination. There were no opportunistic infections or lupus-like syndromes.[23] In a recent publication from this same registry, there were 5 cases of malignancy out of 1260 JIA patients treated with etanercept.[41] In the Dutch registry, in 146 JIA patients (313 patient-years of exposure) there were nine SAEs; treatment was permanently stopped due to AE in six. Three new autoimmune diseases were noted: one case each of sarcoidosis, ulcerative colitis, and Crohn's disease and one case of tuberculosis (TB), but no cases of demyelinating disease, opportunistic infection, or cancer, and no patients died while on etanercept therapy.[24] In the British registry, in 483 JIA patients treated with etanercept (941 patient-years of exposure), 21 patients discontinued the etanercept due to toxicity: 5 discontinued due to infections, 10 due to non-infectious central nervous system (CNS) events (headaches 2, depression 1, anxiety attacks 1, hallucinations 1, optic neuritis 1, blurred vision 1 and uveitis flare 1) and 6 due to other events. One patient developed inflammatory bowel disease (IBD), there were no opportunistic infections, and no patient died while on etanercept therapy.[42]

The safety profile of adalimumab has been less well established. In a phase 3 trial of adalimumab in JIA patients, in 171 JIA patients treated with adalimumab for up to 104 weeks, 14 patients demonstrated a serious adverse event including 7 serious infections; 12 patients discontinued adalimumab due to toxicity. No malignancies, opportunistic infections, TB, demyelinating diseases, new autoimmune diseases and deaths were seen in this population.[27]

The safety profile of infliximab was studied in a phase III RCT in 122 children with JIA with up to 52 weeks of infliximab exposure. In this study, 60 patients were treated with infliximab 3 mg/kg per infusion, 60 patients received placebo infusions for 14 weeks

and then 57 of these patients received infliximab 6 mg/kg per infusion for up to 38 weeks. Overall, there were 26 SAEs on infliximab including 6 serious infections including 1 case of pulmonary TB and 3 mild opportunistic infections (thrush 2, herpes zoster 1). Antibodies to infliximab were seen in 38% of those on 3 mg/kg and 12% of those on 6 mg/kg. Infusions reactions were seen 3–4 times more commonly in those with anti-infliximab antibodies. There were 31 of 117 patients on infliximab who developed an infusion reaction but in only 6 patients was it serious.[26]

The role of anti-TNF therapies in the development of cancer in JIA patients is not clearly understood at this time. In 2009, the United States Food and Drug Administration (FDA) reported on 48 malignancies in children and adolescents who had been treated with an anti-TNF agent. Arthritis was the reason for the anti-TNF treatment in 19 of the 48 cases (JIA 15, juvenile ankylosing spondylitis 3, juvenile psoriatic arthritis 1). There was a large variety of types of cancer. The FDA concluded there may be an increased risk of lymphoma and other cancers associated with the use of anti-TNF agents in children and required that black-box warning language be added to the labelling information for all anti-TNF biologics.[41] However, there are several problems with the FDA database. They have only numerator data in the reporting system and estimated the number of children on anti-TNF agents from external databases of prescribing information; the database combines several paediatric diseases in addition to JIA that are known to have differing rates and types of malignancies (e.g. IBD); and the comparisons are with healthy populations of children, not to children with the disease not treated with biologics. In the German JIA registry, 5 malignancies were reported out of 1260 patients on biological therapy. All had received other immunosuppressants prior to the biologic and several had received more than one biological therapy prior to developing the malignancy. They concluded from this data that the 'benefit/risk ratio has not changed even in light of the rare occurrences of malignancies' and supported the continued careful use of the biologics in those in whom there was an appropriate indication, use of other more traditional therapies first, and ongoing careful monitoring for any suggestion of a malignancy.[41] In a biologic-naive population of patients with JIA and matched healthy controls from the Swedish Patient Registry, those JIA patients with disease onset before 1987 were not at increased risk of cancer, whereas JIA identified in 1987–1999 was significantly associated with incident lymphoproliferative malignancies (relative risk 4.2, 95% confidence interval 1.7–10.7) and cancers overall (relative risk 2.3, 95% confidence interval 1.2–4.4) Sensitivity analysis failed to identify an associated factor with the increased rate.[43] This study suggests that there may be an increased rate of cancer in JIA patients independent of biological therapy and that any future studies of cancer risk with biological therapies needs to include biologic-naive JIA patients as the comparison group rather than healthy children.

Other biologics

The clinical experience with biologics other than the anti-TNF agents is significantly smaller. Abatacept is a T-cell costimulation inhibitor that has been approved for the treatment of JIA. In a phase III trial with 190 JIA patients, in the open-label lead-in phase in which all subjects received abatacept, there were six SAEs (three JIA flares, one each varicella, ovarian cyst, and acute lymphoblastic leukaemia). In the double-blind phase of the study, the rate of AEs did not differ between the abatacept and placebo groups.[31] In a long-term open-label follow-up study of the participants in the trial (n = 153), there were six serious infections, no cases of TB, no opportunistic infections, and one case of multiple sclerosis.[32] An international registry to assess the safety of abatacept for up to 10 years of therapy began enrolment in 2013.

Anakinra is an IL-1 blocking biologic that has been studied in children. In 86 patients with polyarticular JIA, in an open-label lead-in, double-blind randomized withdrawal design treatment with anakinra 1 mg/kg per day for up to 19 months, there was only one serious adverse event thought to be due to anakinra (nephrosis). There were no cases of malignancy, TB, opportunistic infections, or deaths.[44] In a trial of anakinra in 44 patients with systemic JIA, one patient developed Crohn's disease and another hepatitis.[7]

In the phase 3 study of tocilizumab in 112 SJIA patients, there were 39 SAEs including 19 infections (4 varicella, 2 herpes zoster) and 3 MAS events. Opportunistic infection, TB, and cancer were not reported. Three deaths occurred during tocilizumab therapy (1 pneumothorax, 1 auto accident, and 1 streptococcal sepsis). Death also occurred in three patients who received tocilizumab and who had withdrawn from the study (pulmonary hypertension in 2, MAS in 1). Neutropenia developed in 17% and elevation of aminotransferase levels more than 2.5 times the upper limit of normal in 19% of the SJIA patients in the trial.[8]

In the trials of canakinumab in SJIA, there were 23 SAEs in those on canakinumab (13 infections and 3 episodes of MAS). No opportunistic infections, TB, or cancer were observed. Thrombocytopenia was seen in 6% and neutropenia in 6% of those on canakinumab. Two patients died in the trial (urosepsis and MAS in 1, pulmonary hypertension and MAS in 1).[10] In the trial of canakinumab in polyarticular forms of JIA, there were 12.5 SAEs per 100 patient-years of exposure and no deaths, opportunistic infections or malignancies were seen.[48]

Role of biologics in recent treatment recommendations for juvenile idiopathic arthritis

The ACR developed recommendations for the safest and most effective treatment of JIA, based on the available scientific evidence and consensus among stakeholders. Inherent to the guidelines is the necessity that the recommendations require frequent updates to adequately reflect the results from new studies and changes in treatment preferences of healthcare providers.[45] The recommendations are meant to function as a reference and do not serve as a substitute for individualized patient assessment and clinical decision-making, especially when conducted by specialist clinicians familiar with the treatment of JIA. Rather than the ILAR JIA classification, the ACR recommendations employ five so-called 'treatment groups'. They are (a) history of arthritis of four or fewer joints; (b) history of arthritis of five or more joints; (c) active sacroiliac arthritis; (d) systemic arthritis with active systemic features; and (e) systemic arthritis with active arthritis without active systemic features. Treatment recommendations also consider the presence of risk factors for poor outcome as well as the degree of JIA disease activity within each treatment group. It should be noted that the three disease activity levels (mild, moderate, severe) are subjective and not strictly evidence based. Patients with inactive disease were not considered. In a broad sense, the low disease activity level is meant to represent patients at the lowest disease activity level for

Table 84.1 American College of Rheumatology 2010 recommendations for juvenile idiopathic arthritis

Disease activity treatment group	Disease activity	Mainstay of treatment	Poor prognostic features	Treatment progression	Adjunct treatments
4 or fewer joints involved	Mild Moderate Severe	NSAIDs JI MTX, sulfasalazine, leflunomide TNF antagonists	Arthritis of hip or cervical spine Arthritis of ankle or wrist **plus** marked or prolonged inflammatory marker elevation Radiographic damage	Trial of NSAID monotherapy for up to 2 months[a] to achieve disease control For continuous moderate or high severe disease activity, treatment escalation or change after 3 months **with** and after 6 months **without** poor prognostic factors	NSAIDS prn JI prn
5 or more joints involved	Mild Moderate Severe	NSAIDS JI MTX, sulfasalazine, leflunomide TNF antagonists or abatacept	Arthritis of hip or cervical spine Positive RF or ACPA Radiographic damage		
Active sacroiliac arthritis	Mild Moderate Severe	NSAIDS JI MTX, sulfasalazine TNF antagonists	Radiographic damage of any joint		
Systemic arthritis with active systemic features (and without active arthritis);	Mild Moderate Severe	NSAIDs Glucocorticosteroids IL-1 inhibition	6-month duration of significant active systemic disease; requirement for treatment with systemic glucocorticoids	NSAID monotherapy no longer than 1 month for fever or arthritis Assessment of MTX failure after 3 months of therapy for continuous moderate or high severe disease activity	NSAIDs and glucocorticoids prn with IL-1 inhibition
Systemic arthritis with active arthritis (and without active systemic features)	Mild Moderate Severe	NSAIDs MTX TNF antagonists, IL-1 inhibition Abatacept	Arthritis of hip Radiographic damage		NSAIDS prn Joint injections prn

[a]2 weeks for active systemic features.

ACPA, anti-citrullinated peptide antibodies; IL, interleukin; JI, joint injections; MTX, methotrexate; NSAID, non-steroidal anti-inflammatory drug; prn, as the need arises; RF, rheumatoid factor; TNF, tumour necrosis factor.

which a majority of clinicians may consider altering the current medication regimen, and the high disease activity level is meant to represent patients with disease activity that is equivalent to or higher than the 'average' patient who may have been enrolled in a clinical trial of the medications under consideration. The ACR treatment guidelines for JIA are shown in Table 84.1.

Conclusion

In the last decade there have been dramatic advances in the treatment of JIA thanks to the availability of biological agents, the implementation of an adequate paediatric legislation [46,47] to require the performance of clinical testing of new agents in children and the existence of two large, not-for-profit paediatric rheumatology research networks, the Paediatric Rheumatology International Trials Organization (PRINTO) and the Pediatric Rheumatology Collaborative Study Group (PRCSG), covering most of the paediatric rheumatology centres worldwide. Despite progress, there are still problems to be solved including a better understanding of the long-term safety of the drugs as well as to provide more efficacious treatments for those patients that fail to adequately respond to current therapies.

CHAPTER 85

Stem cell therapies

Alan Tyndall and Jacob M. van Laar

Introduction

Stem cells are cells capable both of self-replenishment and of providing progenitor cells for various tissues. There are different types, including **totipotent** (able to develop into a complete individual), **pluripotent** (able to develop into any tissue type), and **multipotent** (able to develop into various subgroups of a tissue type (Figure 85.1). Despite the enormous promise of using pluripotent embryonal stem cells (ESC) in regenerative medicine, problems regarding teratoma development and ethical aspects of ESC acquisition hamper progress. Recently it has been shown that insertion of certain developmental genes into adult differentiated somatic cells may 'reprogram' them back to an ESC-like phenotype; these are called induced pluripotent stem cells (iPSC) (Figure 85.1). Although this avoids the ethical issues of stem cell source, the teratoma development risk is still present. On the other hand, adult or 'postnatal' multipotent stem cells have none of these issues and are in clinical practice. Haematopoietic stem cells (HSC) have been used for decades to fully replenish a host's haematopoietic system after chemical and/or radiation ablation for malignant disorders. This was recently adopted to treat severe autoimmune disease.[1]

Definitions

- **Autologous haematopoietic stem cell transplantation (HSCT)** refers to the use of the patient's own HSC to rebuild an ablated haematopoietic system.

- **Allogeneic HSCT** is the use of another healthy donor's HSC. These need to be mobilized from the bone marrow, or directly harvested via bone marrow aspiration (which mostly needs a general anaesthetic).

- **Mobilization** is the process of driving the HSC from the bone marrow into the peripheral blood using growth factors such as granulocyte colony-stimulating factor (G-CSF) and/or cyclophosphamide (CYC). The HSC are then harvested via leukapheresis.

- **Graft manipulation or purging** is the process of purifying for wanted cells in the graft, e.g. CD34+ HSC using a column, or negatively selecting unwanted cells such as lymphocytes with antibodies.

- **Conditioning** is the protocol used to ablate the unwanted cells in the patient, e.g. leukaemia or solid tumour with chemicals and/radiation. Often antibodies to lymphocytes are also used to deplete the immune system. The haemato/immune system is mostly also ablated, hence the requirement for the HSCT to restore vital functions.

- **Myeloablative conditioning** occurs when the HSC are killed by the conditioning regimen, usually involving busulphan and/or radiation, and the ensuing severe cytopenia requires an HSCT—otherwise the patient would die from marrow failure.

- **Non-myeloablative** refers to a regimen which does not result in significant cytopenia, but due to immunosuppression, allows the donor graft to avoid being rejected by the host.

- **Reduced-intensity conditioning** occurs when the stem cells are not killed but require time to reconstitute the haematopoietic system. The HSCT is used to reduce the critical cytopenic period and hence toxicity.

- **Reconstitution** is the process of recovery following HSCT; haematopoietic reconstitution usually takes 11–14 days but immune reconstitution may take months (e.g. B cells) or several years (e.g. CD4 naive T cells) in adults due to thymic involution.

Haematopoietic stem cell transplantation in autoimmune disease

Over 1500 patients have received a HSCT, mostly autologous, as treatment for a severe autoimmune disease (AD) since the start of the international project in 1997.[1] A recent retrospective analysis of 900 patients from the European League Against Rheumatism (EULAR) combined database showed that the majority had multiple sclerosis (MS; n = 345) followed by systemic sclerosis (SSc; n = 175), systemic lupus erythematosus (SLE; n = 85, rheumatoid arthritis (RA; n = 89), juvenile idiopathic arthritis (JIA; n = 65), and idiopathic thrombocytopenic purpura (ITP; n = 37). An overall 85% 5-year survival and 43% progression-free survival was seen, with 100-day transplant-related mortality (TRM) ranging between 1% (RA) and 11% (SLE and JIA).[2] Around 30% of patients in all disease subgroups had a complete response, often durable despite full immune reconstitution. In many, e.g. SSc, morphological improvement such as reduction of skin collagen and normalization
Fig. 85.1 Stem cell development.

of microvasculature was documented, beyond any predicted known effects of intense immunosuppression alone. It is hoped that the results of the three running large prospective randomized controlled trials (RCTs) will allow modification of the protocols to reduce the high TRM which relates to regimen intensity, age of patient, and comorbidity.

The concept of immune ablation, or at least severe reduction, and 'resetting' of autoimmunity arose from coincidental case reports (HSCT given for malignancy with coexisting AD improvement)[2] and was corroborated by animal model data.[3] The first patient published receiving an HSCT for an AD had SSc with pulmonary artery hypertension,[4] responded satisfactorily, and is still stable 15 years later.

From the outset, an international collaboration ensued which is committed to establishing the place, if any, of HSCT in the treatment of severe therapy-resistant AD in the context of prospective randomized clinical trials, coupled with mechanistic side studies[1]. Although many protocols were employed, they basically ranged from less aggressive, e.g. CYC 200 mg/kg plus anti-thymocyte globulin (ATG) to more intensive, e.g. total body irradiation (TBI) plus CYC/ATG and CD34 selection.

Up to one-third of patients in all groups experienced a significant clinical improvement, including full and drug-free sustained remissions.[5] In some of those studied (SLE, MS, and SSc patients), remission was sustained despite full immune reconstitution. In SLE, the authors demonstrated that humoral responses to recall antigens (tetanus, polio, measles, and mumps) were ablated following autologous HSCT, as would be expected, but in addition, eradication of autoantibodies such as anti-double stranded DNA was also achieved coincident with clinical remission in five cases.[6] Following immune reconstitution, a comparison between the patients' and normal subjects' T-cell receptor Vβ repertoires showed a fully normal pattern. Importantly, no patient had relapsed in the 8 year follow-up reported. Similar findings were described in seven MS patients who remained in remission up to 3 years post-transplant despite

regaining a normal T-cell repertoire.[7] These findings are particularly important, since at the onset of the project many considered autologous HSCT to be doomed to failure, given that the identical 'autoaggressive' immune system was being given back to the patient. However, the initial choice of autologous over allogeneic HSCT was mainly based on the lower toxicity of autologous HSCT, mainly due to absence of graft-vs-host disease (GvHD). It is now appreciated that in many patients who achieved clinical remission, the autoaggressive immune system was 'debulked' rather than fully ablated, allowing re-establishment of normal immune regulation, in part due to increased Treg numbers and activity.[8]

Several groups have described reduced collagen deposition in skin[9] (Figure 85.2) and normalization of microvasculature in SSc patients[10,11] (Figure 85.3) following autologous HSCT. None of these observations are readily explained by either sustained immunosuppression or direct effects on fibroblasts and endothelial cells, and suggest a more profound modulation of the inflammatory niche by mechanisms yet to be fully elucidated. Currently three large prospective randomized trials are running: ASTIS (Autologous Stem cell Transplantation International Scleroderma), SCOT (Scleroderma Cyclophosphamide Or Transplant), and ASTIC (Autologous Stem cell Transplantation International Crohn's). See Table 85.1; further details are available on the respective websites. ASTIS and SCOT are similar in patient selection, control arms, and endpoints, but the transplant protocols differ. SCOT employs a more intense regimen including TBI. Each has experienced its own toxicity issues, all previously known in HSCT medicine. Only time will tell which approach, if any, imparts a clinically useful and durable outcome; ASTIS has finished recruitment (156 patients). The primary endpoint is event-free survival, events being defined as death or end-organ (renal, cardiac or pulmonary) failure. SCOT finished recruitment in May 2011 and ASTIC is nearing its target of 40 patients.[12]

A smaller phase II randomized trial in SSc showed a positive outcome in the 10 transplanted patients compared with 9 control
Fig. 85.2 Resolution of skin fibrosis after autologous haematopoietic stem cell transplant. Resolution of dermal fibrosis after high-dose immunosuppressive therapy (HDIT) and autologous haematopoietic cell transplant (HCT). Full-thickness skin biopsies from patient no. 11, collected at baseline and then at 1 and 5 years after HDIT, were histologically evaluated (H&E). The skin biopsies performed after HDIT were performed at a site adjacent to the baseline skin biopsy. The biopsies in the left column were taken at original magnification ×5, and those in the right column were taken at original magnification ×20. All sections were stained with H&E. (A) Skin biopsy was obtained before HDIT and autologous HCT. Pandermal sclerosis from the dermal–epidermal border to the hypodermis (subcutaneous fat) was observed. The epidermis is mildly acanthotic (thickened) with loss of rete ridges. The reticular dermis is replaced by dense compact collagen without normal fascicular bundles or dermal appendages. This pretransplantation skin biopsy was determined as grade 5 dermal fibrosis. The thickness of the dermis was measured at more than 2 mm. (B) In the higher-power magnification, the straightened dermal–subcutaneous border demonstrates the abnormal, densely packed, homogenized collagen. (C) The skin biopsy at 1 year after HDIT was determined to be a grade 2 dermal fibrosis and has less fibrosis than at baseline. The low-power magnification view shows crowded collagen fascicles with focal areas of residual thickened bundles. (D) A higher-power view of the 1 year skin biopsy from panel C shows thin and collagen bundles admixed with residual thick, straightened, hypereosinophilic collagen bundles without dense homogenization at baseline. The residual eccrine unit lacks any surrounding adipose tissue. (E) The skin biopsy at 5 years shows complete resolution of the dermal fibrosis (grade 0) with a reduction in the thickness of the dermis from baseline to 1 mm. The collagen bands in the dermis are thin with a relative increase in the intervening extracellular matrix (space between the collagen bands). The dermal–epidermal border remains straightened with loss of rete ridges. (F) A higher-power view of collagen in the lower reticular dermis demonstrates the change to thin wavy bundles separated by increased ground substance.

patients who received CYC1 g/m² for 6 months.[13] The conditioning regimen was CYC 200 mg/kg plus five doses of rabbit ATG, each one accompanied by 1 g of intravenous methyl prednisolone. The primary endpoint at 12 months was based on a percentage improvement of the modified Rodnan skin score (mRSS) and/or pulmonary status. Although the low toxicity and positive outcome was gratifying, the low numbers of patients and short follow-up were not conclusive.[13]

Treatment-related mortality

A major issue for physicians dealing with AD was and is that patients rarely die immediately from their disease. However, a growing

literature had suggested that uncontrolled systemic inflammation leads to premature atherosclerosis and cardiovascular deaths,[14] as well as toxicity from chronic immunosuppression, especially glucocorticoids. Despite this, it is still a challenge for a rheumatologist, neurologist, or gastroenterologist to accept an immediate TRM of 5–10%, especially since long-term benefits have yet to be demonstrated. The hypothesis is that in a randomized prospective trial of HSCT vs conventional treatment, early toxicity from TRM would eventually be surpassed by later deaths and/or organ failure from disease progression in the control arm (Figure 85.4). This has yet to be proven.

Apart from the well-known acute toxicity of HSCT (infection and bleeding during the aplastic period and late infection during the
Fig. 85.3 Normalization of microcapillaries after haematopoietic stem cell transplantation (HSCT) in two patients with systemic sclerosis (SSc) (A) and mixed connective tissue disease (MCTD) (B). (A) Patient 1, fourth finger on the right hand. Panel 1: reduced translucency. Massive capillary bleedings (arrow), enlarged capillaries (arrow), and avascular regions (arrow, dotted line) before treatment. Panel 2: remarkable increase in capillary density and reduced bleedings but still some avascular regions after mobilization. Panel 3: normalized capillary number, size, and architecture with no bleedings 5 months after HSCT. (B) Patient 2, fourth finger on the left hand. Panel 1: severe disarrangement, multiple giant capillaries (arrow, double lined) and large avascular fields (arrow, dotted line) before mobilization. Panel 2: increase in capillary numbers and reduced avascular areas. Loss of giant capillaries after mobilization. Panel 3: further increase in capillary density with only hypovascularized regions. Normalization of the capillary architecture but still many capillaries with slightly pathological shapes. White stripes correspond to light reflections from the oily skin surface.

T-cell reconstitution phase), several other factors emerged during the programme. Some SSc patients experienced serious lung toxicity from TBI, while others suffered a scleroderma renal crisis during the conditioning phase, attributed to a combination of rapid fluid and electrolyte shifts and high-dose glucocorticoids given as prophylaxis for ATG-induced cytokine storm. In some children with JIA a fatal macrophage activation syndrome occurred, thought to be infection triggered and due to the profound immunosuppression resulting from TBI and CD34 purging.[15] These toxicity problems were mostly eliminated by lung shielding, concurrent angiotensin converting enzyme (ACE) inhibition, and reduced intensity of the regimen respectively. However, an inevitable TRM will always exist, which must be weighed against the potential long-term benefit, a calculation that requires efficacy data from the randomized trials.

Late complications include not just the well-known fungal and other opportunistic infections during the T-cell reconstitution phase (which may last up to 2 years or more) but also the emergence of second autoimmunity.[16] It is almost always antigen specific— e.g. platelet, erythrocyte, thyroid—and often, but not always, resolves as the Treg network is reconstituted. However some patients have succumbed from this, e.g. acquired haemophilia A antibodies after HSCT for MS.[17]

Non-response and relapse

Two-thirds of transplanted patients either did not respond or responded then relapsed. The factors determining this remain elusive, but some studies in RA suggested that clinical responders (n = 5) had a larger number of cells at baseline expressing CD3,

CD4, CD27, CD45RA, CD45RB, and CD45RO in synovium (p <0.05), higher activity on HIg scans (p = 0.08), and a trend towards higher concentrations of C-reactive protein (CRP) in serum than non-responders (n = 2). Subsequent remissions and relapses in responders paralleled reduction and re-expression, respectively, of T-cell markers. A relatively increased expression of CD45RB and CD45RO on synovial CD3+ T cells was seen after HDC + ASCT. No correlations were found between Disability Activity Scale (DAS) and changes in B cells or macrophage infiltration or synoviocytes.[18]

Summary

Autologous HSCT for severe AD has demonstrated remarkable clinical, laboratory, and morphological improvement in many patients, but at a high price including a TRM up to 10% in some conditions. Retrospective analysis from established databases is inevitably incomplete, especially in those patients 'lost to follow-up' and assumed to be still alive. The advent of biologic agents has reduced the need for more radical therapies such as HSCT in RA and MS, but for SSc and severe forms of Crohn's disease it still remains an option. The results of the prospective RCTs will be critical in deciding the future of this treatment.

Allogeneic HSCT for AD has been performed and a summary of 35 patients so treated showed up to 50% remission induction in some AD subgroups.[19] However, the lack of a clear advantage over autologous HSCT and the risk of GvHD relegates this to a second-line strategy at the moment.

Mesenchymal stem cell transplantation for autoimmune disease

Mesenchymal stem cells (MSC) are stromally derived adult progenitor cells, more accurately called multipotent mesenchymal stromal cells, since their true 'stemness' has not been established. They may be derived from various tissues including bone marrow, placenta and umbilical cord, fat, and teeth. Although a heterogeneous group of progenitor cells, they have been defined by consensus as being plastic adherent, bearing certain stromal surface markers (CD76, CD90, CD105) and lacking hematopoietic cell markers such as CD11a, CD14, CD19, CD34, CD45, and MHC class II. In addition they should have at least adipogenic, osteogenic, and chondrogenic differentiation potential.[20]

Since MSC were first applied in humans for HSC graft enhancement over 15 years ago,[21] there has since developed a major interest in their potential for immune modulating, anti-inflammatory, and tissue protective properties, including AD.[22] Originally considered as 'regenerative' due their ability to transdifferentiate into other tissues, it is now appreciated that the positive effects seen in vitro, in animal models, and in some clinical studies is most likely due to their capacity to initiate various paracrine events, resulting in tissue protection. Some of these effects are via soluble factors such as tissue growth factor (TGF)-β, 2,3-indoleamine dioxygenase, soluble HLA-G, and others via cell–cell contact and reprogramming of target cells.[23] In addition, MSC seem to display certain special properties such as immune privilege (survival in allogeneic environments) and active homing to distressed tissues via surface molecules such as CXCR4. They also preferentially home to tumour stroma,[24] potentially inhibiting tumour immune surveillance.

The role of the MSC in normal tissue homeostasis and repair is not fully clear, but it seems likely that they participate in the inflammatory niche, possibly as part of the resolution phase of injury. Their origin in adult animals is also not defined fully, but potential sources are from pericytes released from blood vessels during injury,[25] epidermal to mesenchymal transition, especially in lung and kidney,[26] and direct release from the bone marrow.

Clinical experience

Following many positive animal models of inflammation, organ transplant, autoimmunity, critical ischaemia, radiation damage, and tissue scarring, MSC entered clinical trials for inflammatory disorders, first in GvHD, then later MS, Crohn's disease (including fistula closure), SLE, and SSc (reviewed by Duijvestein et al.[22]). In addition, many trials relating to ischaemia in myocardium, central nervous system, kidney, and limbs have been performed.

Despite this activity, only 14 phase I/II clinical trials in AD have been published, all of less than 20 patients. Two large randomized prospective trials in Crohn's disease and GvHD were reported as failing to reach their primary endpoints, but as yet have not been published in the peer-reviewed literature.

There is a lack of standardization of cell product regarding heterogeneity, potency, impact of expansion media on phenotype, and suitability of source. Many expansion media employ growth factors such as fibroblast growth factor (FGF)-β, which has been shown to induce proliferation dependent MHC class II expression[27] and in one study, suspected karyotypic changes.[28] The clinical trials so far have used MSC derived from various sources including fat, bone marrow, placenta, and umbilical cord, the former two being either autologous or allogeneic. MSC from the bone marrow of AD patients have been shown to be defective regarding certain functions such as differentiation potential and hematopoietic support, but seem as equally potent as healthy allogeneic MSC in terms of in-vitro anti-proliferative potential.

The efficacy data so far available are difficult to interpret due to variable pre-MSC transplant treatment regimens, non-standardized outcome measures, and lack of long-term follow-up. So far no acute toxicity signals have emerged from the experience of around 1000 patients, though longer-term data are important regarding tumour surveillance.

Future directions

Clearly further small phase I/II trials will not shed further light on the long-term benefit of MSC and we now need larger, randomized double-blind clinical trials, including mechanistic side studies. There are major gaps in our knowledge such as duration of engraftment, impact on normal tissues and organs, and phenotypic changes occurring in the MSC when exposed to the inflammatory/ischemic target tissue. At least interferon-γ and FGF-β will both cause expression of MSC class II on MSC, and in the latter case, this molecule is able to present antigen.[27] It would seem that costimulating molecules are never expressed by MSC, thus rendering the expression of MHC class II molecules potentially 'tolerogenic'. Several groups are planning such studies; the EULAR Stromal Cell Group is finalizing a prospective, double-blind comparative multicentre trial in lupus nephritis using allogeneic MSC, and an MS consortium a prospective comparative trial using autologous MSC.

It will require a determined effort from investigators, regulators, and industry to determine through adequately powered, prospective clinical trials the potential benefit of MSC transplantation in AD and other human disorders. As many of these are investigator-initiated, strategy-based studies, the bureaucratic burden may hamper development.

CHAPTER 86

Tissue engineering

Andrew McCaskie, Paul Genever,
and Cosimo De Bari

Introduction

The field of tissue engineering has developed rapidly over the last few decades and is of great relevance to musculoskeletal therapy and intervention. Early definitions of tissue engineering emerged in the late 1980s[1] and early 1990s and described tissue engineering as an interdisciplinary science involving life sciences and engineering to bring about biological substitutes that restore, maintain, or improve tissue function.[2] At the time, loss or failure of an organ or tissue was already seen as a frequent, devastating, and costly problem in human health care and three tissue engineering strategies were proposed: (1) cell and cell substitutes; (2) tissue-inducing substances; and (3) cells placed within matrices.[2] Even at this early stage, Langer identified the need to develop treatments to create new cartilage and improve bone repair (mesodermal applications). The scope of tissue engineering is both ambitious and broadly based and includes many branches of biological and engineering disciplines. Over the years there have been developments in both science and technology and the understanding of how to apply them clinically and so new terms and definitions have been developed. Regenerative medicine has been defined as

> an emerging interdisciplinary field of research and clinical applications focused on the repair, replacement, or regeneration of cells, tissues, or organs to restore impaired function resulting from any cause, including congenital defects, disease, and trauma. It uses a combination of several technological approaches that moves it beyond traditional transplantation and replacement therapies. These approaches may include, but are not limited to, the use of stem cells, soluble molecules, genetic engineering, tissue engineering, and advanced cell therapy.[3]

More recently this has been shortened to a single explanatory sentence: regenerative medicine replaces or regenerates human cells, tissue, or organs, to restore or establish normal function.[4]

A further term to consider is cell therapy. This has recently been considered in the context of regenerative medicine and was defined as 'the therapeutic application of cells regardless of cell type or clinical application' and was considered a 'platform' technology, useful to a regenerative approach.[5]

Regenerative strategies—cells, scaffolds, and factors

We can now consider how the strategies defined above can be applied and used within musculoskeletal clinical applications. It is useful to consider the relevant anatomy, such as bone, cartilage, muscle, tendon, ligament, and meniscus. Each tissue can be considered in a simplified manner as a mixture of cells and extracellular matrix. The type of cell will influence the biology of the tissue, e.g. cartilage formation with chondrocytes or bone formation with osteoblasts and the matrix will provide a three-dimensional biological and structural environment. The interaction between a cell and its environment is complex but important as it can direct cell function. At the micro- and nanoscale, cell behaviour is influenced by factors such as cell signalling molecules and the properties of surfaces (chemistry and topography). Beyond the small-scale considerations, the fully assembled tissue must provide the intended function and in the case of the musculoskeletal system this can involve significant mechanical performance, e.g. load transmission across a joint.

Tissue engineering strategies are often considered in a simplified form in terms of cells, scaffolds, and additional factors, although it should be noted that successful translation of such a strategy is more complex (Figure 86.1). There are many variations of usage and combination and it is not necessary for all three to be provided by the proposed treatment. However, the regenerative approach must produce both the quantity and quality of target tissue at the level of the cell, matrix, and environment. Moreover, the regenerated tissue must interact with the host tissue with a seamless biological and functional interface.

Cells

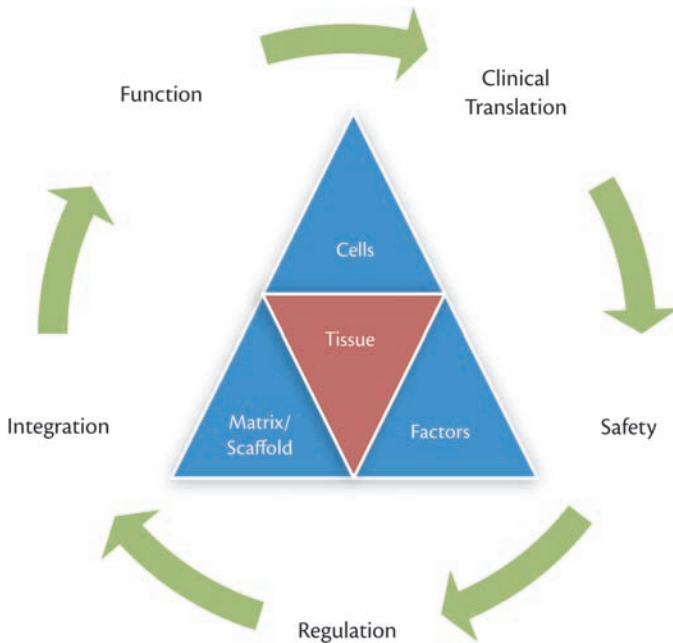
The cell biology of musculoskeletal tissue is of great importance in a regenerative approach. Some orthopaedic applications such as bone graft incorporation, require osteogenesis (osteoblasts) whereas cartilage defects require chondrogenesis (chondrocytes). Some applications may utilize fully differentiated cell types, but recently research has looked to consider the role of stem cells. The multipotent stromal cell/mesenchymal stem cell (MSC) serves many


Fig. 86.1 Schematic representation of some key issues relating to tissue engineering and clinical translation.

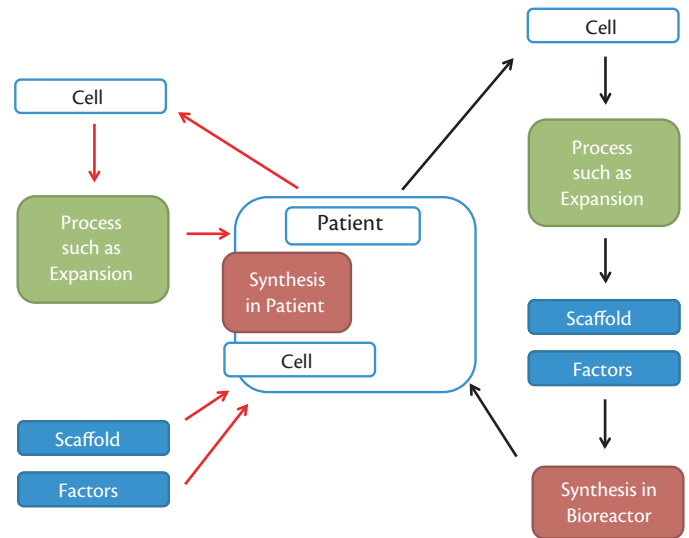
Fig. 86.2 Schematic representation of translational pathways in musculoskeletal regenerative medicine.

important functions within the body including repair and has the potential to differentiate into different cell phenotypes e.g. bone, cartilage, muscle, and tendon lineages. It has the advantage of being available within the adult and in many locations, such as bone marrow, fat, blood, and synovium.[6–9] In addition, relatively simple ex-vivo expansion and differentiation techniques have been developed for use in research and clinical applications. MSCs appear to have an immune-privileged or even an immunosuppressive function following transplantation. In trials of osteogenesis imperfecta, where allogeneic bone marrow-derived MSCs were given to patients after bone marrow transplantation, MSC engraftment was shown and a marked increase in patient recovery was detected.[10] Embryonic stem cells (ESCs) are pluripotent and clearly also have the ability to differentiate into relevant skeletal tissue groups, as well as cell and tissue types from all three embryonic germ layers. There are, however, ethical considerations associated with the use of ESCs in therapies and the need for defined protocols for osteo/chondrogenic differentiation.

Therapeutic adult stem cells, such as MSCs, could be used with or without culture expansion and with the target tissue synthesis taking place in the laboratory or in the human (Figure 86.2). In both approaches, these tissue progenitor cells are central to cell-based tissue engineering strategies that have been described[11,12]:

◆ local targeting of connective tissue progenitor cells
◆ homing connective tissue progenitor cells to new areas
◆ physically transplanting connective tissue progenitor cells
◆ transplantation of culture-expanded or modified connective tissue progenitor cells
◆ transplantation of fully formed tissue.

Scaffolds

The extracellular component of a therapy is often called a scaffold and must facilitate the cell repair processes (such as migration, proliferation, differentiation). In musculoskeletal applications it may also fulfil some biomechanical requirements such as load transmission. Several different types of support materials are available, ranging from natural and synthetic biomaterials and nano-textured scaffolds through to complex self-assembling peptide gels, with different compositional features, including polymers, ceramics, and metals. Increasingly sophisticated bioengineering approaches have been developed to allow precise control over the geometry and architecture of the desired scaffold.[13] When considering the design and selection of scaffolds the following features have been described[11]:


◆ preservation of tissue volume
◆ porosity that can allow mass transport of nutrients
◆ porosity that can allow tissue and vascular ingrowth
◆ a surface optimized for cell attachment migration proliferation and differentiation
◆ the degradation property that allows regeneration and does not cause local toxicity.

Factors

The interaction between a cell and the scaffold can be facilitated by various factors. This includes a range of secreted factors including hormones and locally released cytokines and growth factors.[14] For example, exposure of MSCs to bone morphogenic proteins (BMPs) can induce osteogenic differentiation. Furthermore, it may be important to consider the mechanical and chemical composition of the tissue from which the cells were initially derived. For example, MSCs are believed to exist in a specialized microenvironment, or niche, which can support the MSCs, protect from damaging stimuli and promote niche exit when appropriate differentiation stimuli are received, with growing evidence supporting a perivascular location.[15] A deeper knowledge of the in-vivo stem cell niche and its structure and organization in different tissue types will also contribute to new strategies for bioengineering scaffolds.

Therapy for joint disorders

The generic strategies described above can be applied to joint disorders. Osteoarthritis (OA) is the most common joint disease and is an increasing problem in our society as people age and wish to remain active. For the patient, quality of life is reduced because of the loss of movement and joint pain increases to become continuous. Current treatment options are limited to analgesia and physiotherapy, and to prosthetic joint replacement for endstage disease. There is an unmet need to develop new treatment options that could halt disease progression, at an early stage. Regenerative medicine offers the potential for a long-term solution via biological repair, regeneration, or replacement of the degenerate joint tissues.

Cell therapy has proved very promising in the management of joint surface defects, which if untreated could lead to secondary OA. Post-traumatic OA represents 13% of knee OA and 73% of ankle OA.[16] Symptomatic chronic full-thickness defects of the knee joint surface require surgical intervention for symptom relief and to prevent evolution towards OA. Current treatment options include microfracture and autologous chondrocyte implantation (ACI).[17,18] Microfracture involves creating a surgical communication between the joint space and the subchondral bone and marrow, which can be achieved by using a sharp awl. The theoretical basis for the cartilage regeneration is the release from the marrow space of adult stem cells. ACI involves two surgical procedures. In the first, cartilage is obtained from the patient's joint surface but from an area not required for joint function. From this cartilage, chondrocytes can be obtained and expanded in vitro. A second surgical procedure is carried out to place the expanded chondrocytes within the area of cartilage damage, either membrane bound or secured by a periosteal flap.

ACI was first described in 1994 by Brittberg and colleagues,[19] who reported treatment of symptomatic defects of the joint surface in humans by implantation of autologous, culture-expanded articular chondrocytes underneath a periosteal flap. Chondrocytes were obtained with a cartilage biopsy from an uninvolved and minor loadbearing area of the same joint surface. This study showed symptomatic relief in 14 out of 16 patients with lesions of the femoral condyle at 2 years follow-up. Currently, ACI represents the gold standard of cell therapy for cartilage repair with up to 20 years' follow-up showing ACI being an effective and durable solution for the treatment of large full-thickness cartilage lesions of the knee joint.[20]

Chondrocytes are difficult to grow in culture as they rapidly undergo dedifferentiation, resulting in the loss of their capacity to form cartilage in vivo.[21] MSCs are easy to isolate and culture expand, are chondrogenic, and therefore are attractive chondrocyte substitutes in an ACI-like procedure. For these reasons, the use of MSCs for joint surface repair is intensively sought and has been explored to reconstruct joint surface over eburnated condyles in patients with advanced OA.[22] MSCs could be implanted as undifferentiated cells, either in suspension or in combination with biomaterial scaffolds, while the addition of chondrogenic factors could enhance repair cartilage tissue formation.[23]

As discussed earlier, MSCs are known to be present in many connective tissues of the adult human body.[9] For example, MSCs can be derived from the adult human synovial membrane,[24] which is often exuberant in joint disorders and is therefore removed in diagnostic arthroscopic procedures. Excessive synovium could therefore be a precious source of MSCs for biological joint-resurfacing protocols. However, there is evidence indicating that human MSCs from different tissues possess distinct biological properties,[25,26] and therefore studies are required to identify the source of MSCs with superior chondrogenic potency leading to durable cartilage repair tissue. In addition, there is concern that MSCs may not form hyaline-like cartilage and would instead give rise to the transient cartilage tissue that is replaced with bone during endochondral ossification. In this regard, bone marrow MSCs tend to form a cartilage tissue with a high frequency of chondrocyte hypertrophy,[27] and this could explain the excessive advancement of the bone front at the expense of the articular cartilage as observed in experimental animals.[28] Ultimately, preclinical and clinical studies will be needed to assess the suitability of MSCs for joint surface repair in terms of safety and non-inferiority in clinical effectiveness when compared with chondrocytes.

In addition to their capacity of replacing lost cells, MSCs are also likely to provide trophic factors to the environment, thereby enhancing local intrinsic reparative events.[29] It will therefore be crucial to ensure consistent bioprocessing of the cellular products while studying its mode of action in preclinical models. MSCs could also be implanted immediately after their purification in a one-step procedure, without culture expansion. Minimally manipulated cellular preparations would simplify the regulatory paths of autologous procedures but would equally require quality controls also including identity characterization and potency assessment.

The use of allogeneic MSCs would allow upscalable production of quality-controlled cell preparations, readily available for implantation. This would enhance consistency and abate costs, thus facilitating large-scale distribution for routine clinical application. MSCs appear suitable for allogeneic transplantation for their immune privilege and immunomodulatory properties, although these remain controversial due to conflicting results.[30] In addition, the differentiation into a mature phenotype of the implanted MSCs may result in the loss of the immunological privilege with consequent rejection.[31]

OA is often confined to one or a few large weightbearing joints and therefore intra-articular administration of allogeneic MSCs is being explored, supported by the promising data obtained in a preclinical goat model of OA induced by medial meniscectomy and resection of the anterior cruciate ligament.[32] In this model, intra-articular administration of bone marrow MSCs resulted in the regeneration of a meniscal-like tissue and retarded progression of OA.

In addition to the use of ex-vivo manipulated MSCs, another possible approach contemplates the activation of intrinsic regenerative mechanisms, e.g. by using medications that target the endogenous MSCs that are naturally present in the joint (see Figure 86.2). Several joint-associated tissues such as synovial membrane and fluid, fat pad, periosteum, bone marrow, and even the articular cartilage itself, have been reported to contain cells that, after isolation and culture expansion, display properties of MSCs, but their location and functional roles remain to be elucidated.

Recently, the use of a double nucleoside labelling scheme in a clinically relevant mouse model of joint surface injury[33] allowed the identification and characterization of endogenous resident MSC niches in the knee joint synovium in vivo.[34] An understanding of the molecular regulation of MSC niches in health and joint disorders will provide the scientific basis for the development of novel

interventions that enhance intrinsic regenerative mechanisms in order to treat or even prevent OA. This could be achieved by local administration of drugs or via the controlled release of specific growth factors or morphogens using, for instance, bioactive scaffolds. Another key step will be the identification of the appropriate molecular signal(s) to be delivered. The evidence that the BMP and Wnt signalling pathways are activated in adult articular cartilage in response to mechanical injury[35] suggests that these signalling pathways could be part of a programme of remodelling or repair and therefore possible therapeutic targets to achieve joint tissue repair. Modulation of the Wnt and BMP signalling pathways within the joint environment is likely to affect stem cell fates and related tissue remodelling.

Conclusion

Tissue engineering, regenerative medicine, and cell therapies have developed significantly over the last few decades and are applicable to a wide range of musculoskeletal applications. Many strategies have been identified that would potentially benefit patients but the future will require successful translation from the laboratory into clinical practice. It is important to identify clinical targets where there is both clinical need and an informed view that the approach is likely to be successful. There are already examples of bone substitutes being used for bone loss and expanded chondrocytes being used to regenerate cartilage. The future will see more complex applications such as fracture healing and osteoarthritis. To deliver this, an interaction must be facilitated between many stakeholders such as scientific researchers, clinicians, healthcare providers, industry, regulatory organizations, and of course the patients themselves. The challenge is to provide treatments that are effective and safe but are also cost effective and available to all who require them. The original scope of tissue engineering was to improve upon end-stage treatments such as joint replacement, which utilize metal and plastic. As we move forward, we may see regenerative approaches that attempt to achieve repair and regeneration at an earlier stage, using advanced biomaterials and cell-based technologies.

CHAPTER 87

Injection therapy

Philip Platt and Ismael Atchia

Introduction

Targeted injection for joint and soft tissues pathologies have been reported as far back as the 1930s though the outcomes with initial agents such as glycerin, formalin, and petroleum jelly were poor. Hydrocortisone was found to be more promising and Professor J.L. Hollander was a pioneer in the field with his publications in the 1950s of the results of tens of thousands of injections performed.[1,2] From early on, it was realized that the high solubility of hydrocortisone was perhaps one of the reasons for the short duration of action. Since then glucocorticoid esters with lower solubility have been preferred. Injection therapy has become a core treatment in musculoskeletal medicine.

Injection therapy is usually indicated in the treatment of inflammatory arthritis or soft tissue inflammation affecting structures such as tendons and bursae, but is also used in degenerative conditions. There is evidence of prolonged benefit from intra-articular steroid therapy in rheumatoid arthritis (RA). Joint injection has an important role as an adjunct to disease-modifying anti-rheumatic drug (DMARD) treatment, in achieving tight control in RA. The role of injections in the management of osteoarthritis (OA) has remained poorly defined and its use highly variable. Other intra-articular injections such as hyaluronic acid, silicone, glucosamine, non-steoidal anti-inflammatory drugs (NSAIDs), yttrium, and botulinum have been used,[3,4] as well as novel agents such as tropisetron (a 5 HT-3 receptor antagonist)[5] and interleukin(IL)-1 receptor antagonist.[6] The most widely used by far remain glucocorticoids followed by hyaluronic acid.[4] These agents are reviewed in this chapter with regard to their safety and efficacy.

Injection techniques

Clinically guided injection

Joint injection has usually been performed using anatomical landmarks to guide the needle into the joint. This technique is also referred as 'blind injection'. The ability to perform the procedure accurately depends on the experience and skill of the physician. It relies on clear understanding of static and functional anatomy of the target area and ability to palpate and identify joint contours. The method for identifying different joints and soft tissue areas are covered later in this chapter. Any clinician starting to perform injections will experience a learning curve, with increased

accuracy over time. The advantage of the clinically guided technique is that, in experienced hands, this procedure can be easily and quickly performed within the clinic room setting. One of the potential drawbacks is the uncertain accuracy, unless there is a positive aspirate of synovial fluid. Surrogate criteria for accuracy such as low resistance on injecting can be misleading since periarticular structures such as fat pads around joints can be readily infiltrated.

A small number of studies have addressed the accuracy of injection and reported surprisingly low accuracy. Jones et al.,[7] using methylprednisolone mixed with contrast agent, demonstrated that the accuracy of blind joint injection was only 50% for injections performed at common sites such as the knee and shoulder. However more recent studies have revealed better results, indicating that accuracy probably remains physician dependent.[8]

Image-guided injection

A variety of imaging methods, including fluoroscopic screening, CT scanning, and more recently ultrasound and MRI, have been used to better localize needle placement.[9–13] Fluoroscopy screening improves accuracy but requires radiology staff and a suitably equipped environment, and involves exposure to radiation and injection of contrast material. CT scanning provides more detailed bony imaging and is the preferred option for sacroiliac joint injection but is also associated with radiation exposure. MRI, on the other hand, is safe and detailed imaging of structures is possible. However, like CT, it can (usually) only be performed in a radiology department and is relatively expensive.

Musculoskeletal ultrasound (MSUS)-guided injection does not involve radiation, allows dynamic images to be obtained, and in view of its portability makes it possible to perform procedures in the clinic setting. The use of ultrasound guidance is discussed further in this chapter; the other image-guided modalities tend to be practised by radiologists.

Ultrasound enables the visualization of soft tissue structures and can distinguish synovial fluid and synovial proliferation. Ultrasound can therefore confirm the indication for an injection and determine the most direct and safest route for needling, which avoids neurovascular structures or tendons. There are two techniques of ultrasound-guided injection, direct and indirect. For the indirect method, ultrasound is used to visualize the structures and determine the depth of the target area from the skin surface. The
Fig. 87.1 Ultrasound-guided injection of the prepatellar bursa with real time visualization of the needle (N) and distension of the bursa (B) around the needle tip.

skin is then marked and the injection performed without further use of the ultrasound.

The direct method depends on direct visualization of the target structures and then real time visualization of the needle as shown in Figure 87.1. Injecting the target area can be confirmed from its distension and/or visualization of the material injected, which is hypoechoic for saline or lidocaine and hyperechoic for steroid or steroid/air mixture. Direct ultrasound-guided injections can be technically challenging as they rely on manual dexterity and coordination; usually the dominant hand is used for the syringe, with the probe being held by the non-dominant hand. There are situations when the needle will not be readily visualized, and the maintenance of asepsis during the procedure is clearly of paramount importance.

Glucocorticoid injections

Effects of steroids

The rationale for using steroids in inflammatory arthritis is their broad anti-inflammatory properties based on inhibition of prostaglandin, leukotriene, and proinflammatory cytokine production (see Chapter 79).[14,15] There are steroid receptors within the nucleus of all cells, including synoviocytes, which modulate transcription and expression of cellular proteins. A small study in RA has shown downregulation of a number of proinflammatory cytokines following a single intra-articular injection of triamcinalone,[16] but there are no similar human in-vivo data for OA. The first intra-articular steroids used, such as hydrocortisone acetate, were relatively water soluble, and therefore could permeate through the synovial membrane easily, with poor retention in the joint.[17] Since then less water-soluble forms, such as methylprednisolone acetate, triamcinolone acetonide, and triamcinolone hexacetonide, have been preferred. However, triamcinolone acetonide and trimacinolone hexacetonide are usually avoided for tendons and superficial structures because there is some evidence of increased tendon rupture and skin/fat atrophy.[18–20]

There is good evidence for prolonged benefit of intra-articular glucocorticoids in RA and juvenile idiopathic arthritis (JIA).[21,22]

On the other hand, meta-analyses of OA studies have failed to demonstrate benefit of more than 3 weeks. Recent studies in hip OA have demonstrated more prolonged benefit,[23–25] with evidence of synovitis being a predictor of prolonged response.[26]

There have been no clinical trials comparing both the long-term efficacy and safety between different steroid agents and preparations. One randomized controlled trial (RCT) revealed superior duration of benefit of triamcinolone hexacetonide and triamcinolone acetonide compared to hydrocortisone in the treatment of RA of the knee.[27] Other RCTs have demonstrated efficacy over placebo for OA of large joints and for conditions such as carpal tunnel syndrome. However, there is no consensus with regards to the dose, although there is some agreement that the dose should be proportionate to the size of the joint and perhaps to the degree of inflammation within a joint.

There are wider variations with regard to whether local anaesthetic is used and what volume. Surgeons tend to use higher volumes because they undertake more injections for diagnostic rather than therapeutic purposes. However, there is some debate whether immediate pain reduction from injection is solely due to adequate infiltration of the pathological structure with local anaesthetic as opposed to the possible placebo effect associated with injections.[28]

The overall evidence tends to indicate improved clinical outcomes for accurately delivered glucocorticoid injections.[7–9] However, for sacroiliac joint injections, a recent study revealed that periarticular deposition of glucocorticoid is as effective as accurate intra-articular injection.[29]

Risks/side effects of steroids

Intra-articular injection is a safe procedure but can nevertheless be associated with some adverse effects. These can be related to local trauma in and around the joint, and local or systemic adverse reactions to the injected agent. Postinjection flare is thought to be due to a reactive synovitis to the glucocorticoid crystals and usually should not last more than 24 hours. The most feared complication is septic arthritis, which is associated with significant morbidity and mortality.[30] The incidence of septic arthritis from joint injection is extremely low and usually quoted at around 1:10 000 to 1:20 000.[3,4,31,32] Hollander quoted 18 cases out of 250 000 injections performed and other more recent reviews suggest an even lower risk (4.6 per 100 000 based on a survey of 40 rheumatologists in the United Kingdom,[33] 2 in 100 000 by Gray et al.[34]). French data reported a septic arthritis rate as low as 1/162 000 when glucocorticoid packaged into a sterile syringe was used.[35] Of concern, however, are recent data from Iceland identifying a rate of 0.037%,[36] though this study did not document injection technique used or the clinicians performing the injections.

There is no clear indication whether full aseptic technique reduces the risk compared to the no-touch technique.[37] Overall, when the risk is so low, it is difficult to prove causality. Even if joint infection follows an injection, unless the timeframe precludes an alternative explanation it is important to remember that septic arthritis may also reflect underlying immune compromise secondary to disease factors (such as in RA) or the immunosuppressant effects of drugs.

Haemarthrosis is another potential complication of injection, but the risk is extremely low unless there is an underlying bleeding tendency. Salvati et al.[38] reported 2 cases of postprocedure haemarthrosis on their series of 15 patients on warfarin, but the INR of

these 2 patients was between 3.8 and 5. In contrast, in the prospective study by Thumboo et al.,[39] of 32 soft tissue and joint injection/aspiration procedures the INR was less than 3 or well controlled in all patients and no cases of bleeding occurred. Thus as long as the INR is less than 3, warfarin therapy should not be a contraindication for intra-articular or soft tissue injection. Extra care should be taken to avoid vascular injuries particularly for the small joints, carpometacarpal (CMC), and ankle joint injections. There are reports not just of trauma to blood vessels, but also of cases of arterial emboli from the low-solubility steroids blocking arterioles.

Steroid injections have been linked to cartilage loss in some non-primate animal studies. Triamcinolone hexacetonide injections have been linked to increased progression of cartilage loss in the hands and the hip joint in juvenile arthritis,[40,41] although it is unclear from these observational data whether more aggressive disease in patients given this treatment option or the steroid injection itself was responsible for cartilage loss. In a large prospective RCT of patients receiving multiple intra-articular joint injections for knee OA followed over 2 years, there was no evidence of increased loss of cartilage in the injection group.[42] Our personal view is that this concern has been exaggerated and has resulted in unfounded restrictions in the frequency of intra-articular injections of steroids. This particularly is relevant for an inflamed joint, where untreated inflammation within the joint itself is almost certainly more likely to lead to cartilage loss than any injected glucocorticoid.

There can be systemic effects from local injections although studies have revealed that the effects, even for concurrent multiple joint injections, are minimal when compared with intramuscular steroid. There is no evidence to suggest long-term complications such as osteoporosis, hypertension, weight gain, and diabetes, which are associated with systemic glucocorticoids. Systemic effects are more pronounced in the first 24 hours and patients may experience facial flushing. Diabetic patients may experience higher than usual blood glucose levels, particularly in the first 24 hours following injection. There have been case reports of extremely rare side effects such as steroid psychosis after steroid injection.

Indications/contraindications

Glucocorticoid injections are administered for therapeutic benefits but, usually in combination with local anaesthetic, may also be administered for diagnostic purposes. The therapeutic benefits are reduction in pain by reduction of inflammation and preventing relapse of swelling/synovitis. In mono or oligo inflammatory arthritis, injection is often a better option than systemic steroid or immunosuppressant treatment.

In musculoskeletal presentations when the pathology is not clear (e.g. complex shoulder pain or lower limb/back pain), particularly when surgery is contemplated, a diagnostic injection may be indicated. In these situations a large volume of local anaesthetic is often used (usually in combination with steroid) and bupivacaine or another longer-acting local anaesthetic is preferred. If there is immediate benefit or significant benefit noted within a few hours of the injection, then the area infiltrated is probably the source of the patient's symptoms. However, in cases of intermittent pain, it may not be possible to ascertain the immediate response from the injection and then the potentially longer-acting steroid may clarify the diagnosis. However, the delayed response to an injection may not necessarily confirm the site of pain, since this may be due to the

systemic action of the steroid. Finally, interpretation of a patient's response is further complicated by the strong placebo response to injections.

In summary, there is good rationale for performing joint/soft tissue steroid injections, but further evidence is required to ascertain whether medium/long-term outcomes depend on type of steroid, accuracy of injection, timing/frequency of injection, added benefit of local anaesthetic, and impact of other medical co morbidities, or psychological effects on perceived response.

Method

The techniques for clinically guided injections and also for ultrasound-guided injections of different structures are discussed below. There are common considerations for the different anatomical areas (summarized in Box 87.1). Either a no-touch technique or aseptic technique should be used. With the no-touch technique the target area is palpated to identify the joint contour or soft tissue structure. The overlying skin is then marked, preferably by indentation of the nail or with the tip of a pen. Pen marks, even with special skin marker pens, are best avoided as they may become indistinct with skin cleaning. Once the skin is marked, it is cleaned with an alcohol swab, ideally more than once, or with disinfectant such as chlorhexidine in alcohol, and then without touching the skin again, the injection is performed.

Aseptic technique will consist of sterilizing a wider skin area overlying the region of interest. The area is then usually isolated with sterile drapes. The clinician is gowned and will be using sterile gloves, and hence palpation of the area will not lead to loss of sterility.

When the injection is performed using direct visualization on ultrasound, the ultrasound probe needs to be cleaned with chlorhexidine spray/solution. The chlorhexidine in alcohol spray/solution absolves the requirement for gel, but otherwise sterile gel can be used. Some practitioners advocate the use of sterile sheaths

---

Box 87.1 General principles for joint injections

- Assess indications/contraindications
- Obtain written or verbal consent
- Glucocorticoid: higher dose for large joints
- Local anaesthetic: preinfiltrated or premixed steroid preparation; consideration for total volume
- Identification of anatomical landmarks
- Image guidance or assisted when appropriate/ultrasound to confirm effusion or synovitis
- Aseptic technique or no-touch technique
- Avoid injecting against significant resistance (except for entheses)
- Aspirate before injecting
- Reconsider/avoid injection if aspirate is bloody or potentially infected
- Provide postinjection advice about rest, postinjection flare, analgesia

and gel to cover the ultrasound probe as the preferred method to maintain sterility during the injection.

Injections can consist of just one syringe with one needle, e.g. injection of steroid or premixed steroid/lidocaine preparation. However, one needle and three syringes are usually required for joints needing aspiration and injection: once the area is infiltrated with local anaesthetic, usually all the way into the joint capsule, the syringe is disconnected from the needle, then another syringe is used for aspiration, and then finally a third syringe containing the steroid is connected. In these circumstances, the overall procedure takes longer, requiring handling of the needle end to change the syringe, and the no-touch technique is best avoided. Some practitioners do not infiltrate with local anaesthetic first, using just two syringes. In the paediatric setting the skin can be anesthesized with prior application (about 45 minutes before the procedure) of local anaesthetic cream, such as lidocaine/prilocaine (EMLA). Another option is refrigerant spray such as ethyl chloride, which is applied until the skin turns white, and then the procedure is carried out.

Patients should be always be made aware of the risk of septic arthritis and informed of the symptoms and signs to monitor. This should be distinguished from flare of pain during the first 24 hours, which can be the result of a transient synovitis to glucocorticoid crystals. Excessive weightbearing of the injected joint should usually be avoided for 24 hours following the injection.

Upper limbs

Glenohumeral joint

The joint capsule usually connects and communicates with the biceps tendon. The joint is usually accessed using the anterior or posterior approach; the lateral approach may cause damage to the rotator cuff tendons. Joint injection is indicated for suspected inflammation of the joint and/or if there is associated global restriction of movement.

Anterior approach

- Posture: patient either comfortably sitting up or lying supine.

- Anatomical landmarks: the coracoid process is identified below the distal part of the clavicle. The joint is just lateral and probably easier to access just inferior/lateral to the coracoid process (Figure 87.2).

- Needle: 23 or 21G.

- Approach: aim towards the acromion or fairly perpendicular; usually a 'give' is felt.

- Caution: risk of biceps tendon rupture. In obese patients it can be difficult to feel the bony landmarks. Longer needle may be required and care taken not to advance the needle medially to avoid lung injury.

Posterior approach

- Posture: patient sitting in an upright position and approach from behind.

- Anatomical landmarks: the acromion is palpated at its distal end and at the junction of the spine of the scapula. The area 1 cm under the acromion is marked.

- Needle: 23 or 21G.

Fig. 87.2 Shoulder joint injection. Anterior approach with thumb of free hand positioned over the coracoid process and needle inserted just inferior and lateral.

Fig. 87.3 Subacromial joint injection. The inferior margin of the acromium is outlined.

- Approach: needle is inserted and targeted towards the coracoid process, which can be palpated with the free hand. Aim as deep as possible or if bone contact withdraw slightly. Inject without resistance.

- Caution: the glenohumeral joint from this approach may be more than 3–4 cm deep even for average-sized patients.

Subacromial bursa

This is a large bursa between the deltoid and the rotator cuff tendons/muscles. Isolated bursitis is uncommon. Bursitis is usually associated with underlying rotator cuff pathology or impingement.

- Posture: patient sitting comfortably with the arm vertical and relaxed. The acromion is palpated and the gap between it and the humeral head felt. The skin is marked 1–1.5 cm below the inferior margin of the acromion (Figure 87.3).

- Needle: 23 or 21G.

- Approach: once the skin is punctured, aim the needle upwards under the acromion. Either infiltrate with local anaesthetic first then change syringe for the steroid or inject directly with steroid.
- Caution: the potential space can be obliterated in a full-thickness tear with superior migration of the humeral head.

Acromioclavicular joint

Indicated when there is localized tenderness over the joint. It is very superficial and a small joint, therefore only a small volume can be used. The gap is very difficult to feel and movement of the shoulder can make it easier to feel the joint line. Otherwise the joint can be easily visualized on ultrasound. When performed under clinical guidance, the joint is approached vertically down but with ultrasound the approach can be modified and adapted to avoid any osteophytes.

Elbow joint
Lateral approach

- Posture: patient sitting with arm resting comfortably. The lateral epicondyle is palpated and the radial head palpated-supination/pronation of the arm will facilitate. The entry point is just proximal to the radial head.
- Needle: 23G.
- Approach: once the skin is punctured, direct needle into the joint space. Target may be less than 1 cm deep.
- Caution: this is a difficult joint to inject in the absence of effusion.

Posterior approach

- Posture: patient sitting with palm down. The olecranon and lateral epicondyle are identified. The olecranon groove is just proximal to the olecranon.
- Needle: 23G.
- Approach: skin is marked over the olecranon groove and needled directed vertically. With ultrasound guidance, the needle is inserted more proximally and then aimed towards the olecranon at an angle of about 45°, with direct visualization of the needle (Figure 87.4).

Lateral epicondyle

Injection is indicated for epicondylitis (tennis elbow) with point tenderness over the area or discomfort on resisted wrist extension.

- Posture: elbow flexed at about 90°, arm resting. The lateral epicondyle is readily palpable and most tender spot identified.
- Needle: 23G.
- Approach: ideally the skin is marked 0.5 cm away from the point of maximum tenderness. Once skin is punctured, the needle is then 'tunnelled' to reach the musculotendinous insertion area (Figure 87.5). If point of entry is directly above the area, the steroid may be infiltrated subcutaneously and this can result in skin atrophy. This risk is minimized by using hydrocortisone.
- Caution: the insertion area is tough and resistance felt during this injection

Medial epicondyle

Injection indicated for golfer's elbow with tenderness over the medial epicondyle or with pain on resisted wrist flexion.

Fig. 87.4 Elbow joint injection. Posterior approach, under direct ultrasound visualization of the needle (N) going through the joint capsule (C) targeting the joint effusion (E).

Fig. 87.5 Injection of lateral epicondyle. The point of maximum tenderness over the lateral epicondyle is marked (arrow) and needle inserted about 0.5 cm away and directed to the target area.

- Needle: 23G.
- Approach: skin marked 0.5 cm away. Avoid injection into the ulnar groove and check with patient about tingling/pins and needles which may indicate contact of needle with the ulnar nerve.
- Caution: ulnar nerve injury

Wrist

It is not possible to inject individual carpal joints under clinical guidance. Usually the gap between the distal radius and the scaphoid and lunate is palpated with the wrist in flexion. This is the target for injection.

- Posture: hand resting on a pillow with wrist flexed.
- Needle: 23 or 25G.

◆ Approach: Approach distally with needle at 60–90° angle (Figure 87.6).

◆ Caution: avoid the overlying extensor tendons

First carpometacarpal joint

OA of this joint is common and can be associated with localized tenderness on palpation and crepitus on movement. The thumb is gently flexed and extended and the joint line felt in the snuffbox between the extensor pollicus longus tendon and the combined tendon sheath of the extensor pollicus brevis and adductor pollicus longus. The radial artery should be palpated to ensure it does not lie along the joint line in the snuff box. If this is the case, then the joint should be approached just anterior to the combined tendon sheath of the extensor pollicus brevis and adductor pollicus longus.

◆ Needle: 23 or 25G.

◆ Approach: gentle flexion of the thumb. Approach distally with needle at 60–90° angle (Figure 87.7).

◆ Caution: avoid the radial artery.

Fig. 87.6 Wrist joint injection.

Fig. 87.7 Carpometacarpal joint injection. The thumb is flexed and gently pulled with the free hand to aid injection.

Carpal tunnel

The median nerve runs just deep to the flexor retinaculum, with palmaris longus overlying the area. Palmaris longus tendon is identified by juxta opposing thumb and little finger. Skin marked just ulnar to the tendon on the distal palmar crease (Figure 87.8).

◆ Needle: 25G.

◆ Approach: needle at around 45°. Retract if patient feels increased tingling or pins and needles.

◆ Caution: avoid lidocaine.

Metacarpophalangeal joint

In the absence of effusion the target area is the joint line which is located distal to the knuckle crest and felt by passive movement of the finger and gentle pull/distraction. The extensor tendon overlying the joint is identified.

◆ Approach: distally at angle of 60°. Skin punctured lateral to extensor tendon and aiming under the tendon (Figure 87.9).

◆ Needle: 25G.

◆ Caution: risk of trauma to neurovascular structures.

Fig. 87.8 Carpal tunnel injection.

Fig. 87.9 Metacarpophalangeal joint injection. The joint line is marked just lateral to the extensor tendon. The finger is gently pulled with the free hand.

Interphalangeal joint

Joint line felt by passive movement of the joint.

- Approach: skin punctured just lateral to extensor tendon aiming under the tendon.
- Needle: 25G.
- Caution: risk of trauma to neurovascular structures.

De Quervain's tenosynovitis

Inflammation of the extensor pollicis brevis and/or the abductor pollicis longus. There can be associated swelling, crepitus or localized pain over the tendon.

- Approach: area of tenderness or swelling along the tendon usually in the snuff box area. Tangentially along the tendon.
- Needle: 23 or 25G.
- Caution: avoid injecting against resistance.

Flexor tenosynovitis

May be associated with history of triggering with triggering on examination, flexion of digit, or swelling of the tendon

- Approach: proximal approach tangentially to 30°, skin punctures around palmar crease and aiming distally (Figure 87.10).
- Needle: 25G.

Lower limbs

Hip joint

Injection of the hip joint is usually performed under image guidance only, though there are reports of clinically guided injection technique with reasonable accuracy rate.

Approach (ultrasound guided)

The hip joint can be accurately injected under ultrasound guidance using the direct approach. The patient lies flat and the hip joint and capsule are visualized as shown in Figure 87.11. The area on the skin is then marked and the injection prepared. Under direct visualization, local anaesthetic is infiltrated and distension of skin and then underlying fascia and muscles are seen. Resistance is usually felt just before puncture of the capsule. Once within the capsule,

Fig. 87.10 Flexor tendon sheath injection.

accuracy can be further confirmed with visualization of distension of the capsule.

- Needle: spinal needle 21G.

Greater trochanteric bursa

Pain in this area is not always related to confirmed presence of bursitis. The most common bursitis is that underneath the gluteus maximus and is usually located on the posterolateral aspect of the greater trochanter. There are a large number of bursae in the area. Even in the absence of effusion, patients may benefit from injection of the painful area.

- Posture: usually patient lies on the contralateral side with the leg straight and the affected side leg flexed. Alternatively both hips can be in flexion, in fetal position, for this procedure.
- Approach: the tender area is marked and infiltrated. Perpendicular, aiming to touch bone and then retracting by a few millimetres, but response may improve by infiltrating a wider area (withdrawing and changing direction of the needle then infiltrating).
- Needle: 21G.
- Caution: even in thin people the bursa is deeper than the perceived depth on manual palpation and long needles are often required.

Knee

The joint can be approached medially, laterally, and via a suprapatellar approach. The infrapatellar approach is best avoided as the patellar tendon can easily be damaged.

- Posture: patient lies on the couch with the knee extended but not fully in order to ensure the patella is mobile and not locked in extension.
- Needle: 21G

Medial approach

Site of entry is just below the midline of the patella. Needle trajectory is horizontal and towards the suprapatellar area. Gentle pressure on the lateral patella may help to increase the gap, particularly in the presence of osteophytes in OA.

Lateral approach

Site of entry is just inferior to the margin of the upper and middle third of the patella (Figure 87.12). Pressure on the medial patellar may increase the gap underneath the patella.

Ankle joint

The talotibial joint is best accessed anteriorly by identifying a gap between the overlying tendons, usually just lateral to anterior tibialis (Figure 87.13). Dorsalis pedis artery should be palpated as anatomical variations exist and may be more medial than expected in some patients and occasionally the safest approach may be just medial to the anterior tibialis tendon.

- Posture: position the foot in neutral or plantarflexion, approaching from the distal end at an angle of about 45–90°.
- Needle: 23G.
- Caution: injury to overlying tendon and dorsalis pedis artery.
Fig. 87.11 Ultrasound-guided hip joint injection. The area is scanned and probe position marked (image i—white circle denoting level of anterior superior iliac spine and black circle at the level of greater trochanter) before thorough skin and probe cleaning. Using a spinal needle, the skin is punctured and infiltrated with local anaesthetic and then the needle advanced and deeper layers injected with local anaesthetic (images ii and iii). Once capsule is punctured (image iv) accuracy is ascertained with demonstration of capsular distension (arrowheads) and hyperechoic steroid infiltration (arrow).

Talonavicular joint

Patients not responding to ankle joint injection may have talonavicular involvement which can be missed clinically. Ultrasound can easily identify and differentiate between inflammation of the ankle joint and talonavicular joint and is also useful to guide injection.

- Approach: the probe is positioned so that that the talonavicular joint is in the midline. The needle is then inserted right next to the midline of the probe, aiming vertically to the joint capsule.
- Needle: 23 G

Subtalar joint

Pain around the ankle can be due to the subtalar joint. The subtalar joint is difficult to inject and usually 'blind' injection results in infiltration of the sinus tarsi rather than the joint. Because the joint is covered by the malleoli it is difficult to visualize, and hence, even with ultrasound it is difficult to inject accurately. The joint can be approached medially, but because of the overlying tendons and neurovascular structures on the medial side, the lateral approach is usually preferred.

- Approach: the joint line is felt just inferior and anterior to the lateral malleolus. Inversion/eversion of the foot may help to identify the joint line.
- Needle: 23G.

Metatarsophalangeal joint

The joint line is identified dorsally by movement of the toe. The gap/joint line may be more easily identified by gentle pulling of the toe. The extensor tendon is identified and point of entry of needle should be just medial or lateral to this structure.

- Needle: 25G
- Caution: injury to extensor tendon or neurovascular structures.

Tendons

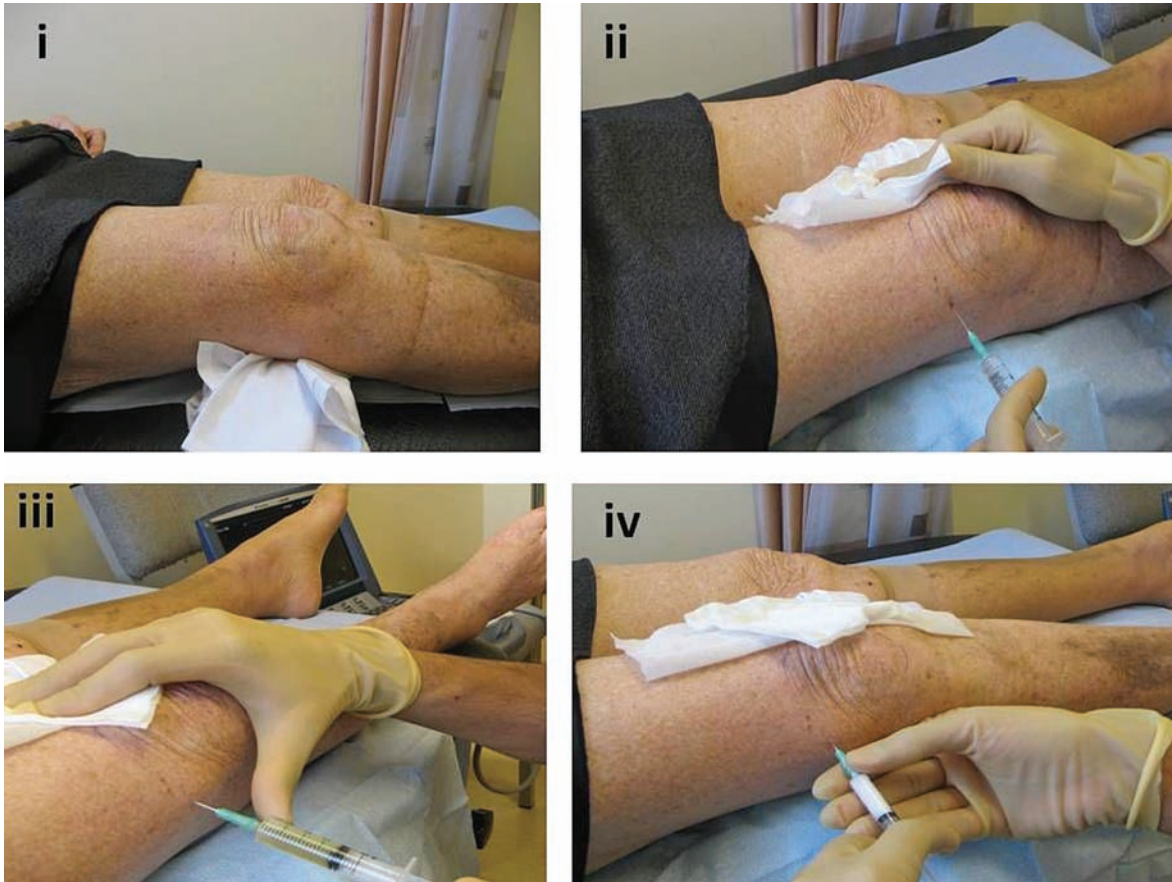
Swelling around the ankle can be related to tendon swelling or subcutaneous oedema rather than joint pathology. Inflamed tendon sheaths can respond well to steroid injections. Posterior tibialis is located posterior to the medial malleolus, anterior tibialis anterolateral, and peroneal tendons posterior to the lateral malleolus. Achilles tendon is usually not injected as there is no tendon sheath and direct infiltration of steroid within the tendon substance may


Fig. 87.12 Knee joint aspiration and injection. Knee joint is approached on the lateral aspect in slightly flexed position and skin marked inferior to the patella (image i, in this case close to the proximal border of the patella). Skin surface is cleaned and needle directed horizontally with free hand pressing on the medial side. Local anaesthetic is infiltrated (image ii) up to the joint which is then aspirated (image iii), syringe then changed and the knee then injected with corticosteroid (image iv).

Fig. 87.13 Ankle joint injection. Here the gap (white arrow) between the anterior tibialis and extensor hallucis longus (outlined by the arrowheads) is marked. Ultrasound is helpful to ensure the location of dorsalis pedis and to visualize joint distension.

lead to rupture. Pain/tenderness around the insertion/calcaneus may be due to retrocalcaneal bursitis, which may respond to intrabursal injection.

- ◆ Needle: 23 or 25G.
- ◆ Caution: avoid injecting against resistance. Use ultrasound if available.

Plantar fasciitis

Heel pain can be due to plantar fasciitis relating to localized tenderness of the proximal fascia close to insertion to the calcaneus. Ultrasound enables measurement of the thickness and aids in the diagnosis of the condition.

- ◆ Approach: direct approach through the sole is usually avoided due to the thickness of the overlying skin and possible increased risk of infection. The entry point is from the medial side to the area of maximum tenderness.
- ◆ Needle: 23G.
- ◆ Caution: small risk of causing rupture.

Hyaluronic acid injections

Hyaluronic acid, also known as hyaluronan, is a high molecular weight glycosaminoglycan present in synovial fluid. It is thought to be critical for the homeostasis of the joint, in part because it provides the viscosity and elastic properties of the synovial fluid. These properties depend on both the concentration and molecular weight of the hyaluronan. In OA, the hyaluronan is lower both in molecular weight and in concentration. Hence the rationale for injecting hyaluronans into OA joints is to increase these properties towards normal—this is termed viscosupplementation. Hyaluronan acts not just as a viscous lubricant but also as a shock absorber during physical activities. Also, there are data suggesting that hyaluronans may act as immunomodulators, and as facilitators of solute exchange, as well as having other properties.[43] These may contribute to their clinical benefit which, in some studies, far outlasts their half-life within the synovial fluid.

Types of hyaluronic acid

There are different types of hyaluronic acids with variable molecular weights, high molecular weight forms usually staying longer in the joints.[44] Macromolecular derivates of hyaluronic acid, mainly of avian cartilage origin, or combinations of hyaluronans and more recently non-animal products, designed to avoid allergic reactions, are available for injections. Most of these products are licensed as devices rather than drugs and they are relatively expensive when compared with injectable glucocorticoid.

Efficacy/safety

There have been numerous studies demonstrating efficacy for the treatment of OA of different joints. These tend to demonstrate more prolonged benefit compared to glucocorticoid for mild to moderate OA.[45,46] However, review of the literature has highlighted some methodological issues for individual studies and a difference in outcomes for different preparations, with no direct studies comparing different hyaluronans. Subsequent RCTs directly comparing glucocorticoids with hyaluronic acid have failed to demonstrate increased duration of benefit with hyaluronic acid.[23,26,47] The local

adverse events are similar to glucocorticoid. Significant flare can occur and can last more than 24 hours, mimicking septic arthritis. In our experience, the presence of an effusion leads to higher risk of flares and any effusion needs to be aspirated prior to injection.

Other injections

Radiation/chemical synovectomy

This treatment can be considered for patients with inflammatory joint disease refractory to treatment including intra-articular steroid injections. Accuracy is extremely important not only for efficacy but also to minimize complications, as extra-articular injection can lead to significant soft tissue irritation. Different radio nucleotides have been used, yttrium-90 being commonly used for the knee joint, with significant evidence of efficacy.[48,49] These substances require special handling and can only be administered by clinicians suitably trained and meeting local requirements. They are contraindicated in pregnancy.

Arthroscopic washout with/without steroid injections

For knee OA, the KIVIS study revealed superior duration of benefit from arthroscopic washout compared to intra-articular glucocorticoid injection.[50] For inflammatory knee arthritis, arthroscopic washout followed by injection was found to have significantly reduced relapse rate when compared with either arthroscopy washout without injection or with intra-articular glucocorticoid injection.[51] However in these two studies the patients were not blinded and it has been previously demonstrated that sham arthroscopy has a strong placebo effect. In addition, arthroscopy is more invasive, with potentially increased risks of complications and is usually only performed by an orthopaedic surgeon in theatre. However there are some rheumatologists who have developed expertise in performing arthroscopies, which can be performed in a suitable non-theatre environment.

Plasma-rich products

Plasma-rich products have been used particularly in sports medicine for the treatment of ligament and tendon injuries such as Achilles tendinopathy. The underlying principle is to provide an injured area with natural growth factors isolated from an autologous blood sample, which is thought to be safe and to promote healing. There is some evidence supporting its use for soft tissue injuries but minimal evidence to support intra-articular use.[52,53]

Biologics

There have been case series reporting efficacy of intra-articular anti-TNF in the treatment of inflammatory knee arthritis. However, RCTs have not shown any benefit from either anakinra in knee OA[54] or of infliximab in inflammatory knee arthritis.[55] The evidence so far therefore does not justify the use of intra-articular biologics.

Conclusion

Joint and soft tissue injections remain a critical aspect of the management of musculoskeletal conditions. Informed consent should be obtained from the patient, taking into account the potential risks and side effects (Box 87.2). The indications for the procedure need to be carefully assessed and in expert hands, injection therapy is safe and effective, causing no or very little discomfort to patients.

| Box 87.2 | Joint injections: contraindications and risks |

Contraindications

Absolute

◆ Local infection

◆ Systemic infection

◆ Allergy to local anaesthetic or glucocorticoid preparation

◆ Arthroplasty

Relative

◆ Anticoagulation

◆ Bleeding diathesis

◆ Syncope after previous procedures

◆ Poorly controlled or unstable diabetes

◆ Imminent surgery to target joint

◆ Overlying skin psoriasis

Side effects and complications

Early (within 1–2 hours)

◆ Pain at injection site

◆ Bleeding/bruising

◆ Syncope

◆ Facial flushing

◆ Anaphylaxis

◆ Nerve trauma

Delayed

◆ Disturbed diabetic control

◆ Post injection flare

◆ Subcutaneous/skin atrophy and depigmentation

◆ Tendon rupture

◆ Septic arthritis

◆ Soft tissue calcification

◆ Avascular necrosis

CHAPTER 88

Diet and obesity

Dorothy Pattison

Introduction

The role of diet in the management of rheumatic disease is being increasingly recognized. Dietary manipulation includes not only measures targeted at obesity but also the introduction or removal of specific nutritional substances.

Osteoarthritis

The primary dietary intervention in the management of osteoarthritis (OA) is the prevention and treatment of obesity. Weight reduction may be influential in slowing disease progression in these patients, particularly of knee OA,[1] and surgical intervention may be avoided. Weight reduction improves the outcome of joint replacement surgery in obese patients. This is an important issue given the increase in both the frequency of knee OA and of partial and total knee arthroplasty for primary OA especially in younger adults (<60 years of age) over recent decades.[2,3] Although no single reason has been identified to explain these findings, an increasingly older and obese population are likely contributing factors. In addition, weight reduction can be part of the management of and impact on related comorbidities.

Pharmacological treatments for OA remain generally palliative and symptomatic and there is little evidence that progression of disease is affected. Drugs can also cause unwanted side effects for some patients. Therefore, the possible use of alternative symptom-relieving treatments, including diet and dietary supplements, is of interest to both health professionals and patients.

Obesity

Obesity is a well-recognized risk factor for the development of OA.[4] A high body mass index (BMI) is also associated with more severe disease in terms of greater pain levels[5] and the need for joint replacement surgery.[6]

Every step taken increases the load on the hip or knee joint by around three to five times body weight, hence the physical stresses imposed on the joints by excessive body weight are considerable.[4] Each kilogram of weight loss will result in a fourfold reduction in the load exerted, for example on the knee, per step during daily activities. Despite this, the effect of obesity on the progression of OA, specifically joint space narrowing, has not been consistently shown. Some studies have shown a higher rate of joint space narrowing in obese subjects compared to non-obese, while others have found no association between obesity and disease progression in knee OA.[7,8] However, a longitudinal study of 3585 subjects aged at least 55 years, with radiographic data at baseline and follow-up, found that a high BMI was associated with loss of joint space in knee OA but not at the hip.[9] The disparity in these results could be due to several factors including study design, patient selection, loss to follow-up, and for knee OA, the degree of knee malalignment. The way in which these joint structures are built and maintained contributes to the development and progression of OA.

Increasing adiposity is also associated with an increased frequency of and worsening symptoms in OA of non-weightbearing joints: for example, primary nodal OA of the hand.[10] This affects mainly middle-aged women in sedentary roles, which cannot be attributed to the effect of increased physical load. This association is most likely related to the metabolic activity of adipose tissue, secreting various inflammatory mediators and hormones, such as cytokines, tumour necrosis factor (TNF), and leptin. The biological activity of adipose tissue may be integral in the aetiology and progression of OA. Thus, a reduction in adipose tissue rather than body weight alone may be responsible for improvement in symptoms.[4] It is most likely the aetiology of OA involves an interaction between mechanical and systemic factors.[3] A study of 22 obese patients with knee OA who completed a weight control programme for 6 weeks clearly demonstrated that reducing fat mass and increasing physical activity gave greater symptomatic relief that could be explained by the reduction in body weight alone.[11] Other clinical trials have also shown that body weight reduction in combination with increased physical activity can improve pain and stiffness symptoms, primarily in OA knee.[12] Patients who are overweight or obese should participate in weight loss programmes aimed at reducing fat mass, particularly abdominal fat mass.[11] Early intervention with dietary guidance and an exercise programme is effective to reduce symptoms of OA.[12]

Comorbidities

Factors consistent with the metabolic syndrome, such as hypertension, hypercholesterolaemia, and insulin resistance are prevalent in OA, in some cases independent of obesity, demonstrating the involvement of significant systemic and metabolic components in the aetiology of OA.[13] However, the efficacy of dietary therapy in cases where hyperlipidaemia and other factors of the metabolic syndrome are present in this population has yet to be demonstrated.[14]

Nutrition and orthopaedic surgery

Hip and knee replacement surgery is mainly performed for OA in late middle age and elderly patients, although recent data suggests an increase in surgery in younger age groups.[2,3] Lower levels of haemoglobin, ferritin, albumin, and protein intakes have been demonstrated in OA and RA patients 10 days after joint replacement surgery compared to preoperative levels, thus impeding postoperative recovery.[15] Poor nutritional status is particularly relevant in elderly and/or frail patients. Nutritional support administered as part of a rapid-recovery programme for lower extremity arthroplasty has demonstrated improved postoperative recovery in elderly patients (measured as decreased hospital length of stay) undergoing hip replacement.[16] Malnutrition remains a somewhat unrecognized, yet preventable, problem in hospital patients and highlights the need for ongoing education on clinical nutrition.

Dietary supplements

Glucosamine and chondroitin

Glucosamine is found naturally in the body. It plays an important role in the synthesis of glycosaminoglycans and glycoproteins which are the building blocks of many structures of the joints. Chondroitin also occurs naturally in the body and is a vital part of joint cartilage. The compound chondroitin sulphate is a complex sugar derived from the cartilage of cows, pigs, and sharks.

Results from randomized controlled trials (RCTs) examining the effectiveness of chondroitin and glucosamine are conflicting. Studies reporting sizeable effects on joint pain tend to be of poor quality and/or small sample size, whereas larger, methodologically robust trials generally found only small or no effects.[14] A meta-analysis of 20 studies of glucosamine in the management of OA of the knee and hip included 2570 patients. Pooled results from studies using a preparation of glucosamine sulphate (1500 mg/day) in patients with symptomatic OA failed to show benefit in pain and function.[17] A more recent meta-analysis of RCTs of glucosamine, chondroitin, or a combination of both included a pooled analysis of 3803 patients with hip or knee OA. No clinically relevant effect of either supplement or in combination was found on perceived joint pain or minimal joint space width.[18] Both meta-analyses reported that glucosamine/chondroitin is safe, compared with placebo.

Herbal and other dietary supplements

As pharmacological treatments for OA are ineffective in some patients and some, such as non-steroidal anti-inflammatory drugs (NSAIDs), can have serious side effects, many patients frequently turn to complementary/alternative medicines (see Chapter 89).

Many manufacturers of dietary supplements claim that their product will reduce symptoms or even alter the course of disease, but there is only weak scientific evidence to support the use of nutritional supplements in the management of OA. Most types of supplements promoted for the treatment of OA are unlikely to cause harm, but some plant-based remedies can be toxic.

A recent systematic review of herbal medicines and plant extracts (oral or topical) in OA included 12 RCTs and 2 systematic reviews. Moderately strong evidence (defined as 3 RCTs or more with significant clinically relevant benefits) was available for one preparation—a compound of plant extracts (Phytodolor), thought to inhibit prostaglandins and inflammatory mediators.[19] Devil's claw (*Harpagophytum procumbens*) and avocado soybean unsaponifiables (ASU) preparations have shown favourable outcomes in at least two RCTs, but for all other oral preparations included in the review there was only weak or no compelling evidence of efficacy.[20]

As yet there is no convincing evidence that fish oil supplementation provides clinical benefit in the clinical management of OA.

Gout

Gout is a common arthritis caused by the deposition of monosodium urate crystals within joints, and usually related to chronic hyperuricaemia. Large-scale studies have identified a number of associations between dietary factors and gout and a substantial burden from comorbidities. Patient education, appropriate lifestyle advice, and treatment of comorbidities are an important part of the management of patients with gout. Evidence supports gradual weight loss with exercise, limiting the consumption of purine-rich foods, sugary drinks, and alcohol, especially beer, not only to reduce the risk of gout but also that of hypertension, dyslipidaemia, and insulin resistance.[21]

Diet therapies in rheumatoid arthritis

RA is a chronic, inflammatory joint disorder that can last for decades, and although pharmacological intervention has been the mainstay of treatment, not all patients respond, and non-drug therapies have a definite place in disease management.[22] Poor eating patterns and nutritionally inadequate diets have consistently been found in people with RA.[23,24] There are various reasons for malnutrition in RA and these should be explored with the individual patient in the clinical setting.

- The pain and fatigue associated with RA can impair appetite considerably, particularly during an acute flare-up.
- The effects of RA on mobility, functional ability, and manual dexterity can make shopping, food preparation and cooking difficult, complex, and tiring.
- Medications for RA can cause nausea and anorexia or interact with nutrients. Examples of the former include NSAIDs and of the latter the effect of methotrexate on folate metabolism.
- So-called 'diets for arthritis' are popular with patients but lack scientific evidence and are very likely to compromise nutritional status

Dietitians and rheumatology occupational therapists (OT) work together to assess dietary intake, functional ability, and the living environment and advise patients how to improve circumstances and help to maintain a desirable nutritional status.

Dietary supplements

Antioxidants

Dietary antioxidant nutrients are associated with the risk of developing inflammatory arthritis.[25,26] A lower intake of vitamin C (lowest third compared to the highest) increased the risk of developing inflammatory polyarthritis more than threefold (adjusted odds ratio 3.3, 95% confidence interval 1.4–7.9).[25] Lower levels of serum antioxidants have been found in healthy individuals who went onto develop RA than those who did not develop the disease.[27] Because

of the study design it is not possible to identify the reason for this: for example, whether it was a low consumption of dietary antioxidants, or antioxidant depletion due to increased activity of the endogenous immune system activity, or a combination of factors.

A recent systematic review concluded that there is no robust evidence that antioxidant supplements, vitamins A, C, E and selenium, provide any symptomatic benefit in patients with RA, OA or other inflammatory conditions.[28] However, individual patients may get some symptomatic improvement with these supplements and if taken in the recommended doses they do not cause harmful side effects.

Dietary fatty acids

The polyunsaturated fatty acids (PUFAs), omega-6 (n-6) and omega-3 (n-3) have several functions but of most importance in arthritis is their function as precursors of inflammatory mediators, including prostaglandins and leukotrienes. Conversion of the n-3 PUFA, α-linolenic acid (ALA) to long-chain n-3 PUFAs eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) and of the n-6 PUFA linoleic acid (LA) to the long-chain n-6 PUFAs dihomo-γ-linolenic acid (DGLA) and arachidonic acid (AA) requires competition for the same enzyme systems. Exogenous sources of AA come primarily from the consumption of meat and meat products whereas oily fish provide the richest source of EPA and DHA. The inflammatory series 2 prostaglandins (PGE_2) and series-4 leukotrienes (LTB_4) originate from AA, whereas EPA is metabolized to the less inflammatory series 3 prostaglandins (PGE_3) and series-5 leukotrienes (LTB_5). EPA-derived PGEs can attenuate the proinflammatory effects of PGE_2 and LTB_4 and decrease the formation of proinflammatory n-6 eicosanoids, but only if the intake of EPA is sufficiently high compared to that of AA. n-3 PUFAs do this by decreasing the amount of AA in inflammatory cell membrane phospholipids and competitively inhibiting the production of AA-derived eicosanoids from cyclooxygenase (COX) and 5-LOX (Figure 88.1).[29,30] n-3 PUFAs can also decrease the production of proinflammatory cytokines (e.g. interleukin-1-beta and alpha (IL-1β, IL-1α) and TNF) and of reactive oxygen species.

Clinical trials of fish oil supplementation in RA have shown consistently favourable outcomes. Evidence from clinical trials of fish oil supplementation has shown that n-3 PUFA-rich supplements taken for a period of 3 months can significantly reduce the tender joint count (mean difference −2.9; p = 0.001) and duration of early morning stiffness (mean difference −25.9 min; p = 0.01) in patients with RA.[31] Furthermore, a meta-analysis of data from 17 RCTs of fish oil supplementation in RA found that n-3 PUFAs taken over 3–4 months significantly reduced patient-reported joint pain (p = 0.03); minutes of morning stiffness (p = 0.003); number of painful and/or tender joints (p = 0.003), and NSAID consumption (p = 0.01).[32] The potential for long-chain n-3-rich cod liver oil supplements to reduce the need for NSAIDs in RA patients has also been shown. In RA patients who consumed 10 g of fish oil, containing 2.2 g n-3 PUFA, daily for 9 months, 40% of patients in the treatment group were able to reduce NSAID consumption by 30% compared with only 10% in the placebo group.[33]

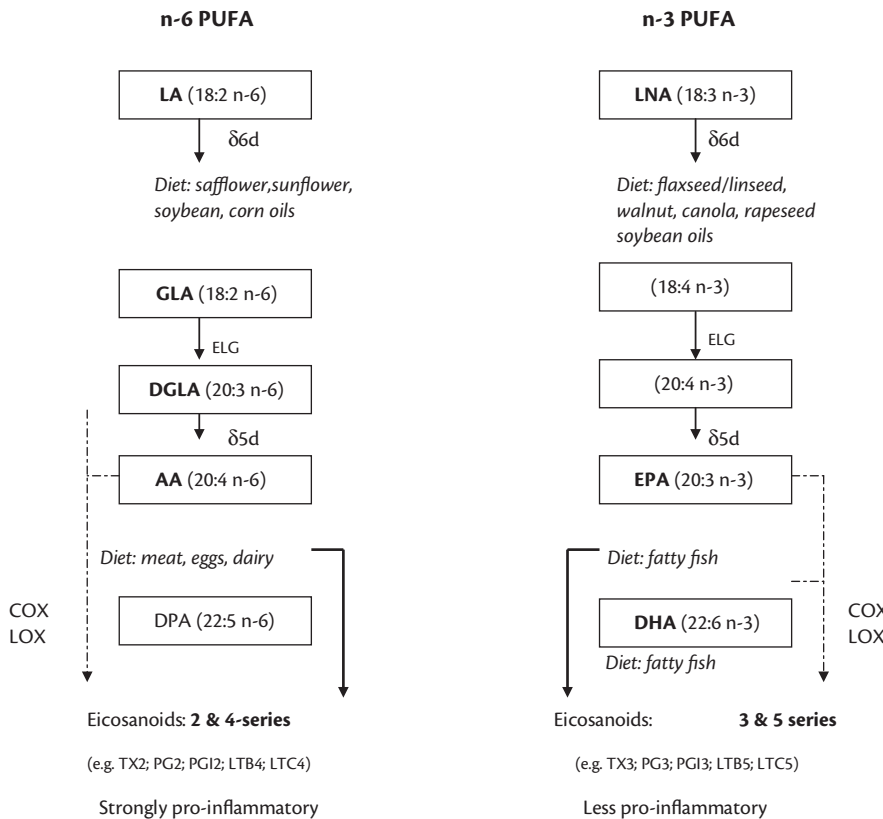
The possible use of n-3 PUFA supplementation as an adjunctive treatment for joint pain associated with RA, with a corresponding


Fig. 88.1 Metabolism of n-6 and n-3 fatty acids. Key: LA: Linoleic acid; GLA: Gamma-linolenic acid; DGLA: Dihimo-gamma-linolenic acid; AA: Arachidonic acid; DPA: Docosapentaenoic acid; LNA: Linolenic acid; EPA: Eicosapentaenoic acid; DHA: Docosahexaenoic acid; COX: Cyclooxygenases; LOX: Lipoxygenases; ELG: Elongase; PG: Prostaglandin; LT: Leukotrienes; TX: Thromboxanes

reduction in NSAID use, thus attenuating the risk of gastrointestinal and/or cardiovascular side effects associated with these drugs, is not routinely considered in clinical practice.[33]

The benefits gained from increasing n-3 PUFA intake are thought to be enhanced by a simultaneous reduction in the consumption of n-6 PUFAs, thus increasing the n-3 PUFA to n-6 PUFA ratio.[34] It is of some note that over the past 100 years or so, the Western diet has become increasingly rich in n-6 PUFAs while the consumption of n-3 PUFAs has been decreasing.

Other supplements

As in many people with chronic diseases, the use of dietary therapies and complementary and alternative medicines (CAMs) are popular in patients with RA.

Common supplements include cod liver oil, evening primrose oil, iron, garlic, apple cider vinegar, vitamin C, selenium, B vitamins, calcium, general multivitamins and antioxidant supplements; extract of New Zealand green-lipped mussel; gamma-linolenic acid (GLA)-rich oils such as evening primrose oil, borage seed oil, or blackcurrant seed oil.[35,36] There is only weak or no evidence to support the use of these supplements in the management of RA symptoms. Gastrointestinal side effects were increased with GLA supplementation.[36]

Food intolerance and exclusion diets

Starvation greatly reduces symptoms in RA; for example, in the pre/postoperative state. It has been reported that the withdrawal of food in patients with RA results in a decreased production of the chemical mediators of inflammation but with the return of symptoms on the reintroduction of foodstuffs.[37]

Observational studies have reported food intolerance in RA patients, most commonly to milk, corn, wheat, and azo dyes, but there is no evidence that the prevalence of food intolerance is greater than in the general population or that the practice of food avoidance can be recommended to RA patients.[38] However, self-imposed food restrictions are popular with RA patients, most commonly citrus fruits, tomatoes, vinegars, pickles, dairy products, red meat, and alcohol. Clearly, the greater the number of foods avoided the greater the risk of malnutrition or nutrient deficiency.

Vegetarian and vegan diets

Vegetarian diets (preceded by fasting) for up to 4 months duration have resulted in symptomatic benefits in RA such as duration of morning stiffness, number of tender and swollen joints, and joint pain. However, there have been only a few studies, all with small sample size and at high risk of confounding.[39] Evidence is lacking for the routine use of vegan diets in the management of RA symptoms.

Although symptomatic improvements are experienced after fasting and/or elemental diet or vegetarian diet, the reasons for this are unclear. It is possible that the effect of excluding certain foods on symptoms of RA correlates with a reduction in antibodies to a food antigen,[40] or that inflammatory activity is attenuated by caloric restriction or reduction in gut involvement. However, these effects could also be a result of coincidental disease remission or weight loss, or due to a placebo effect.[37]

Mediterranean-type diet

Despite the folklore a 'diet for arthritis' has never been proven. However, there is evidence to support the role of n-3 fatty acids in the amelioration of inflammation and RA symptoms, with some epidemiological evidence for a role of antioxidants in reducing the risk of inflammatory arthritis.[25,26,41] Although conflicting results have been reported, high red meat consumption may have a role in increasing the risk of developing RA.[42,43] These studies have investigated foods individually, but collectively they form the basis of a Mediterranean-type diet which may provide symptomatic benefit in patients with RA. Studies of other foods and nutrients which have been investigated for a role in the aetiology of RA have been reviewed elsewhere.[44]

A modified Mediterranean diet followed for 3 months resulted in a significant reduction in disease activity (DAS28 score), functional ability (Health Assessment Questionnaire (HAQ) score), and improved vitality, compared to following a control diet.[45] Despite an increase in reported consumption of antioxidant-rich foods in the Mediterranean diet group, the levels of plasma antioxidants and urinary malondialdehyde (MDA), a marker of oxidative stress, did not change, although plasma levels of vitamin C, retinol, and uric acid were inversely correlated to variables related to RA disease activity.[46]

In a study which used a very different approach, women with established RA (n = 75) who came from socially deprived areas of Glasgow completed a 6 week educational programme with an emphasis on cooking and eating a 'Mediterranean-type' diet. Controls (n = 55) were given general healthy eating information only. Compared with controls, women in the intervention group reported a healthier dietary intake and showed significant improvement in patient global assessment at 6 months, pain score at 3 and 6 months, duration of early morning stiffness at 6 months, and HAQ score at 3 months.[47]

Comorbidities

Obesity is common in RA patients, partly due to a reduction in physical activity as a consequence of their symptoms of pain, stiffness, and poor mobility. Obesity is associated with the presence of traditional cardiovascular disease (CVD) risk factors as it is in the general population.[48] Patients with RA have an increased risk of CVD, especially ischaemic heart disease (IHD) and heart failure, and more than 50% of premature deaths in RA are due to CVD.[49] In fact, recent studies suggest that CVD mortality and morbidity in RA are of similar magnitude to that seen in people with type 2 diabetes mellitus.[50] The increase in risk of CVD observed in RA may be because traditional risk factors for CVD occur more frequently in RA, or that they have an additional deleterious effect. Alternatively, some of the excess CVD risk might be explained by the adverse impact of inflammation and immune changes of RA on blood vessel walls.[49] Abdominal fat is associated with insulin resistance and inflammatory load in patients with RA and in such patients is distributed differently between visceral and subcutaneous compartments, with visceral fat being more strongly associated with CVD risk than subcutaneous adiposity.[51] Since RA is an independent risk factor for IHD, cardiovascular risk assessment should be applied in all patients and dietary measures to treat obesity and CVD risk factors offered where appropriate. Although hyperlipidaemia is less frequent in RA than the general population, a meta-analysis confirmed that dyslipidaemia might affect up to half of all patients with RA, principally low levels of high-density lipoprotein (HDL) cholesterol.[52] Further studies are required to assess the value of dietary modification

for dyslipidaemia and obesity in this population. However, until more is known the best strategy is to manage risk factors as for the general population, along with aggressive treatment of disease activity. Future research is needed to establish whether using lower targets for cholesterol and blood pressure management will be of benefit of CVD risk factors.

Anaemia in rheumatoid arthritis

Tiredness and fatigue are common in RA, caused in part by anaemia, a well-recognized complication of RA, even early on in disease.[53] The most common is a normochromic normocytic anaemia related to disease severity in the so-called 'anaemia of chronic disease' (ACD), in which iron and ferritin levels are not reduced, and responds to better disease control. Iron deficiency may be caused either by blood loss from chronic gastrointestinal ulceration and long-term NSAID or by a poor diet. Iron supplements are recommended for the former but not necessarily for the latter, where the deficiency can be corrected if foods rich in iron are eaten regularly (e.g. lean red meat especially offal, eggs, green leafy vegetables, pulses, dried fruits, and fortified breakfast cereals). The absorption of iron from food is enhanced if a source of vitamin C is eaten at the same time. A glass of orange juice at mealtimes is a good example. It should not be assumed that anaemia in RA is due to ACD, and all patients should be screened for other causes, especially vitamin deficiencies as these are so easily corrected, and further prevented with the correct nutritional and dietary advice.

Osteoporosis

Patients with RA and other forms of inflammatory arthritis are at an elevated risk of developing osteoporosis (see Chapter 142). RA is an independent risk factor for osteoporosis, thus risk assessments should be applied in all patients and dietary measures to maintain bone mass offered where appropriate. Dietary advice focuses on an appropriate calcium intake from the diet (e.g. from dairy products including low fat types; fruit and vegetables, especially green leafy vegetables; soya drinks with added calcium, and fish with edible bones). Calcium supplementation is usually only necessary when dietary intake is insufficient, combined with inadequate exposure to sunlight. Dietary sources of vitamin D are few: they include oily fish, eggs, fortified breakfast cereals, and margarines.

Other forms of arthritis and arthralgia

Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is an autoimmune disease that primarily affects young women, particularly of Afro-Caribbean and Asian origin. Evidence is lacking for any definite dietary triggers although anecdotal experience may be relevant to individual patients. Adults with SLE have an increased risk of cardiovascular mortality and morbidity, compared with the general population, with the risk increasing with disease duration, although this complication is apparent even in the early years of the disease.[49] As well as the standard and intensive treatment of active disease, the recommended management strategy for SLE should include screening for and management of traditional cardiovascular risk factors using at least the same targets as used for the general population. Future research is needed to establish if more aggressive management of obesity, cholesterol levels, and blood pressure, for example, will be of benefit.[49]

Vitamin D and joint pain

There has been increased interest in the role of vitamin D in musculoskeletal conditions in recent years since the measurement of vitamin D levels are now readily available.

The findings of a recent study in Ireland are of some relevance. Of 231 consecutive new patients to general rheumatology clinics 70% had vitamin D deficiency (defined as ≤53 nmol/litre) and 26% had severe deficiency (defined as ≤25 nmol/litre).[54] In patients diagnosed with OA and inflammatory joint disease 62% and 69% respectively were deficient in vitamin D.

Osteomalacia is a bone disease caused by chronic and severe calcium, vitamin D, or phosphate depletion of any cause. Bone pain, muscle weakness, tenderness, and difficulty walking are common manifestations of osteomalacia. In past years the most common causes of osteomalacia were malabsorption or prolonged lack of exposure to sunlight. However, nutritional deficiency, often in combination with UV light deficiency, is now a more common issue in the United Kingdom.

CHAPTER 89

Alternative therapies

Edzard Ernst

Introduction

This chapter is aimed at briefly summarizing the evidence regarding a range of alternative therapies for rheumatic conditions. As this is a very broad area, the focus is on areas where recent reliable evidence has become available.

Definitions

The terminology around alternative medicine is confusing. Ill-defined terms such as 'complementary', 'natural', 'holistic', or 'integrative' medicine are frequently used almost interchangeably. To avoid misunderstandings, this chapter merely discusses specific interventions and, as far as possible, avoids such umbrella terms. Short definitions of the alternative therapies covered in this chapter are provided in Table 89.1.[1]

Prevalence

The prevalence of the use of alternative therapies varies considerably from country to country. There is, however, general agreement that pain caused by rheumatic conditions is high on the list of reasons for patients to try alternative therapies. The lifetime prevalence of alternative therapy usage in the United Kingdom is 51% for pain and 38% for arthritis.[2]

Acupuncture

Acupuncture typically involves manual needling at specific points, but many variations of this theme exist. Numerous (around 1000) clinical trials have been published and are summarized repeatedly in systematic reviews. A recent overview included 57 systematic reviews of acupuncture for pain published since 2000.[3] Unanimously positive conclusions from more than one high-quality systematic review existed for only neck pain. The National Institute for Health and Clinical Excellence (NICE) recently recommended acupuncture as a treatment of persistent low back pain but not for osteoarthritis of the knee. For both indications, the evidence from systematic reviews is predominantly but not unanimously positive.[3]

Acupuncture is associated with sizeable placebo effects and only some trials adequately control for them. There is also evidence that the (non-verbal) interactions between the acupuncturist and the patient modify the clinical outcome.[4] As acupuncturists are never blinded to group allocation, this factor cannot easily be controlled for in clinical trials and may thus influence their results.

Several large prospective studies suggest that acupuncture is relatively safe; only about 10% of patients experience mild, transient adverse effects.[5] These studies have been conducted with relatively well-trained acupuncturists in the West, and their findings may thus not apply to other situations. Serious adverse effects, including death, continue to be associated with acupuncture.[3]

Chiropractic spinal manipulation

Chiropractors mostly but not exclusively treat back pain. NICE has recently recommended spinal manipulation or mobilization for persistent low back pain. Yet the evidence is not as straightforward as it may seem; a more recent Cochrane review included 26 randomized controlled trials (RCTs) and concluded that 'high quality evidence suggests that there is no clinically relevant difference between spinal manipulative therapy and other interventions for reducing pain and improving function in patients with chronic low back pain'.[6] Therefore other factors such as cost or safety (see below) should determine the choice of the optimal therapeutic approach.

For other rheumatic conditions, the evidence is even less convincing. Based on 33 RCTs, a Cochrane review demonstrated that, when combined with exercise, spinal manipulation treatments are beneficial for neck pain but, when done alone, they are not.[7] We concluded, in a systematic review of four RCTs which tested the effectiveness of chiropractic spinal manipulation for neck pain, that none of the studies 'convincingly demonstrated the superiority of chiropractic spinal manipulation over other interventions'.[8]

For other rheumatic conditions, including fibromyalgia and carpel tunnel syndrome, the evidence fails to suggest that chiropractic spinal manipulation is an effective treatment.[9] Reviews that arrive at more positive conclusions are misleading as they are not specifically of chiropractic manipulation but also include modalities such as exercise and other physical therapies (e.g. Schneider et al.[10]).

Chiropractic is associated with sizeable placebo effects which are difficult to control for in clinical trials.[11] Thus some of the outcomes seen in some of the RCTs might not rely on any specific effects of chiropractic spinal manipulation.

Chiropractic spinal manipulations are associated with an extraordinarily high rate of adverse effects. About one-half of all patients

Table 89.1 Definition of some relevant alternative therapies

Therapy	Definition
Acupuncture	Insertion of a needle into the skin and underlying tissues in special sites known as points for therapeutic or preventive purposes
Chiropractic	A health profession concerned with the diagnosis, treatment, and prevention of mechanical disorders of the musculoskeletal system, and the effects of these disorders on the function of the nervous system and general health. There is an emphasis on manual treatments including spinal manipulation or adjustment
Herbal medicine	The medical use of preparations that contain exclusively plant material
Homeopathy	A therapeutic method, often using highly diluted preparations of substances whose effects when administered to healthy subjects correspond to the manifestations of the disorder (symptoms, clinical signs and pathological states) in the unwell patient
Magnet therapy (static)	Application of static magnetic fields for therapeutic purposes
Massage therapy	A method of manipulating the soft tissue of body areas using pressure and traction (with primary focus on 'Swedish massage')
Osteopathy	Form of manual therapy (and diagnosis) involving the manipulation of soft tissues and the mobilization or manipulation of peripheral and spinal joints
Qigong	An Asian healing art that uses gentle, focused, exercises for mind and body to increase and restore the flow of qi (life energy) or to accumulate qi with the aim of encouraging and accelerating the healing process
T'ai chi	A system of movements and postures rooted in ancient Chinese philosophy and martial arts used to enhance mental and physical health

From Ernst et al.[1]

experience mild to moderate symptoms for one or two days.[12] In addition, several hundred cases of severe complications are on record. They are frequently caused by vertebral arterial dissections after neck manipulations (e.g. Di Fabio[13], Ernst[14]). Considering these risks, it is difficult to conclude that chiropractic is associated with a positive risk–benefit profile.

Herbal and other supplements

Two systematic reviews of herbal and other dietary supplements have been published by the charity Arthritis Research UK. One was based on seven RCTs and concluded that 'there is insufficient evidence on any complementary and alternative medicine, taken orally or applied topically, for fibromyalgia'.[15] The second review included 56 RCTs of supplements for the treatment of osteoarthritis (OA). It found

> consistent evidence that capsaicin gel and *S*-adenosyl methionine were effective in the management of OA. There was also some consistency to the evidence that Indian Frankincense, methylsulphonylmethane and rose hip may be effective. For other substances with promising evidence, the evidence base was either insufficiently large

or the evidence base was inconsistent. Most of the CAM [complementary and alternative medicine] compounds studied were free of major adverse effects.[16]

A Cochrane review of herbal medicines for rheumatoid arthritis (RA) included 22 RCTs.[17] The authors found that:

> there is moderate evidence that oils containing GLA [gamma-linolenic acid] ((evening primrose, borage, or blackcurrant seed oil) afford some benefit in relieving symptoms for RA, while evidence for Phytodolor® N is less convincing. *Tripterygium wilfordii* products may reduce some RA symptoms, however, oral use may be associated with several side effects.[17]

Specifically reviewing the RCT evidence for Ayurvedic herbal medicine for RA, we found seven such studies. The quality of these trials was disappointing and we concluded that they 'fail to show convincingly that such treatments are effective therapeutic options'.[18]

Even though many studies and systematic reviews have investigated the efficacy of chondroitin and glucosamine for osteoarthritis, the results continue to be contradictory. This is perhaps best summarized by quoting two recent and authoritative systematic reviews. Black et al. provided an overview of five systematic reviews and concluded that 'there was evidence that glucosamine sulphate shows some clinical effectiveness in the treatment of osteoarthritis of the knee'.[19] Yet a more recent meta-analysis arrived at far less optimistic conclusions: 'Compared with placebo, glucosamine, chondroitin, and their combination do not reduce joint pain or have an impact on narrowing of joint space'.[20]

The safety of supplements is a complex issue for which generalizations are problematic. Some seem to cause little more adverse effects than placebo, while others are outright toxic.[21] Other safety issues to consider are interactions with prescription drugs, contamination (e.g. with heavy metals), and adulteration with prescription drugs. Thus risk–benefit profiles have to be checked for each category and perhaps even for every preparation on offer.

Homeopathy

Homeopathy is perhaps the most implausible of all alternative treatments. Yet it is popular in many countries, particularly for the treatment of chronic conditions. Therefore it is relevant to know the evidence related to this subject.

A systematic review included four RCTs of homeopathy for osteoarthritis. Because of the low number and quality of the studies no firm conclusions regarding effectiveness were deemed possible.[22] Another systematic review included four RCTs of homeopathy for fibromyalgia. Because of the paucity of the trial data, no firm conclusions could be drawn about the effectiveness of homeopathic remedies.[23] A recent RCT was aimed at assessing whether the benefit many patients suffering from RA seem to experience after consulting a homeopath is due to specific effects of the homeopathic remedy or the non-specific effect of the consultation. The study used a factorial cross-over design and the conclusions could not have been clearer: 'homeopathic consultations but not homeopathic remedies are associated with clinically relevant benefits…'.[24]

Homeopathy is generally considered to be risk-free. This may apply to the homeopathic remedy but not necessarily to the homeopath. For instance, homeopaths frequently advise patients to forego effective treatments in favour of homeopathy.[25] On balance, therefore, the risk–benefit profile of homeopathy is not positive.

Magnet therapy

Many patients suffering from rheumatic conditions wear static magnets in the form of bracelets, belts, inlays, etc. in the hope of reducing pain effectively. Our systematic review of nine RCTs testing the effectiveness of this approach came to a sobering conclusion:

> The evidence does not support the use of static magnets for pain relief, and therefore magnets cannot be recommended as an effective treatment. For osteoarthritis, the evidence is insufficient to exclude a clinically important benefit, which creates an opportunity for further investigation.[26]

Direct adverse effects of static magnets are not to be expected. Yet, considering the often considerable costs of such devices, patients should be discouraged from using them.

Massage therapy

There are many variations of massage therapy—e.g. Shiatsu, Bowen technique, soft tissue massage, lymph drainage, Rolfing—of which 'Swedish' or classical muscle massage is the best-researched and most popular.

A Cochrane review included 13 RCTs of massage therapy for low back pain. Eight of these studies were of poor methodological quality. Even though most results suggested effectiveness, the authors drew cautious conclusions: 'Massage might be beneficial for patients with subacute and chronic non-specific low back pain…'.[27]

A systematic review of 19 RCTs of massage therapy for neck pain arrived at even more cautious conclusions. Most of the studies were of low quality and only six tested massage as a stand-alone therapy. The authors stated that 'the effectiveness of massage for neck pain remains uncertain'.[28]

A systematic review of massage for fibromyalgia symptoms included six RCTs. All of them suggested short-term benefits but all had serious methodological limitations. Therefore the author concluded that the RCT data provide 'modest support for the use of massage therapy in treating fibromyalgia'.[29] For other rheumatic conditions, the evidence related to massage therapy is too scarce to arrive at meaningful verdicts.

The risks of adequately administered massage therapy are very minor. The adverse effects that have been reported are rare and mostly due to inadequate technique or incompetent therapists.[30]

Osteopathy

Osteopathy is a manual treatment with many similarities to chiropractic (see above). In the United States, osteopaths are a fully recognized medical profession that today uses most conventional treatments alongside osteopathic techniques. In most other countries, osteopaths are considered alternative practitioners. Thus, in the United States, osteopaths would treat any condition, whereas elsewhere they would mostly treat musculoskeletal complaints.

A systematic review including six RCTs of osteopathic manipulations for low back pain concluded that this approach generates greater pain reductions than a range of active control interventions, placebo, or no treatment at all.[31] Our own systematic review of osteopathy for any type of musculoskeletal pain included 16 RCTs.[32] Their methodological quality was mostly poor. Only five of these studies suggested that osteopathy might cause more pain reduction than various control interventions. The evidence for other rheumatic conditions is scarce and unconvincing.[1,33]

Like other physical treatments, osteopathy might be associated with relatively large placebo effects. These are difficult to control for in RCTs. Thus some of the positive results might at least partly rely on non-specific results rather than specific effects of the treatment per se.

Osteopathy is, like chiropractic, associated with both frequent mild and infrequent serious adverse effects.[34] However, osteopathic techniques tend to be less forceful and less often include rotational thrusts of the cervical spine. Thus serious complications such as vertebral artery dissection seem to occur less frequently than with chiropractic.[34]

Qigong

Qigong is a traditional Chinese method; two different forms can be differentiated. External qigong is a form of 'energy healing' where a therapist channels healing 'energy' into a patient's body. This 'energy' allegedly stimulates the body's capacity to heal itself.

A systematic review of external qigong for reducing pain from any condition included five RCTs.[35] Some of these studies suggested positive effects; however, most were burdened with significant flaws. Thus firm conclusions about the effectiveness of this approach are not possible.

Internal qigong uses gentle, slow, meditative exercises. This allegedly increases the flow of energy through the body which, in turn, stimulates the body's healing capacity. A systematic review of this approach for reducing pain of any origin included four RCTs and three non-randomized studies.[36] Most of these studies included patients suffering from musculoskeletal problems. Again, most trials were of disappointing methodological quality. Even though these data included several encouraging results, the overall conclusion was that the totality of the evidence is less than convincing.

No serious risks have been associated with either form of qigong.

T'ai chi

T'ai chi is a meditative form of aerobic exercise involving slow movements, relaxation, and deep breathing techniques. It originates from China and has recently become popular in many Western countries.

Our systematic review included nine RCTs of t'ai chi for osteoarthritis most of which had significant methodological flaws.[37] A meta-analysis generated a positive effect on pain, physical function, and joint stiffness compared with a range of control interventions. Because of the relative small number of RCTs and their often weak designs, the conclusion had to be cautious.

For RA the evidence is less convincing. A systematic review found just two RCTs and three non-randomized studies.[38] Even though some positive results were reported in some trials for t'ai chi on disability, quality of life, and mood of patients with RA, the more rigorous RCTs failed to demonstrate any relevant clinical benefit.

T'ai chi is generally regarded as safe and no serious complications are to be expected.

Conclusion

This overview indicates that, in general, the evidence related to alternative therapies for rheumatic conditions is scarce. Few rigorous trials are available from which to draw firm conclusions about

their efficacy in common rheumatic diseases. For less common rheumatic conditions, good evidence is almost entirely absent (e.g. Chou[39]). The safety of these approaches remains grossly under-researched. Thus it is impossible to be certain whether any alternative treatments generate more benefit than harm.

Even in areas where the evidence seems encouraging, important caveats persist. For instance, the quality of the research is often disappointing. Another concern is the clinical relevance of any documented effects. In most cases, they are small and thus questionable. In no case are they demonstrably superior to those of conventional therapeutic options.

Thus it seems that the popularity of alternative treatments is currently not supported by the findings from reliable scientific investigations.

Principles of upper limb surgery

Ian McNab and Chris Little

Introduction

Inflammatory arthritis primarily involves synovial tissue. The associated immune response releases cytokines and degradative enzymes that lead to articular cartilage destruction, and the attenuation of joint-stabilizing ligaments and tendons. The mainstay of treatment of inflammatory joint disease is medical control of synovitis. However, if the symptoms persist despite optimal medical management and, in particular, once irreversible joint damage has occurred, reconstructive surgical treatment may be indicated. Wherever possible this should be undertaken before the patient becomes severely incapacitated; salvage options exist where irreversible damage has arisen, but prophylactic interventions are better.

Most patients referred for a surgical opinion on the management of a rheumatic disease have rheumatoid arthritis (RA), but the surgical principles of managing most inflammatory arthropathies are similar. This chapter therefore focuses primarily on the principles of managing RA, using this as an exemplar for similar conditions. Box 90.1 shows the investigations that may be required prior to surgery.

Operative treatment

Patient fitness should be optimized, ideally with good medical control of synovitis and no chest, urinary, or skin sepsis. Care must be taken perioperatively with renal function, hydration, and increased steroid requirements (see Chapter 93).

Surgical treatment forms only a part of the continuing management of the patient by the whole medical team. Active disease and the use of glucocorticoids are not contraindications to surgery, although the timing of surgery will need to consider cycles of biological or some immune-suppressive treatments.

Ultimately a successful outcome for patients (especially when undergoing upper limb surgery) is determined by matching the correct patient to the correct procedure, meticulous attention to surgical detail and technique, and especially by the motivation and hard work of the nurses, physiotherapists, occupational therapists, and patients themselves, during their postoperative rehabilitation (see Box 90.2).

Box 90.2 General perioperative considerations

- Timing of surgery in relation to medical treatment/control of arthritis (optimized with DMARDs—usually continued)
- Use of immunosuppressants and/or steroids increases the risk of infection
- Past medical history, general health, treatment history
- Cardiovascular and respiratory assessment, poor jaw mobility, micrognathia, reduced lung capacity, range of cervical spine movement (imaging to exclude subluxation), anticipate potential anaesthetic problems
- Walking ability and use of suitable walking aids, presence of significant lower limb problems, thoracolumbar spine problems
- Skin condition (including ulcers or thin skin)
- Presence/treatment of vasculitis
- Presence/treatment of osteoporosis
- Anaemia of chronic disease
- Polyarticular involvement with contractures—risk of pressure sores, requires careful positioning/padding
- Home environment, and functional abilities/requirements
- Optimization of occupational therapy, physiotherapy, splints, and aids

---

Box 90.1 Investigations prior to surgery

- Plain radiograph (usually suffices)
- Ultrasound scan (synovium, tendon, ligament)
- MRI
- Biopsy (confirm diagnosis, exclude infection)

The order of procedures should be tailored to the individual. Operations most likely to be successful are usually performed first, in order to build patient confidence. It is usually best to correct lower limb abnormalities before addressing upper limb problems because of the potential for damage to upper limb reconstructions with subsequent use of walking aids. In patients who require intubation, it is essential to check their clinical and radiographic cervical spine mobility and stability. Patients are susceptible to perioperative pressure sores and peripheral compression neuropathies.

Upper limb surgical management

Rapid improvements in medical treatment appear to be impacting on the course and pattern of RA presenting to upper limb surgeons. However, RA continues to cause pain and impaired function for patients, many of whom still require reconstructive surgery to their shoulders, elbows, hands, and wrists. The basic principles of this surgery are to preserve hand function and to maintain stable, comfortable proximal upper limb joints that will allow the patient to position their hand in space adequately, so that it can perform its essential functions.

Patient assessment and planning upper limb surgery

Initially, patients adapt their activities to accommodate their reduced upper limb function. However, if their function and pain continue to deteriorate despite maximal medical therapy, physiotherapy, occupational therapy, functional aids, and night splintage (to slow the progression of deformities), then they may require surgical intervention.

Patients with these complex and challenging upper limb, hand, and wrist problems require a highly integrated approach to their assessment and treatment. This is often best provided at a combined medical and surgical RA clinic. The extended multidisciplinary team includes rheumatologists, radiologists, nurses, physiotherapists, occupational therapists, surgeons, and anaesthetists (see Box 90.3 for a checklist prior to upper limb surgery).

The primary goals of any surgical treatment are to help alleviate pain and to maintain or improve function. A secondary consequence of correcting deformities may also be an improved appearance, particularly of the hand.

In addition to careful patient selection, and meticulous surgical planning and technique, extremely careful physiotherapy and hand therapy are also required to ensure success following all of the procedures listed below.

Indications and timing of surgery

The indications for and the timing of surgery are discussed in the sections relating to each anatomical region in the upper limb. However, these general principles must be carefully tailored to each individual patient's clinical presentation, general health, the current status of their RA, their optimal medications and the degree of disease control, the available physiotherapy and occupational therapy support, and their social and functional requirements and abilities (for home, work, and hobbies).

In patients who require multiple surgical interventions, careful planning is required as to which order to perform the procedures, and on which occasions. This initial plan may need to be adjusted as the programme of surgical treatment progresses.

> **Box 90.3** Surgical assessment checklist prior to hand and upper limb surgery
>
> - Global upper limb examination: shoulder and elbow movements—positioning the hand in space for function (above the head, behind the back); adequate shoulder abduction and external rotation is required for regional anaesthetic and surgical positioning
> - Test forearm rotation: supination and pronation requires free movement of both the proximal and distal radioulnar joints (elbow and wrist).
> - Assess distal radioulnar joints and extensor tendons
> - Assess carpal tunnel and flexor tendons
> - Wrist movement should be approximately 50:50 radiocarpal and midcarpal joint function
> - Check thumb CMC and MCP joints and look for swan-neck and boutonnière deformities
> - Check fingers for MCP disease, ulnar drift or subluxation, abnormalities of PIPs and DIPs, and the presence of swan-neck and boutonnière deformities
> - Test the intrinsic muscles which flex the MCP and extend the PIP joints and are placed under maximum tension when the MCP joints are passively extended and the PIP joints are passively flexed
> - Intrinsic tightness test: compare PIP flexion with the MCP joint in extension vs flexion
> - Assess skin and nails
> - Neurovascular assessment—specifically check for nerve compression
>
> CMC, carpometacarpal; DIP, distal interphalangeal; MCP, metacarpophalangeal; PIP, proximal interphalangeal.

Because lower limb generally requires the patient to mobilize with walking aids (so weightbearing through the upper limbs) postoperatively, these should usually be addressed prior to embarking on upper limb surgery.

If multiple-level surgery is required in the upper limb itself, it is generally best to correct problems sequentially working from proximal towards more distal joints, or to address the most symptomatic or severely affected region first.

The concept of performing a 'winner procedure' as the first operation is also important. These procedures should have both predictable and good results without undue rehabilitation requirements that will hopefully ensure the patient's first experience of surgery is a positive one. Therefore, replacement arthroplasty of the shoulder or elbow, or arthrodesis (or arthroplasty) of the wrist is often undertaken first.

Occasionally, urgent surgery is required to prevent sudden further deterioration. For example, following rupture of the extensor tendons to the little finger, urgent excision of the ulnar head and tenosynovectomy is required to prevent multiple extensor tendon ruptures.

Shoulder

Acromioclavicular joint

This is commonly affected by rheumatoid synovitis, often with radiographic changes, but because symptoms are similar to those from rotator cuff disease it is important to determine the source of pain. The typical features of acromioclavicular joint (ACJ) involvement in RA are:

◆ Pain usually well localized to the joint.

◆ Pain reproduced by high arc (>120°—end of range) elevation movements (abducting the outstretched arm above the patient's head) and by horizontal flexion (crossing the arm towards the opposite shoulder when elevated by 90°; the 'scarf test').

◆ The ACJ is tender.

Initial treatment is by intra-articular steroid. Since the orientation of the joint varies (lateral clavicle often over- or underrides the acromion), a plain radiograph shows the best angle for the needle. Surgery should be considered if this fails to improve the symptoms; excision arthroplasty (arthroscopically removing the lateral centimetre of the clavicle) improves symptoms in 80% of patients

Glenohumeral joint

The radiographic pattern of disease may be

◆ dry (with loss of joint space, bony sclerosis, and marked stiffness)

◆ wet (with marked synovitis, marginal humeral head erosions, and central glenoid erosion)

◆ resorptive (with marked bone loss, often with glenoid loss down to or beyond the coracoid process).

Intra-articular steroid injections can give good transient relief. The degree of bone loss, particularly from the glenoid, often makes total shoulder replacement inadvisable, due to problems with securely fixing a glenoid component in place, and hemiarthroplasty (humeral head replacement) is usually used, giving good pain control but limited improvement in function. Reverse geometry replacements (with a ball—glenosphere—placed in the glenoid, and a cup in the proximal humerus) carries potential advantages where the cuff is deficient, but glenoid bone loss will often render this inadvisable.

Rotator cuff

Impingement pain is felt in the region of the deltoid insertion with arm elevation. Rest and night pain occurring in a similar area suggests that a cuff tear is present (seen in up to 40%) with loss of movement due to pain or altered shoulder mechanics if the tear is large (which may give rise to a lag sign, with the patient unable to maintain the position of the passively placed arm, indicating a massive tear).

Initial non-operative treatment is indicated, with steroid injections into the subacromial bursa and physiotherapy to improve scapular positioning, because cuff repair is often technically difficult due to poor tissue quality, which would result in a high rate of repeat tears. Arthroscopic surgery to debride the bursa often helps those patients who respond transiently to non-operative treatments (even those with full-thickness cuff tears). Fistula formation from the arthroscopic port sites is more common than in non-rheumatoid patients.

Elbow

Ulnohumeral and radiocapitellar joints

This can present with:

◆ diffuse pain around the elbow

◆ stiffness, with loss of function; elbow flexion/extension and forearm rotation can be affected, causing difficulty with positioning the hand.

◆ instability due to bone erosion and soft tissue attenuation ('flail elbow').

Radiographic changes do not directly correlate with symptoms. Intra-articular steroid injections may help transiently with the pain from synovitis; optimizing systemic disease control is also required for longer-term improvement. Some patients, particularly those with lateral pain and restricted forearm rotation, are helped in the medium term by radial head excision coupled with a synovectomy; however, symptoms commonly recur.

Joint replacement components may be unlinked (surface replacement of the distal humerus and proximal ulna, with excision of the radial head), with stability dependent on soft tissue balance and reconstructions. Alternatively, linked components can be used (the humeral and ulnar components are connected, providing stability but potentially increasing mechanical loosening with time), particularly in flail elbows. 'Sloppy hinge' implants allow a little varus/valgus tilt between linked components to minimize mechanical loosening.

In the absence of complications, pain control is usually good and motion improved by around 20° of flexion/extension. The risk of infection or wound breakdown and nerve damage (ulnar nerve) is greater than with other commonly replaced large joints (hip/knee), and radiographic loosening is common (but may be asymptomatic, particularly given the polyarticular nature of the patient's disease). The 5 year implant survival rate (with revision surgery as the endpoint) is 90%.

Ulnar nerve compression

Symptomatic ulnar nerve compression is surprisingly uncommon in rheumatoid patients, given that subclinical disease and neurophysiological changes are very common. Presentation is with:

◆ intermittent tingling in the little and ring fingers (with or without objective sensory changes)

◆ intrinsic wasting (especially of the first dorsal interosseous muscle)

◆ irritability of the ulnar nerve behind the medial epicondyle.

Failure to improve with simple avoidance of local pressure and prolonged flexion indicates the need for neurophysiological testing (to confirm nerve compression at the elbow) and a surgical review. Simple surgical decompression would not be recommended

if it leaves the nerve in a 'hostile' bed; anterior transposition is preferred.

Posterior interosseous nerve palsy

This is usually due to local compression by cysts from the elbow joint, compression by local fibrous bands or vasculitis. Presentation is with wrist drop and the inability to dorsiflex fingers at the MCP. Remember that IP joint extension can be achieved by the hand intrinsic muscles, which are innervated by the ulnar and median nerves.

It is important to exclude extensor tendon attrition rupture (due to tenosynovitis and distal radioulnar joint synovitis at the wrist) and extensor mechanism subluxation at the MCPJ as the cause of the dropped fingers (see Box 90.4). Surgical exploration to decompress the nerve and to remove any local swelling is the treatment of choice.

Olecranon bursitis and rheumatoid nodules

In patients with RA, the olecranon bursa is a common site of pressure and friction. Pressure avoidance with or without aspiration of the bursa is the initial treatment of choice. Surgical excision is possible, but carries the potential for healing problems and prolonged drainage.

Hand and wrist

RA in the hand can affect multiple joints, but especially the wrist and distal radio ulnar joint (DRUJ), the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints of the fingers and the carpometacarpal (CMC) and MCP joints of the thumb. In addition to the direct destruction of articulating joint surfaces, the synovitis associated with RA causes attenuation and

---

> **Box 90.4**   Differential diagnosis of apparent finger extension lag
>
> - Posterior interosseous nerve palsy caused by elbow synovitis (a tenodesis test will show intact extensor tendons producing finger extension during maximal passive wrist flexion)
> - Extensor tendon rupture (loss of both active finger extension and passive extension on the tenodesis test)
> - EDC tendon sagittal band rupture allowing subluxation of the extensor tendon into the valley between the metacarpal heads (if fingers are first placed in extension, allowing the extensor tendons to align centrally over the dorsum of the metacarpal heads, this position can be maintained actively; if fingers are first placed in flexion the subluxed extensor tendons cannot actively extend the MCP joints)
> - Locked trigger finger (usually also has flexion of the PIP)
> - Locked MCP joint (usually in osteoarthritis with active and passive extension except for the last 40° at MCP joint), or MCP joint subluxation
> - Dupuytren's disease

---

rupture of important joint-stabilizing ligaments and tendons, which leads to progressive joint subluxation and dislocation, and to the development of several characteristic zigzag collapse deformities in the hand. Fibrosis and contracture of the intrinsic muscles of the hand also contributes to the development of finger deformities.

Loss of finger extension is a common presentation; Box 90.4 outlines how to establish the cause, which will help management planning.

Distal radioulnar joint and extensor tendon surgery

Tenosynovitis (either flexor or extensor) that fails to respond to full medical treatment for 3–6 months (including steroid injection) may benefit from surgical tenosynovectomy, which may also reduce the rate of tendon rupture. Joint synovectomy may decrease symptoms but does not halt the progression of joint disease.

Caput ulna syndrome

Caput ulna syndrome is due to extensor tenosynovitis associated with DRUJ synovitis, leading to erosion and dorsal subluxation of the ulnar head through the dorsal joint capsule and consequent extensor tendon rupture. Extensor digiti minimi (EDM) and EDC to little finger usually rupture first, causing an extensor lag to the little finger. The other EDC tendons may then sequentially rupture from the ulnar side, creating a much more difficult reconstructive problem; rapid surgical intervention can prevent this. The surgical options are listed in Table 90.1.

Carpal tunnel and flexor tendon problems

Flexor tenosynovitis associated with carpal tunnel syndrome may occasionally be the first presenting feature of RA. If it fails to respond rapidly to steroid injections, it may require urgent carpal tunnel decompression (through an extended approach) with a flexor tenosynovectomy. Flexor tenosynovitis in the digits may cause triggering or result in the presence of a greater passive than active range of motion. If this persists despite medical management and steroid injections a tenosynovectomy may be performed (preserving the A1 pulley to prevent bowstringing and ulnar drift). Flexor pollicis longus (FPL) is the most common flexor tendon to rupture (Mannerfelt syndrome), due to palmar wrist synovitis and prominent bone spurs from the scaphoid and trapezium, along with flexor digitorum profundus (FDP) to the index finger. If the thumb interphalangeal (IP) joint is stiff or ankylosed, then function may be maintained without intervention. If not, the options for surgical reconstruction include arthrodesis of the thumb IP joint; repair or palmaris longus grafting of the FPL tendon; transfer of ring finger FDS tendon to FPL. Rupture of finger flexor tendons is less common but may require similar tendon repair, grafting, or transfers. Careful rehabilitation is required following all these procedures.

Wrist

Synovitis causes progressive attenuation and destruction of the intrinsic intercarpal ligaments and the extrinsic intracapsular ligaments of the wrist. The scapholunate ligament may rupture and the whole carpus tends to slide down the articular surface of

Table 90.1 Surgical options for caput ulna syndrome

Procedure	Comments
Ulnar head excision (Darrach procedure) plus soft tissue stabilization of the distal ulna	Most commonly perfomed for RA where there is often significant destruction of the ulnar head
Hemi-resection ulna head plus soft tissue interposition/stabilization (Bowers procedure)	A possibility in earlier disease, as it requires an intact/reconstructable TFCC
DRUJ arthrodesis plus pseudarthrosis proximal to the ulnar head (Sauve Kapandji procedure)	A proven alternative that has the theoretical advantage of maintaining some support to the ulnar carpus, so possibly reducing ulnar translation of the carpus. However, it can give unreliable results, and create almost unsalvageable problems from ulnar stump instability unless executed with precise techniques
Prosthetic ulnar head replacement (partial or total)	Established implants and techniques are now available, but as long-term results are not yet known, this is mainly performed by specialist hand surgeons and/or is reserved as a secondary salvage procedure
Extensor tenosynovectomy and tendon repairs, grafts, or transfers, plus retinaculum transposition (deep to the tendons)	Usually combined with one of the above procedures. Many reconstructive options are available and the exact combination of procedures is tailored to the findings at the time of surgery. Rupture of EDM and EDC to the little finger is commonly reconstructed by transferring the EIP tendon from the index finger. EDC to the ring finger can be transferred ('piggy-backed') onto the adjacent intact EDC tendon to the middle finger or combined with the EDM reconstruction. Multiple extensor tendon ruptures may require the transfer of additional motors, such as FDS from the ring finger.
Rehabilitation following tendon reconstruction	From 2 weeks after surgery gentle controlled range of motion exercises are commenced from a custom splint

DRUJ, distal radioulnar joint; EDC, extensor digitorum communis; EDM, extensor digiti minimi; EIP, extensor indicis proprius; FDS, flexor digitorum superficialis; RA, rheumatoid arthritis; TFCC, triangular fibrocartilage complex.

Table 90.2 Surgical options for wrist problems in rheumatoid arthritis

Procedure	Comments
Synovectomy of the wrist (open or arthroscopic)	May be useful in the early stage of the disease with joint preservation but significant synovitis that is resistant to medical therapy
ECRL to ECU transfer	Useful if the wrist joint surfaces are still healthy, to dynamically correct radial deviation of the carpus and metacarpals, prior to addressing finger MCP joint ulnar deviation
Radiolunate arthrodesis (or radioscapholunate arthrodesis)	Indicated with isolated radiocarpal joint involvement, early ulnar translation of the carpus, and preservation of >60° arc of motion. This will prevent further radiocarpal joint subluxation and preserves some midcarpal joint movement
Total wrist arthrodesis (using a dorsal wrist fusion plate, or intermedullary metacarporadial pins)	Indicated when both radiocarpal and midcarpal joints are involved, there is significant subluxation and pain, and <60°arc of motion is preserved
Total wrist arthroplasty	Historically, it has proved difficult to design and implant reliable total wrist prostheses. Until the long-term results of newer implants are known, this procedure should be performed in specialist hand surgery units. One approach has been to perform an arthroplasty on the dominant wrist, thus preserving some dexterity and flexion for performing tasks (such as personal hygiene), and to perform an arthrodesis on the non-dominant wrist, thus ensuring a stable wrist for power activities
Correction and stabilization of wrist subluxation and deformity	Restores a relatively normal carpal and metacarpal alignment, creating a stable base upon which the thumb and fingers can be reconstructed and can function

ECRL, extensor carpi radialis longus; ECU, extensor carpi ulnaris.

the radius into ulnar translation, palmar subluxation, and supination, with a secondary radial deviation of the metacarpals. The degree of surgical intervention required is matched to the level of the patient's pain and existing range of motion, the stage of the disease, and the pattern of joint destruction. Surgical options are listed in Table 90.2.

Thumb

Common problems are summarized in Table 90.3.

Metacarpophalangeal joints of the fingers

Common problems are summarized in Table 90.4.

Table 90.3 Common problems affecting the thumb

Problem/deformity	Comment
Synovitis	If it commences primarily in the thumb MCP joint, it causes a boutonnière deformity, but if it commences primarily in the CMC joint, it causes a swan-neck deformity
Boutonnière deformity	MCP joint synovitis leads to EPB tendon rupture, weakness of proximal phalanx extension, and progressive 'buttonholing' of the metacarpal head through the extensor apparatus. EPL subluxes anterior to the axis of MCP joint rotation, causing progressive flexion of the MCP joint and extension of the IP joint—a 'Z collapse' deformity
Early flexible boutonnière deformity	May be treated by transferring EPL on to the distal stump of EPB at the proximal phalanx base (some IP joint extension will be maintained by the intrinsic muscles)
Moderate late rigid boutonnière deformity (MCP flexion <45°)	May be pain free and functional, requiring only occasional splintage
Painful severe late rigid boutonnière deformity (MCP flexion >45°)	May be treated by MCP joint arthrodesis, plus lengthening of the EPL tendon, or IP joint arthrodesis, to reduce the disabling IP joint hyperextension
Boutonnière deformity with associated CMC involvement	Requires correction of the metacarpal position by performing a CMC joint excision arthroplasty, and an arthrodesis of the MCP joint etc. as above
Swan-neck deformity	CMC joint synovitis attenuates the anterior oblique ligament causing dorsal subluxation of the metacarpal base, and a 'thumb in the palm' deformity. Associated progressive MCP joint hyperextension and EPL subluxation palmar to the axis of rotation of the IP joint, and so IP joint hyperflexion, create the characteristic deformity
Symptomatic disabling swan-neck deformity	Requires correction of the metacarpal position by performing a CMC joint excision arthroplasty, and an arthrodesis of the MCP joint (or occasionally a MCP joint palmar plate advancement, if the joint remains healthy)
Thumb MCP joint ulnar collateral ligament insufficiency	Might be amenable to soft tissue reconstruction if the joint remains healthy, but often MCP joint arthrodesis is a more reliable procedure

CMC, carpometacarpal; EDC, extensor digitorum communis; EPB, extensor pollicis brevis; EPL, extensor pollicis longus; IP, interphalangeal; MCP, metacarpophalangeal.

Table 90.4 Common problems affecting finger MCP joints

Problem/deformity	Comment
MCP joint synovitis	Causes attenuation of the joint capsule and collateral ligaments, and progressive ulnar drift and palmar subluxation of the base of the proximal phalanx
Ulnar drift	Multifactorial: there is a natural 'push' towards MCP joint ulnar deviation caused by power gripping with the wrist in ulnar deviation; changes at the wrist described above cause the metacarpals to deform into radial deviation placing ulnar bias onto the EDC tendon's direction of pull; MCP joint synovitis also causes attenuation of the stabilizing sagittal bands and EDC tendon subluxation down the ulnar side of the metacarpal heads
Palmar subluxation	Driven by attenuation of the thin dorsal capsule, the powerful long flexor tendons to the fingers, and intrinsic muscle fibrosis and tightness
Early MCP joint ulnar drift	May be halted or corrected by the careful use of a resting night splint, and the modification of activities and walking aids etc. to minimize the ulnar deviation forces placed on the fingers
Splintage or surgical intervention to correct wrist deformities	This is also important when either preventing or correcting finger MCP joint ulnar deviation
MCP joint synovectomy and soft tissue rebalancing (± crossed intrinsic transfer)	Occasionally useful in the presence of well-preserved joint surfaces and synovitis resistant to medical intervention. Releasing the ulnar-sided tight intrinsic tendon will allow deformity correction; the tendon can be transferred to the radial side of the adjacent digit, so providing a corrective force to that ray as well as releasing a deforming force from its 'home' ray
MCP joint silicon arthroplasty and soft tissue rebalancing (± crossed intrinsic transfer)	When performed carefully (often simultaneously on multiple fingers) can produce excellent results with good pain relief and correction of deformity, the maintenance of about 45° of flexion, and around 90% implant survival at 5 years. When the silicon spacer eventually fractures, if no symptoms or deformity develop, then no intervention is required

EDC, extensor digitorum communis; MCP, metacarpophalangeal.

Proximal interphalangeal joints of the fingers

Common problems are summarized in Table 90.5.

Table 90.5 Common problems affecting finger PIP joints

Problem/deformity	Comment
PIP joint synovitis	Affecting predominantly either the dorsal or palmar structures, in combination with intrinsic muscle contracture, results in the characteristic Z-shaped RA finger deformities
Boutonnière deformity	This progressive deformity starts with the PIP joint synovitis causing attenuation of the central slip and weakness of PIP joint extension. The intrinsic muscles are employed increasingly in an attempt to extend the IP joints and the lateral bands sublux in a palmar direction, until they pass the axis of rotation and become flexors of the PIP joint. Intrinsic muscle action and contracture drives further PIP joint flexion and DIP joint extension
Early mild flexible boutonnière deformity (PIP joint contracture <30°)	May correct with a simple 'Fowler's' release of the central third of the extensor tendon (performed at the junction of the proximal and middle thirds of the middle phalanx)
Moderate flexible boutonnière deformity (PIP joint contracture >30°)	If passively correctable with a healthy joint, the deformity may respond to a careful procedure to shorten the central slip with release and dorsal relocation and suturing of the lateral bands (± Fowler's release, for residual DIP joint hyperextension)
Severe rigid boutonnière deformity (PIP joint contracture >60° and DIP joint contracture >20°)	If symptomatic, with such a poor range of PIP joint motion, the most reliable procedure is a PIP joint arthrodesis using K-wires and tension band (± Fowler's release, for residual DIP joint hyperextension)
Swan-neck deformity	PIP joint synovitis causes attenuation of the palmar plate and the transverse retinacular ligament, allowing PIP joint hyperextension and dorsal subluxation of the lateral bands. Intrinsic muscle tightness and shortening of the extensor apparatus drive the finger further into MCP joint flexion, PIP joint hyperextension, and DIP joint flexion
Early flexible swan-neck deformity	During active flexion (possibly with some passive assistance) the finger may suddenly snap from hyperextension into flexion, often with some pain. Treatment options include: ◆ Trialling the use of an extension block 'silver ring' splint ◆ Stabilizing the palmar aspect of the PIP joint with a tenodesis using one of the FDS tendon slips ◆ Reconstructing the oblique retinacular ligament with the ulnar lateral band (Litteler's procedure), or a tendon graft ◆ Rerouting one lateral band through the flexor tendon sheath at the level of the PIP joint (Zancolli procedure)
Late rigid swan-neck deformity	If symptomatic, with PIP joint damage, the most reliable procedure is a PIP joint arthrodesis in a better position for function (± shortening of the distal part of EDC to correct DIP flexion, or DIP arthrodesis)

DIP, distal interphalangeal; EDC, extensor digitorum communis; FDS, flexor digitorum superficialis; MCP, metacarpophalangeal; PIP, proximal interphalangeal, RA, rheumatoid arthritis.

CHAPTER 91

Principles of lower limb surgery

Peter Wall, Matthew Wyse, and Damian Griffin

Introduction

Surgical intervention for lower limb rheumatological disease can be broadly divided into five categories: injections, joint-preserving procedures, soft tissue procedures, arthrodesis, and arthroplasty. The art of surgery is in the effective use of these interventions in the course of a patient's disease. Modern practice usually involves a combined care approach between physicians and surgeons in order to manage diseases such as rheumatoid arthritis (RA) and expedite surgery at the most propitious moment. The focus of this chapter is not the details of surgery; rather, the timing, preoperative planning, and reducing the risk of surgery once a decision to operate has been made.

Planning surgery

Timing of surgical interventions

It is no longer acceptable for orthopaedic surgeons to work in isolation. For diseases such as RA it is regarded as good practice for patients to be managed by a multidisciplinary team including orthopaedic surgeons (see Case history 1). The timing of elective surgery should be made by the multidisciplinary team in order to address such issues as alterations to disease-modifying drugs (although this remains controversial; see Chapter 92) and prompt surgical input for cases of imminent or acute tendon rupture.[1,2]

Case history 1

Ankle fusion for rheumatoid arthritis

A 60 year old retired woman with RA was managed by a team including a rheumatologist and an orthopaedic surgeon. She had bilateral painful flat feet and a history of tibialis posterior tendon rupture bilaterally. Surgery involving a calcaneal osteotomy and spring ligament reconstruction was undertaken 5 years previously. The patient's symptoms were worsening in the left foot, and shoe orthotics no longer controlled her symptoms. Radiographs showed significant arthritis of subtalar and midfoot joints. A decision was made to undertake left triple joint arthrodesis (subtalar, talonavicular, and calcaneocuboid joints). At 6 month follow-up the patient was able to walk to the shops comfortably again.

Lower limb arthroplasty used to be reserved for patients with cases of severe symptomatic arthritis, but this philosophy is now changing. Although surgery should not be undertaken when the risks will outweigh the benefits, it should not be restricted to only those patients with the most severe symptoms. Evidence is building that the health benefit of arthroplasty surgery is less in those patients whose surgery is delayed.[3]

Preoperative assessment

It is now routine for patients scheduled for elective surgery in the United Kingdom to attend a preoperative assessment clinic. The purpose of these clinics is to improve the provision of patient information and care by careful preoperative evaluation of the patient with coexisting diseases.[4] An assessment of the patient's general health is made and further tests may be arranged depending on the patient's ASA grade (American Society of Anaesthesiologists grade—a simple scale which describes fitness to undergo an anaesthetic) and the level of surgery being undertaken. Tests that may be considered include blood tests (full blood count, renal function, random glucose, and clotting), electrocardiogram (ECG) and urine analysis (dipstick tests for pH, protein, glucose, ketones, blood/haemoglobin).[5]

Imaging

Imaging is essential for adequate preoperative planning and postoperative follow-up. Plain radiographs are used most frequently to make an assessment of lower limb joints. Two radiographic views are required as a minimum for any joint. Arthroplasty surgeons use these images to template a prosthesis before it is inserted (see Figure 91.1) so that they can anticipate any special implant sizes or designs that may be required. Weightbearing radiographs are usually preferred in order to appreciate the joint under normal load. Plain radiographs are also taken after surgery both in the early postoperative phase to check adequate alignment and placement of the prosthesis and in the longer term to check for any early signs of wear or loosening of the prosthesis.

Other imaging modalities include:

- CT: examples of application include accurately measuring the length of long bones and identifying exact bony anatomy and orientation prior to surgery.
Fig. 91.1 Pelvis radiograph showing preoperative templating of a total hip arthroplasty.
Reproduced with kind permission from Voyant Health Support.

Fig. 91.2 Modern ultraclean theatre with laminar flow hood and staff member wearing hood and suit with exhaust system.

- MRI: examples of application include checking the integrity of soft tissues around a joint or determining the extent of articular cartilage damage within a joint prior to embarking on arthroscopic or arthroplasty surgery.
- Ultrasound can be used to guide intervention within soft tissues, particularly needle aspiration or injection.

General surgical principles

Theatre design and practice

In the United Kingdom it is regarded as good practice for procedures involving bony exposure to be undertaken in an operating theatre with laminar flow (ultraclean theatre) and for the operating surgeon and assistants to wear sterile suits and helmets with

an exhaust system (see Figure 91.2). These principles are based on evidence that these measures significantly reduce the risk of sepsis.[6] Other important factors that reduce bacterial counts in theatre include staff covering their noses with masks, all body piercings being covered, and all scrub staff removing finger rings.[7–9]

Anaesthesia and analgesia

Anaesthesia for lower limb surgery can be divided into three broad categories; general anaesthesia, neuroaxial anaesthesia, and peripheral nerve blockade. The choice in an individual patient will be determined by patient preference, coexisting morbidity, and site of surgery. There is no evidence to support one technique over any other in respect of mortality or long-term outcomes. However, virtually all surgery in the lower limb can be performed with a neuroaxial technique such as a spinal anaesthetic unless there are absolute contraindications such as anticoagulation therapy or patient refusal. Neuroaxial techniques have advantages in providing better early analgesia and early mobilization and reduced morbidity such as nausea and vomiting. Peripheral nerve blocks may be used as a sole technique but most commonly are used to supplement general and spinal anaesthesia and to provide postoperative analgesia. Blocks may be single-shot techniques whereby a bolus of local anaesthetic is deposited around a nerve or plexus, or a catheter may be placed in proximity to the nerve for continuous infusion of local anaesthetic or repeated boluses. The duration of effect depends on the agent used and the site of the block: a single shot of long-acting local anaesthetic such as bupivacaine or ropivacaine may give up to 24 hours of analgesia although 12–18 hours is more typical (see Table 91.1).

Enhanced recovery programme (ERP) or fast-track surgery refers to a package of interventions designed to lead to early mobilization and discharge from hospital. Recent evidence also suggests that ERP may reduce postoperative mortality rates.[10] The ERP approach is widely employed for patients undergoing hip or knee arthroplasty. The key interventions are detailed preoperative assessment; optimizing comorbidities; providing patient information and reassurance so that patient expectations are managed; and minimizing preoperative starvation. The anaesthetic technique will avoid opiates and peripheral nerve blockade although short-acting neuroaxial blockade is often employed. The postoperative analgesia regime will be based around paracetamol, non-steroidal anti-inflammatory drugs (NSAIDs) and novel analgesics such as gabapentin commenced preoperatively and continued regularly postoperatively. If opiates are required the oral route will be used. In the postoperative phase oral intake will be encouraged, and the patient mobilized as rapidly as tolerated. Typically an ERP for arthroplasty will reduce the length of in-patient stay to 3 days or so.

Skin preparation and cleaning

Surgical sites with significant hair coverage require shaving, which should be undertaken just before surgery—the trauma of shaving induces proliferation of local skin bacteria which could increase the risk of infection if undertaken hours or days before surgery (the evidence supporting this is equivocal).[11] Surgical site skin antisepsis is achieved with either alcohol, chlorhexidine, or aqueous povidone-iodine based solution.

Controlling and managing blood loss

A surgeon can minimize the amount of blood lost during surgery by careful tissue handling and adequate haemostasis with sutures and diathermy during dissection. It is the role of both the surgeon and the anaesthetist to manage blood loss in a safe and controlled manner. Surgery should proceed with minimal disruption and the patient should recover without too many side effects from anaemia. Intraoperatively the surgeon, anaesthetist, and scrub nurse communicate in order to estimate the amount of blood being lost, using information from:

◆ blood at the surgical site

◆ soakage and increased weight of surgical swabs

◆ amount of blood in suction containers

◆ patient's physiology including pulse, blood pressure, and urine output.

Antifibrinolytic agents such as tranexamic acid are becoming increasingly popular in lower limb arthroplasty and revision surgery to help reduce the amount of blood lost during surgery and reduce postoperative transfusion requirements.[12] Tranexamic acid is a relatively cheap intervention and has a low side effect profile.

Tourniquets

Tourniquets are routinely used for knee, ankle, and foot procedures. Modern tourniquets are made from padded material and use a pneumatic pressure cuff to exert their limb-occlusive effects. They are regarded as safe devices under normal use and have small microcomputers to regulate cuff pressures to within 1% of the intended setting.[13] Complications from tourniquets increase with time.[13] The maximum safe duration of application is not known; however, most surgeons would regard a tourniquet time beyond 2 hours as excessive.

Table 91.1 Examples of peripheral nerve blocks for lower limb surgery

Surgical site anaesthesia	Peripheral nerve block	Duration of analgesia
Hip	Lumbar plexus	8–12 hours
Hip	Femoral nerve	12–18 hours
Knee	Femoral nerve (±sciatic nerve)	12–18 hours
Foot and ankle	Sciatic nerve or popliteal fossa (tibial nerve)	12–24 hours
Toes and forefoot	Ankle (posterior tibial nerve, saphenous, deep and superficial peroneal nerve ± sural nerve)	12–18 hours

Blood transfusions

Allogenic packed red cells are the most common type of transfusion in orthopaedics.[14] Blood transfusions increase a patient's oxygen-carrying capacity in the circulation. Blood should not be used to expand intravascular volume. The threshold for initiating allogenic blood transfusion is controversial. In a young, healthy patient blood losses of 30–40% can typically be controlled with crystalloids alone and, provided a patient is asymptomatic and has an adequate intra-vascular volume, haemoglobin levels of 7 g/dL or even lower are safe.[15,16] When surgeon and anaesthetist anticipate significant vol-umes of blood loss it is usual practice to cross-match sufficient blood to allow a surplus using a maximum blood-ordering schedule. This schedule is based on historical data either locally or nationally for the procedure being undertaken.[14] Autologous blood transfusions are becoming more popular in orthopaedic practice. Blood donated by the patient preoperatively or salvaged during/after the operation can be used, and this removes the risk of infectious disease transmission associated with allogenic blood transfusions. There is evidence that the use of autologous blood salvaged after lower limb joint arthro-plasty reduces the need for allogenic blood transfusions.[17]

Surgical procedures

Joint injection

Joint injections can be used to diagnose lower limb pathology. Patients typically have numerous aches and pains, and attributing these to a specific disease or joint can be difficult from history and examination alone. Administration of local anaesthetic to a joint will temporarily reduce or abolish intra-articular pain and allow the surgeon to determine the likely success of proposed future surgery. Joint injections are also used therapeutically, particularly administration of steroids. There is also emerging evidence that administration of hyaluronic acid to a joint can provide relief of symptoms in the short to medium term (see Case history 2).[18,19]

Case history 2

Total knee arthroplasty for osteoarthritis

A 45 year old man with osteoarthritis of his knee and hyperten-sion initially obtained relief from analgesia and hyaluronic acid injections. However, the pain deteriorated and he was unable to continue working as a schoolteacher. The decision was made to undertake total knee arthroplasty. The patient attended a preop-erative assessment clinic, and 2 weeks later was admitted for surgery. Three months after the operation, the patient returned to fulltime work. He continues to be satisfied with the outcome 5 years postoperatively.

Arthroscopy

Arthroscopy can be used to aid diagnosis (actual visualization of the pathology or taking tissue biopsies). The hip, knee, and ankle are the joints typically examined. Hip and ankle arthroscopy require traction in order to distract the joint surfaces sufficiently to allow instrument access, which is via portals inserted through small incisions. Irrigation of the joint is required with normal saline under pressure, which has a tamponade effect on any small bleeding blood vessels and helps distend the synovial cavity. A rigid endoscope with a light source attached is inserted through one of the portals and via a series of lenses and a video camera an image is collected, magnified and projected on to a monitor. Probes, grabbers, shavers, and burrs can be inserted through other portals allowing therapeutic procedures to be undertaken. The therapeutic options of arthroscopy are expanding rapidly with advances in instrument technology: see Table 91.2 and Case his-tory 3 for some examples.

Case history 3

Knee arthroscopy for meniscal tear

A 42 year old woman experienced intermittent 'locking' of her right knee, and the knee 'gave way' occasionally. These symp-toms prevented her from continuing with recreational run-ning. A course of physiotherapy provided no symptom relief. Investigation by her GP revealed a meniscal tear on MRI. Knee arthroscopy was undertaken as a day-case procedure. This con-firmed a degenerative medial meniscal tear, which was debrided. Postoperative rehabilitation was supervised by a physiotherapist. The patient was able to return to running after 12 weeks.

The use of arthroscopic knee washouts as a treatment for osteoar-thritis remains controversial and no clinical benefit has been shown in either the short or the long term.[20]

Arthrodesis

Arthrodesis (joint fusion) remains a reliable method of reliev-ing the pain of arthritis where future stiffness is not going to be a significant problem. In order to achieve joint fusion articu-lar cartilage needs to be removed from all surfaces, which are then held rigidly opposed to one another using either internal or external fixation. Fusion of the joint should be done in the most functional position and it should avoid significantly alter-ing the normal mechanical axis of the lower limb. A specific risk of arthrodesis is non-union, which if painful will require further surgery. With the success of total joint arthroplasty, hip and knee

Table 91.2 Examples of interventions possible with lower limb arthroscopy

Joint	Treatable pathology	Typical length of in-patient stay
Hip	Correction of femoroacetabular impingement	1–2 days
Knee	Debridement of a degenerate meniscal tear	<24 hours
Knee	Synovectomy for rheumatoid arthritis	<24 hours
Ankle	Synovectomy for rheumatoid arthritis	<24 hours
Ankle	Cartilage debridement during arthroscopic assisted ankle fusion	1–2 days

fusion is now uncommon. Ankle fusion, however, remains a popular procedure for arthritis because ankle arthroplasty has not enjoyed the same success as hip and knee arthroplasty.

Joint-preserving procedures

Many techniques have been described over the years in order to delay the need for arthroplasty and slow the progression of arthritis. Osteotomies have been successfully used in the hip, knee, ankle, and foot in order to realign the joint and offload areas of symptomatic arthritis.

Corrective surgery for joint shape abnormalities is an area of interest in hip surgery at present. Femoroacetabular impingement (FAI), sometimes called hip impingement, describes a collection of subtle deformities of the hip which cause impingement between the femoral neck and anterior rim of the acetabulum.[21] Excess contact forces between the proximal femur and the acetabular rim during the terminal motion of the hip lead to lesions of the acetabular labrum and the adjacent acetabular cartilage.[21] FAI seems to be associated with progressive articular degeneration and probably accounts for a large proportion of idiopathic osteoarthritis.[22] Although many surgeons have been reporting favourable results (reduced pain and improved hip function) from shape-corrective surgery for FAI (see Case history 4), it is not yet clear if this surgery has any effect on the development of subsequent osteoarthritis.[23]

Case history 4

Shape-corrective surgery for femoroacetabular impingement

A 30 year old man, a farmer who played recreational cricket for a local village team, had right groin pain for 4–5 years. There was no evidence of groin hernias or hip osteoarthritis. Physiotherapy provided no relief and made his symptoms worse. Examination with right hip in flexion and internal rotation reproduced the pain. Imaging (radiographs and MRI) suggested femoroacetabular impingement with a labral tear. Arthroscopic femoral head–neck junction reshaping and labral tear debridement was undertaken. Postoperative rehabilitation was supervised by a physiotherapist. The patient resumed his farming work and playing cricket pain free after 16 weeks.

Soft tissue procedures

The aim of this group of procedures is to improve joint function and/or correct deformity. Some procedures may be undertaken in isolation, such as:

- tendon transfers of the foot and ankle for tendon rupture secondary to RA (see Case history 1)
- synovectomy for florid synovitis refractory to medical treatment.

Alternatively, soft tissue surgery may be used to augment a bony procedure and improve the overall effect; examples include:

- release of the collateral ligaments during total knee arthroplasty to improve alignment

- adductor longus release to correct adduction deformity after total hip arthroplasty
- tightening of medial collateral ligaments after osteotomy correction of hallux valgus.

Arthroplasty

Arthroplasty encompasses any refashioning of the joint and includes excision arthroplasty such as a girdlestone procedure for the hip. Total joint arthroplasty remains one of the most successful treatment options for arthritis of the hip and knee.[24,25] Sir John Charnley can be credited with the most significant advances in arthoplasty surgery.[26] It was the success of his 'low friction arthroplasty' that also stimulated significant improvements in the design of total joint arthroplasty prostheses.[24] There are numerous designs of modern total hip and knee prostheses; the main differences/choices to be made are (1) the mode of fixation, e.g. uncemented or cemented designs and (2) the bearing surface, e.g. metal on polyethylene, metal-on-metal, ceramic-on-ceramic. Recently metal-on-metal bearing surfaces have been associated with higher than average failure rates.[27] The reasons for this are not completely clear but seem to relate to metal wear debris causing local soft tissue reactions.[28] For this reason many researchers and governing bodies, particularly in the United Kingdom, no longer advocate the use of metal-on-metal bearings.[27]

The lifespan of total hip replacements in the United Kingdom is expected to be greater than 90% at 10 years, with similar survival rates reported for contemporary total knee replacements.[29,30] As previously mentioned, total ankle arthroplasty has not enjoyed the same success as the hip and knee with survival rates of approximately 70% at 10 years.[31] The main risks of total joint arthroplasty are outlined in Table 91.3.

Risks

Infection

Surgical site infection (SSI) represents a significant risk when undertaking lower limb surgery. The effect on a patient can be profound (see Case history 5), with mortality rates doubled amongst those patients with a SSI.[32] It is estimated that SSI leads to an additional hospital stay of 6.5 days at a cost of £3246 per patient.[33] Early infection rates in patients undergoing total joint arthroplasty were historically 5–10%, but this has now reduced to approximately 1%, as a result of measures including prophylactic antibiotics and modern theatre design and clothing.[34] Ensuring that patients have clean healthy skin, no open wounds, good dental hygiene, and screening

Table 91.3 Details of the main risks of lower limb arthroplasty

Total joint arthroplasty	Main procedure-specific risks
Hip	Dislocation, leg length discrepancy, loosening, and infection
Knee	Difficulty kneeling, loosening, and infection
Ankle	Poor wound healing, early failure due to infection or loosening

for asymptomatic urinary tract infections and meticillin-resistant *Staphylococcus aureus* (MRSA) preoperatively are important factors in minimizing the potential for bacteraemia at the time of surgery, and subsequent SSI.

Case history 5

Infected total hip arthroplasty

A 75 year old retired man with type 2 diabetes mellitus underwent right-sided total hip replacement. Two months after the operation he had increased right hip pain and an erythematous wound. Joint aspiration and blood cultures were taken and evidence of *Staphylococcus aureus* infection was found. The hip replacement was removed and the patient left with a temporary girdlestone. After 3 months of intravenous antibiotics there was no evidence of ongoing infection. A further hip replacement was inserted at 4 months. At 1 year follow-up the patient was mobilizing and pain free.

Antibiotics

Prophylactic antibiotics are now routinely used when implants are inserted during lower limb arthroplasty, where their value in preventing SSI significantly outweighs the risks and cost of the antibiotic; the value in lower limb surgery not involving insertion of an implant remains equivocal.[33] The American Academy of Orthopaedic Surgeons has issued recommendations for prophylactic antibiotics in total joint arthroplasty:[35]

- The antibiotic used for prophylaxis should be carefully selected, consistent with current recommendations and or local guidelines, taking into account the issues of resistance and patient allergies.
- Timing and dosage of antibiotic administration should optimize the efficacy of the therapy.
- Duration of prophylactic antibiotic administration should not exceed the 24 hour postoperative period.

Venous thromboembolism

Lower limb surgery lasting more than 60 minutes represents a significant risk factor for venous thromboembolism and as a result many patients receive some form of chemical (typically low molecular weight heparin) and/or mechanical (intermittent pneumatic calf compression pumps) venous thromboprophylaxis intraoperatively and in the immediate postoperative period. The National Institute of Health and Clinical Excellence recommends continuing chemical prophylaxis in hip and knee arthroplasty cases for 28–35 days and 10–14 days respectively.[36]

There are a number of newer oral anticoagulants, either thrombin or factor Xa inhibitors, licensed for prevention of postoperative thromboembolism. These are typically oral preparations taken once or twice daily. The oral preparations have the advantage that they are easier to take than self-administering low molecular weight heparins at home.

It is essential to consider other simple measures in order to reduce a patient's risk of a thrombembolic event including:

- encouraging patients to stop smoking
- encouraging overweight patients to lose weight preoperatively
- adequate hydration perioperatively
- early mobilization of patients postoperatively.

Despite risk reduction venous thromboembolic events still occur, with an incidence of approximately 1%.[37] Patients suspected of having either a deep vein thrombosis or pulmonary embolism should be commenced on therapeutic doses of low molecular weight heparin pending confirmatory imaging. Imaging should be expedited to minimize the duration of antithrombotic agent use in those patients who have a subsequent negative result, in order to reduce the risk of iatrogenic bleeding at the site of surgery.

Effectiveness of surgery

Despite the risks, most patients who undergo lower limb orthopaedic surgery experience an improved health-related quality of life; however, there are significant variations between procedures.[38] Modern healthcare systems increasingly measure the cost-effectiveness of treatments in order to rationalize resources. Both hip and knee arthroplasty have a proven track record of providing a significant and prolonged effect on health-related quality of life and are considered procedures that provide a cost-effective solution for arthritis (see Case history 2).[38–40]

Conclusion

Lower limb surgery is now principally undertaken with the oversight of a multidisciplinary team from diagnosis and preoperative assessment, right through to postsurgery follow-up. Modern surgery focuses on risk reduction, particularly infection and venous thromboembolism, in order to maximize the potential benefits. The outcome of most lower limb procedures is favourable; however, total hip and knee arthroplasty remain two of the most effective procedures for achieving pain relief in patients with arthritis. A new understanding of the aetiology of primary hip osteoarthritis (FAI) has led to some exciting surgical advances in treatment, which are likely to be explored for effectiveness over the next decade.

CHAPTER 92

Principles of spine surgery

Jeremy Fairbank and Nuno Batista

Introduction

This chapter considers the main ways that surgery can be applied to clinical problems affecting the spine (Box 92.1). In the last 20 years there have been dramatic advances in implant design, surgical techniques, and imaging. There have also been advances in clinical evidence for surgical techniques. How much this has translated into improved outcomes is hard to measure. Back pain remains a major clinical challenge. The application of surgery to treating back pain can be effective, but also has the capacity to make a bad situation worse. The spine is the critical supporting structure of the trunk and the head and protects the spinal cord and cauda equina. It is normally 'straight' in the coronal plane and with well-defined curves in the sagittal plane. It is also flexible in the cervical and lumbar regions. The orientation and 'balance' of the spine are critical to its proper function. Loss of sagittal balance is a cause of disability, contributed to not only by spinal deformity (almost always progressive kyphosis), but also by pelvic orientation and lower limb deformity (usually hip and knee arthritis).

Evidence of efficacy has lagged behind surgical capability, although important clinical trials are beginning to emerge, with improving methodology to cope with the complex issues that surround surgical interventions.

Epidemiology

The datasets on the Hospital Episode Statistics website (www.hesonline.nhs.uk) provide a summary of spinal surgical procedures carried out in England in 2010–2011.[1] The United Kingdom Department of Health has also reported on work done by working groups on the delivery of spinal surgery.[2] The Spinal Taskforce document can be found at www.ukssb.com/pages/News-and-Information.html

In many clinical areas it is well known that surgical rates tend to be higher in the United States than elsewhere. There are large variations within the country as well. The most striking difference between the United States and Europe is the rapidly rising rate (and costs) of spinal fusion for back pain, especially in older patients.[3] The reasons for this are complex, and include rapid development in implants with strong marketing, reimbursement strategies, and widespread use of expensive bone substitutes and bone morphogenic proteins to promote spinal fusion.[4]

Roles of surgery

Surgery for radicular pain and neurological compression

Surgery has a clear role in the management of acute spinal cord compression, whether by trauma, tumour, epidural haematoma, or spinal kyphosis.

Cauda equina compression

This is managed surgically. The main causes are disc prolapse, either massive with a wide spinal canal or less massive with a narrow spinal canal. Tumours and epidural haematomas can also present with cauda equina syndrome. This condition is important because the long-term consequences of urinary and faecal incontinence and sexual dysfunction are devastating. It is a major cause of litigation in the United Kingdom because of diagnostic or treatment delays. The common presentations are of severe back pain, unilateral or (more typically) bilateral leg pain, some relief with sitting, loss of perianal sensation (loss of feeling when wiping the bottom), and bladder retention or incontinence. It is a diagnosis that must always be considered. Diagnosis is clinical (especially loss of perineal sensation unilaterally or bilaterally) and by urgent MRI scan. The presentation may be seen in individuals with severe uncontrolled back pain. Treatment is surgical decompression as soon as feasible. More details can be found in Lavy et al.[5]

Nerve root compression

This is usually caused by disc herniation (prolapse). Other pathologies include tumour, infection, or neuritis. MRI scans of asymptomatic individuals detect disc herniation in up to 25%. Genetics

---

Box 92.1 Aims of spinal surgery

◆ Alter the balance and orientation of the spine

◆ Fix one or more segments of the spine to another with implants, secured in the long term by establishing a spinal fusion

◆ Decompress the spinal cord and emerging nerve roots

◆ Excise or palliate both malignant and benign tumours

◆ Contribute to the management of infection

◆ Insert implants to replace diseased parts and to restore mobility

explains 60% of the aetiology of new cases, with minimal contributions from environmental factors such as smoking and trauma.[6] True nerve root pain has a lifetime prevalence of less than 5%. Root pain caused by disc prolapse is usually preceded by back pain. The interval varies from a few minutes to years. Although back pain may coexist, the severity of the leg pain predominates. The majority of symptomatic disc herniation occurs at L4/5 or L5/S1, usually involving the L4, L5, or S1 nerve roots.

Lumbosacral nerve root pain radiates in the distribution of one or more dermatomes and may be associated with neurological deficits. Pain is exacerbated by coughing and sneezing, walking and standing. Night pain is common. Pain may be relieved by lying and flexing the spine. Root pain (sciatica) can be extremely severe, and associated with numbness and parasthesiae. Weakness may be experienced with poor push-off, flapping gait, and foot drop. The appearance of foot drop is sometimes associated with pain improvement. Perineal numbness, and associated bladder or bowel symptoms, are important indicators of cauda equina syndrome but the latter may be associated with pain severity and analgesic intake. Examination should include an assessment of sensation to both light touch and pinprick. Straight leg raising is restricted. We prefer to flex the hip and knee first, and then gradually and gently extend the knee. This allows assessment of hip pain, and is unfamiliar to experienced patients with illness behaviour. Weakness should be sought particularly in extension of the great toe and foot, foot eversion, and knee extension. Ankle and knee reflexes must be recorded.

Imaging is best done by MRI (CT and/or myelography may be used). Disc herniations are seen in up to 25% of normal scans, so it is essential to interpret the scan in the light of the clinical picture. Large discs tend to respond better to surgical treatment than small ones. Attention should be paid to the vertebral canal diameter. Small canals give more trouble than large ones. Look out for other contributing factors to nerve pain such as lateral recess and exit foraminal stenosis.

Nerve root pain

Nerve root pain caused by disc herniation usually gets better. Unfortunately the timescale is unpredictable. Clinical practice, observational data, and now some useful randomized controlled trials (RCTs) have given reasonably clear guidance on management. Evidence shows no benefit of non-operative treatments compared to natural history. However, explanation and analgesia, possibly combined with muscle relaxants, are important. Epidurals (either spinal or caudal) do not alter natural history, though the short-term relief of root pain may be convenient for some. Surgery may be indicated from 8 weeks from onset, unless there is evidence of cauda equina involvement or progressive neurological deficit, when surgery is indicated straight away. This strategy is informed by the trials of Weber,[7] the SPORT study,[8] and, most recently Peul et al.[9] who compared early with delayed surgical intervention. All of these favour early surgery over non-operative care in the short/medium term. The patient has to weigh up the risks of persisting pain, nerve damage, cauda equina damage (rare but devastating), dural tears, and recurrence against a 90% chance of relief of nerve root pain but not back pain. Earlier studies give a recurrence rate of 10% in 10 years, but Peul et al.[9] found 20% at 2 years.

Strong indications for surgical intervention are bladder and bowel involvement and progressive motor deficit. Relative indications for surgical intervention are failure of conservative treatment. Conservative treatment should last for at least 6 weeks and not more than 3–4 months, and result in improvement in the patient's symptoms and signs. Rarely, a patient will not respond to any form of pharmacological or physical pain control, in which case their severe incapacitating pain merits urgent surgical consideration. Recurrent episodic pain may also respond to surgery. Patients with significant motor deficit and diminished straight leg raising eventually recover just as well with non-surgical intervention.[7] However, often these patients are in extreme pain and will not wait for the benefits of conservative care. Occasionally, they present with a history of severe pain which has resolved while the neurologic deficit has increased. This rare patient is also a surgical candidate.

Disc herniation in young patients

The young patient with a disc herniation deserves special consideration because of the high proteoglycan content of the discal material (responsive to chymopapain) and the prevalence of disc protrusions rather than disc extrusions in this age group. The optimum treatment is chemonucleolysis rather than surgical intervention. Unfortunately chyomopapain is not currently available for commercial reasons, although there are hopes that it may return to the market. Surgery can be effective but the recurrence rate is significantly higher than with chymopapain.

Recurrence and scarring

The patient who has successful relief of sciatica after disc excision has a 5–20% chance of a recurrent disc rupture causing sciatica. Unfortunately, most recurrent disc herniations are at the same level and on the same side, and scar tissue from the previous surgery introduces a new element in diagnosis and treatment. Scarring 'tacks' down the dura to the back of the disc space so that a smaller amount of herniated nuclear material may produce significant pain and neurologic deficit in the relatively immobile nerve root. Because of the immobility of the scarred dura, transdural ruptures, although rare, can occur. Almost invariably the scar between the dura and the disc restricts migration of the recurrent disc fragments, i.e. on exploration they are routinely found opposite the disc space.

Health Technology Assessment has recently published a review of 'sciatica' which has conflated referred pain and root pain, and not addressed severity or failed treatment in its literature review.[10]

Spinal stenosis and neurogenic claudication

It is curious that neurogenic claudication, causing back and leg pain with walking, has taken such a long time to be recognized. Spinal stenosis was described in 1954 by Verbiest.[11] It causes a syndrome that is usually easy to recognize, including difficulty with walking (neurogenic claudication). Once considered rare, it is now clear that this syndrome occurs frequently with advancing years. Verbiest recognized two forms, developmental and acquired. Developmental stenosis may be localized to a single level or involve the whole spine. It is almost universally present in achondroplasia. People with narrow canals are probably more likely to run into trouble with back symptoms than those with wide canals, although the evidence for this statement is not robust. Acquired stenosis is associated with distortions of the spinal canal and exiting nerve root canals. This is secondary to disc degeneration causing narrowing of the disc space, disc bulges, and herniations. This in turn distorts facet joints, which degenerate and throw out osteophytes. The ligamentum flavum

loses its elasticity and tends to crumple and thicken, occupying the vertebral canal and compressing the thecal sac and nerve roots. All of this is more marked when the lumbar spine is extended, particularly during standing and walking, and less marked when sitting or squatting. Many patients find they cannot lie on their back and have to sleep in a fetal position.

Neurogenic claudication refers to the symptoms experienced secondary to spinal stenosis. Typically patients present with a gradual onset of back, buttock, and/or leg pain which progressively limits their ability to walk or stand, but is relieved by sitting, bending or squatting. It may take 10 minutes or more to recover—much slower than vascular claudication. Many are helped with walking aids such as a supermarket trolley. Some are all right walking fast but cannot dawdle. Others just have trouble standing still. Severity frequently varies from day to day. Patients may also report lower limb fatigue, a feeling that the legs will give way, a sensation of heaviness, paraesthesia, cramp, or coldness; 12% report bladder disturbance. A few develop an acute drop foot, which can be painless. Objectively, those who are severely affected may have a simian stance or a wide-based gait. People with spinal stenosis can usually fully flex and have unrestricted straight leg raise. When sitting they are often bent forward and many are most comfortable standing when flexed or squatting.

Management of neurogenic claudication

Investigation is by imaging of the lumbar spine, usually with MRI (Figure 92.1). Where this is unavailable or contraindicated, CT or myelography are inferior substitutes. It is important to exclude other causes of claudication, such as peripheral vascular disease. MRI is best at demonstrating both bony and soft tissue stenosis, but there is a lack of correlation between severity of radiological and clinical findings. For example, 20% of asymptomatic people over the age of 65 have radiological spinal stenosis.

Non-operative treatment includes explanation, which can often be highly effective, simple analgesics such as paracetamol and sometimes non-steroidal anti-inflammatory drugs (NSAIDs). One trial has supported the use of gabapentin; epidural steroids may help; walking aids including portable seats and all-terrain rollators with a seat fitted; light rucksacks (many find carrying shopping in bags increases their symptoms).

Surgery involves decompressing the cauda equina, lateral recesses, and exit foramina, depending on the radiological anatomy, clinical symptoms, and signs. This can be achieved by a variety of techniques ranging from laminectomy to microdecompression. There is controversy concerning the use of fusion either with or without implants. Fusion is more commonly employed in the United States than elsewhere. It is more likely to be used if the patient has a degenerative spondylolisthesis. This condition most commonly occurs at L4/5, and is much more frequent in women than in men. There is a range of devices that can be inserted between the spinous processes to maintain the motion segment in flexion. The role of these devices and their duration of action remain controversial.

The outcome of surgery depends on comorbidity and age.[12] Patients over the age of 80 tend to have worse outcomes (but they also have more comorbidity). As a rule of thumb 70% of patients will have a good outcome.[13] The Swedish Spine Register data suggests that this figure may be optimistic (reporting good outcomes in only 55%). Even so, few will obtain the walking capacity of their fit contemporaries.[13,14] Complication rates vary, but for decision-making, we tell patients 5% will be worse off and may regret the decision to proceed with surgery. This may be due to root damage, cauda equina damage, impaired vascularity, infection, and recurrence. It is not always possible to tell why outcome is poor in a particular case, but it is important to ensure that the decompression was complete.

Surgery for back pain

Patients with chronic low back pain are frequently referred to orthopaedic surgeons. The majority of these patients do not require surgical treatment, and should be managed by non-operative means. A small proportion may benefit from surgical stabilization of the spine or disc replacement.

The surgeon and patient have to take a decision after weighing up the risks and benefits of the procedure (often hard to define) against the disability. Spinal fusion may be regarded as either an attempt
Fig. 92.1 Spinal stenosis (lumbar spine). The second image highlights the vertebral canal available for the cauda equina (blue). The areas for the transiting nerve roots (or lateral recesses) are coloured red. In a normal spine, both the blue and the red areas would be much larger, giving much more space for the neurological structures.

to speed up the natural progress of degenerative changes towards a functional ankylosis or a prevention of progressive deformity or instability. The aim is to reduce the severity of back pain and improve functional ability. Our understanding of spinal pain is developing rapidly. Peripheral pain generators are of two major types, nociceptive (tissue) and neuropathic (nerve). Distinguishing between them is important because the causes and treatments are different. Ideally, the causes of both types of pain will be identified and treated, resulting in pain relief. The experience of pain is modulated in the central nervous system (CNS) by the spinal cord and many parts of the brain. The surgeon has to be alert to these complexities, as surgery can usually only influence pain generated outside the CNS. Surgeons may be able to influence CNS pain in a variety of ways that are outside the scope of this chapter.[15] Surgery has great capacity to harm so surgeons, and others recommending surgery or referring to surgeons, need to be aware of the influence of what they say on patients' experience and attitude to pain.

The treatment of spine-related pain conditions may include active core stabilization exercises, body mechanics training, passive modalities, spinal injections, and surgery. Comprehensive management of acute and chronic spinal pain also includes a rational pharmacologic approach and may include the use of NSAIDs, oral steroids, opioids, antidepressants, neuropathic agents, and sleep agents. Nociceptive pain is generally responsive to NSAIDs and opioids. Conditions associated with inflammation, bone pain, and joint disease are particularly responsive to NSAIDs.

Neuropathic pain is relatively resistant to NSAIDs and opioids, although they may be helpful in certain cases. The major classes of medications useful for neuropathic pain include tricyclic antidepressants, anticonvulsants, and sodium channel blockers.

The evidence on which to base treatment decisions is developing.[16] A variety of less invasive interbody fusion techniques have emerged, but no well-designed clinical trials have yet been reported. Several randomized trials of spinal fusion have now been completed. In Sweden, Fritzell and others showed an outcome advantage of fusion over conventional physiotherapy, but could show no difference between 3 different surgical techniques.[17] Brox et al.[18] in Norway and Fairbank et al.[19] in the United Kingdom could show no advantage of surgery over intensive rehabilitation. These trials have caused controversy, especially in the United States, where there are high rates of surgery for back pain. Long-term follow-up of these patients suggest that these results are maintained.

'Soft' or flexible fusion, using a variety of posterior devices, has been practiced for 20 years, but no large trial has been completed. The rationale remains experimental, not least because of our poor understanding of intersegmental biomechanics in relation to pain. Many ingenious devices have been developed to alter these, but results are anecdotal.

Disc replacement has evolved in the last 30 years, with only cohort studies reported until two trials approved by the United States Food and Drug Aaministration. The Charite study was against a BAK anterior cage procedure (now abandoned) that showed non-inferiority.[20] The ProDisc study showed non-inferiority over 360§ fusion using an unvalidated version of the Oswestry Disability Index (www.mapi-trust.org/services/questionnairelicensing/catalog-questionnaires/266-odi.[21] Both these trials show a non-statistically significant advantage to disc replacement, and it is likely that they were underpowered. No study against rehabilitation has yet been reported. Surgeons should consider the difficulties of selecting

patients and the high risks of revision surgery before recommending this procedure. A Norwegian study group has reported an RCT of disc replacement vs intensive rehabilitation with a statistically better Oswestry Disability Index (ODI) improvement in the surgical group, although this did not meet their predefined criteria of clinically significant difference.[9,22] This study is the first RCT of disc replacement that was not commercially funded.[10]

Rationale

It is assumed that back pain may be generated from the low back by 'mechanical' means or through a source of 'inflammatory' agents (usually assumed to be the intervertebral disc) irritating neural tissues.

◆ **Mechanical back pain** is generated by movement, and may be controlled by rest or immobilization by external splintage (corsets, braces, plaster), or internal splintage (fusion, with or without internal fixation, or limitation of movement by special implants). In some cases there may be instability of the spine, actual or perceived, which can be controlled by spinal fusion.

◆ **Inflammatory pain** may be managed surgically by excision of a whole disc, or at least a substantial part of it, and replacement of it by allograft or autograft bone, cages made of various materials containing bone, or artificial disc prostheses designed to replace either the nucleus or whole disc.

◆ Both mechanical and inflammatory pain may be involved in patients with previous root decompression surgery.

Unfortunately, reality has not always followed expectation, and the results of treatment have varied considerably. Carragee used discography to identify 'best bet' patients for spinal fusion.[23] Only 27% met his strict criteria of success compared with 72% of a control-spondylolisthesis group.

Spinal instability

Spinal stability is a much abused term. There are at least four ways in which this can be conceived:

1. In **mechanical terms**, as summarized in White and Punjabi's[24] definition of stability for a functional spinal unit—i.e. two vertebrae and an intervening three joint complex (a disc and two facet joints).

2. In **temporal terms**, where symptoms wax and wane more or less predictably with time. Some patients report increasing frequency and duration of attacks of pain.

3. In **perceptual terms**, where the spine feels unstable although no abnormal motion or position can be detected by conventional radiography.

4. In **postural terms**, where the whole spine is unbalanced.

White and Punjabi[24] defined stability as 'a condition of the spine under normal physiological loading where there is neither abnormal strain nor excessive or abnormal motion in the functional spinal unit'. The functional spinal unit is a motion segment, consisting of bone, disc, and bone, as well as its supporting joints, ligaments, and muscles. Instability is the loss of the ability of the spine under physiological loads to maintain relationships between vertebrae in such a way that there is neither damage or subsequent irritation to the spinal cord or nerve roots and, in addition, there is no

development of incapacitating deformity or pain from structural changes.

Perceived or functional instability is sometimes called 'instability syndrome'. The patient complains of giving way, getting stuck, a ratchety flexion in the spine, and, occasionally, a sensation of disconnection of the top of the body from the bottom. Panjabi's hypothesis is based on a concept that a single trauma or cumulative microtrauma causes subfailure injuries of the ligaments and embedded mechanoreceptors leading to disturbed muscle control.[25] Harris has suggested that mismatch between expected and actual proprioceptive information may be a potent source of 'distress' in the CNS, experienced as pain.[26] There is a strong body of evidence suggesting proprioceptive dysfunction in chronic back pain patients, but there is little evidence for mechanical instability as a cause of back pain.

Sagittal balance

Humans stand and walk best if they can keep their frame in balance. This means that, when standing, the head is over the hips, which are in turn over the heels. In other words the gravity line goes through the cervicothoracic junction and the lumbosacral joint. Deviations from this (usually forwards) overload the posterior lumbar musculature and require compensatory pelvic rotation, hip extension and knee flexion. In a standing lateral radiograph the sacrum is vertical, as the pelvis is maximally rotated backwards. All may be well at skeletal maturity, but loss of balance may follow kyphosis due to disc degeneration and fractures. Imbalance has become increasingly recognized as an important cause of back pain. Surgery can be used to correct imbalance by osteotomy or facetectomy during fusion, but milder cases may well respond to rehabilitation and exercise.

Assessment of instability

A good history is essential. The 'ideal' patient for spinal fusion may have some or all of the following characteristics: a nonsmoking 'normal citizen'; no litigation outstanding or other potential secondary gains from their pain; a clear history; and a crescendo of symptoms, but with pain-free or low-pain intervals. Some patients with recurrent attacks of pain report prodromal symptoms preceding an attack. Surgeons have tried many methods to identify good responders: for example, a trial period in external splintage, or a rational response to discography. External fixation has also been tried, but has not proved popular because of complications and poor predictive ability. Flexion–extension radiographs have been used for many years, but their value is very limited. Standing views may be of value if the gravity line or whole body can be included. This approach remains experimental.

Confounding factors

A technically correct operation achieving a solid fusion may not relieve pain, and indeed it can make it worse. Failures of the surgical approach can be attributed to two main areas: the patient and the surgical methodology.

The patient

1. Patient selection. Often significant psychosocial factors contribute to the extent of pain- related distress and disability. Even the most experienced surgeons can be caught out. Some surgeons make use of psychological questionnaires to aid in the selection of patients, but there is no good study to show that using these methods improves results. Ideally a pain psychologist should identify the degree of psychosocial involvement before the surgeon embarks upon surgical treatment. Pain-related distress should be treated first.

2. Poor recognition of sagittal imbalance.

3. The wrong levels may be selected for surgery.

4. Smoking cigarettes has been associated with a high pseudarthrosis rate in many studies.

5. Involvement in litigation or worker's compensation has long been recognized as being associated with poor clinical results.

Surgical methodology

The objective of most procedures is to obtain a solid bony fusion, avoiding damage to the surrounding soft tissues. A wide variety of methods are available, and comparisons between them are difficult. Posterolateral fusions tend to be easier to perform, but are probably less reliable in terms of both fusion rates and in immobilizing a segment (or functional spinal unit). Interbody fusions, either from the back or from the front, are more likely to fuse with instrumentation, but are technically more difficult to perform, and carry a higher risk of complication. Spinal instrumentation has evolved rapidly, increasing in complexity and expense. It has been difficult to demonstrate that its use has any advantage. Some studies, but not all, suggest that the use of instrumentation increases the fusion rate. Unfortunately this is not necessarily accompanied by an improvement in clinical results. The evidence base supports the use of uninstrumented posterolateral fusion as best option with lowest complication rate.

Discography

It is likely that a significant proportion of patients have discogenic or segmental pain. Proponents of this view use provocative discography to identify painful segments. Discography can identify segments where pain is reproduced by injection of saline into the disc and adjacent normal discs. It identifies patients with inappropriate responses (over-reaction to local anaesthetic or skin penetration by needle) and inappropriate or multilevel response to disc injection. The 'normal' disc is usually pain free when injected. There is a large literature on this, but many studies are flawed. Carragee's studies are a good starting point. He was able to demonstrate a predictive value for discography of only 50–60% in spinal fusion patients. In a cohort of 'normal' subjects who had discography, Carragee has found an increased incidence of disc degeneration, back pain, and back surgery.[27] This suggests discography should be used with extreme caution.

Other surgical indications

Spinal deformity

Spinal deformity (mainly scoliosis and kyphosis) affects children and adults. Surgery has an important part to play in management, depending on age (growth potential), aetiology, severity, and comorbidity. There is not space in this chapter to discuss this in detail, and the reader is referred to the *Oxford Textbook of Trauma and Orthopaedics*.[28] Adult deformity in both sagittal and coronal planes is an increasing issue as the population ages in better general health.

Tumours

Primary spinal tumours, both CNS and bony, are rare. They may present with pain, progressive neurological deficit, and spinal deformity. It can be challenging to diagnose the few cases in the generality of these common presenting symptoms. Continuous, atypical, and night pains should lower the threshold for obtaining an MRI scan to exclude such tumours. Surgical treatment is often required.

In contrast, metastases in the spine are extremely common, perhaps affecting 50% of cancer cases. Recent trials have supported the use of surgical management for uncontrolled pain and particularly for spinal cord compression. In the United Kingdom the National Institute for Health and Clinical Excellence (NICE) has issued guidance supporting the use of surgery combined with radiotherapy rather than radiotherapy alone.[29]

Trauma

The main indications for surgery of the injured spine are actual or potential instability of the spine likely to cause pain, deformity, and loss of function. There are also indications when neurological integrity is at risk. This is a complex area outside the scope of this book. The reader is referred to the *Oxford Textbook of Trauma and Orthopaedics*.[28]

Infection

Spinal tuberculosis was one of the first topics explored with high-quality clinical studies by the Medical Research Council in the United Kingdom after the Second World War. These and later studies confirmed the value of antimicrobial treatment with or without surgery. Surgery has a role when there is actual or potential spinal deformity (mainly kyphosis) that is threatening spinal cord function.

Non-specific infection of the spine can be very serious and even life threatening. Surgery may be needed for diagnosis and reconstruction of the spine. Details of this are beyond the scope of this textbook.

Cervical stenosis

Cervical stenosis may be congenital or acquired. Absolute (anteroposterior canal diameter <10 mm) or relative (10–13 mm diameter) stenosis predisposes the patient to development of radiculopathy, myelopathy, or both from relatively minor disc pathology or trauma. Minor trauma such as hyperextension may lead to a central cord syndrome even without overt skeletal manifestations. In relative stenosis, radicular symptoms usually predominate. Surgery may serve a prophylactic function but is usually reserved for patients who develop myelopathy or radiculopathy.

Cervical rheumatoid spondylitis

Cervical spine involvement is common in rheumatoid arthritis (RA) and is usually a result of pannus formation at the synovial joints between the dens and the ring of C1, resulting in destruction of the transverse ligament, the dens or both causing instability. Basilar invagination and subaxial subluxation may also occur but are less frequent. Neck pain, decreased range of movement, crepitation, and occipital headaches are the more common complaints. Neurological impairment in patients with RA usually occurs gradually and is often overlooked or attributed to other joint disease; it

is therefore essential to look for subtle neurological signs. Surgery may not reverse significant neurological deterioration but it can stabilize it. Indications for surgical stabilization include instability, pain, and neurologic deficit.

CHAPTER 93

Perioperative management of immunosuppression

Loreto Carmona and Maria Galindo

Introduction

Surgery is a common necessity for many rheumatic patients. Current therapeutic approaches have resulted in a lower frequency of reconstruction and replacement surgery, but some patients may still need surgery to regain function or control pain. Other non-orthopaedic interventions, both elective and emergency surgical procedures, may be also required at any given point. We, as rheumatologists, must recognize and communicate the risks of surgery in our patients, which are often higher than in non-rheumatic disease patients, and which are frequently under recognized by other specialists. Additionally, many patients are on immunosuppressive medications that must be managed appropriately at the time of elective surgery.

Surgical complications can range from minimal, such as wound dehiscence or numbness, to death, and include loss of function, excess blood loss, non-healing of the surgical wound, and infection.[1] Many risk factors for surgical complications have been recognized. These can be grouped into those related to (1) the patient's general health and specific rheumatic condition, (2) the ailment that lead to the operation, and (3) the procedure itself.[2] The patient's health and condition may determine the anaesthetic procedure to be used, and other arrangements, like the operating table, or the availability of extra blood. Sometimes it may determine the delay or indeterminate cancellation of surgery. It may also have an impact on the patient's recovery after surgery. The ailment requiring surgery may also influence the outcome and complications; cardiac surgery or neck surgery, for instance, increases the risk of perioperative mortality. The procedure itself may be revised in the light of added risk factors.

Aspects that should be acknowledged and corrected before surgery

Before elective surgery, some patient characteristics must be documented, and corrected if possible, in order to minimize the risk of surgery.[3] The anaesthetist and the physician in charge of the postoperative period must be aware of these, and a rheumatologist should be available at all times if not routinely involved in perioperative care. The following are a suggested list of aspects that should be considered and notified to the anaesthetist and surgeon:

- The **site of arthritic involvement** may itself be a source of risk. Cervical spine involvement may complicate anaesthesia by impeding cervical extension and endotracheal intubation, with the associated serious risk of spinal cord damage when there is instability. Other forms of anaesthesia should therefore be used in these patients, and the operating table adapted to the posture of the spine. Cord impingement may delay elective surgery until treated.

- **Airway involvement** may also complicate anaesthetic procedures. Crycoaritenoid arthritis, for instance, may interfere with intubation. This rare manifestation of rheumatoid arthritis (RA) should be fully treated before surgery, to avoid the potential need for tracheostomy.

- **Lung disease**, secondary either to the rheumatic condition or to its treatment, may increase the rate of pulmonary complications during anaesthesia. Preoperative recommendations are (in addition to a complete set of lung function tests, chest radiograph, and blood gases) avoidance of smoking or inhaling smoke for at least 4 weeks, bronchodilator therapy, or breathing exercises.

- **Anaemia** is frequent in patients with chronic inflammation, and orthopaedic surgery, especially that of large joints, may cause large loss of blood. All procedures aimed to reduce blood loss during surgery and to bring the patient to their optimum haemoglobin level before operation should be fully implemented.

- **Osteoporotic bones**, secondary to immobilization, glucocorticoids, age, and other causes, should be taken into account when mobilizing the patient, and when deciding the best prosthetic stem to use in a specific joint replacement.

- **Vasculitis** may underlie the lack of healing of a skin ulcer or a surgical wound. Surgery should consequently be delayed until the vasculitis is under control.

- **Heart involvement** should be fully checked before surgery and corrected if possible, as heart abnormalities are responsible for over one-third of intraoperative deaths.

◆ The **background risk of infection** should be taken into account. The risk of infection is increased in many rheumatic patients, especially those with lupus or RA, or with concomitant diabetes, and even more if they are immunosuppressed. The risk of infectious complications after surgery in a patient with RA, for instance, is nearly three times greater than that of osteoarthritis patients.[4] Antibiotic prophylaxis should therefore be considered for all surgery, independent of the apparent baseline risk of infection.

Perioperative use of immunosuppression

Any surgical operation is a stressful situation for an already stressed body; furthermore, patients on glucocorticoids may have a disrupted response to stress. Additionally, immunosuppressants may affect inflammation and local immune responses, which are necessary for proper wound healing, thereby potentially resulting in undesirable postoperative complications. The use of immunosuppression has been linked to the slow healing of surgical wounds and to an increased risk of infectious complications. On the other hand, stopping immunosuppressive medication may leave the patient at undesirable levels of disease activity, which itself may delay rehabilitation and require treatment escalation. Furthermore, in diseases such as RA, disease activity may reduce immune function. Factors such as blood count, drug type and dose, previous postoperative complications, type of surgery, and other factors should be taken into account when deciding how to manage perioperative immunosuppression. The timing of treatment discontinuation and reinstatement perioperatively also differs significantly among rheumatologists and even national guidelines vary. In a questionnaire sent to 200 randomly selected rheumatologists, Steuer et al.[5] reported the consensus on this issue: (1) 35% of respondents were concerned about disease-modifying antirheumatic drugs (DMARDs) increasing postoperative complications; (2) 14% 'always' advised stopping DMARDs perioperatively; (3) 48% advocated 'sometimes' stopping drugs perioperatively, depending on patient characteristics; (4) the timing of stopping treatment preoperatively and restarting after surgery also differed significantly among rheumatologists (from 1 week to more than 4 weeks). Even within in the same centre practice may vary.[4,6]

Unfortunately, only very limited data are available to support any decision and most available evidence comes from observational studies, only a few of which are of acceptable quality. While there is some information on the impact of non-steroidal anti-inflammatory drugs (NSAIDs), glucocorticoids and methotrexate (MTX), in the perioperative period,[7–10] we lack such data on DMARDs other than MTX, including biologics (e.g. TNF antagonists). In these cases, recommendations are rarely based on clinical trial evidence but more commonly on pharmacological considerations, experimental and animal models, and extrapolation from trials with the same drug in other diseases. Clearly, the implementation of randomized controlled trials in the perioperative period is complicated, as shown by Alarcon et al. in a clinical trial of three perioperative strategies that never reached the pre-planned sample size.[11] The main obstacle to participation was preconceived opinions on perioperative immune suppression, both from the rheumatologists and the orthopaedic surgeons. Curiously, physicians were equally divided between those who thought it unethical to suspend immunosuppressant therapy and those who thought that it was unethical to continue it.

Ultimately the objective is clearly to obtain a balance between maintaining disease control and avoiding an unfavourable impact on wound healing and postoperative complications.[9] To accomplish this, and prior to surgery, it is mandatory to document all medications that the patient is taking, including supplements and alternative medicines. All medications whose abrupt discontinuation may lead to increased morbidity should be maintained; it may even be necessary to substitute a parenteral form temporarily. All medications that may pose a surgical risk and are not essential for the patient's perioperative condition should be discontinued. A judgement should then be made on all other medications. For those drugs with limited or no data in this setting, the use of pharmacokinetic properties and biological effects of each drug may assist the judgement.[2]

Glucocorticoids

Glucocorticoids are clearly associated with skin fragility that may delay the healing process and also increase the risk of infection. It is generally believed that patients receiving long-term glucocorticoid therapy require supplemental perioperative (stress) doses owing to presumed suppression of the hypothalamic–pituitary–adrenal (HPA) axis (see Chapter 79). This hormonal system determines the body's response to stress, including surgical stress, which ranges from minimal to very high depending on the type of surgery. Failure to provide supplemental perioperative glucocorticoid therapy may result in adrenal crisis, although recent pooled evidence shows that this is not always the case if patients continue to receive their usual daily dose.[12] The anaesthetist, surgeon, and intensivist must be aware that the patient was receiving suppressive doses of glucocorticoids, necessitating close perioperative haemodynamic monitoring and the use of stress doses of hydrocortisone in patients with volume-refractory hypotension. As a rule, there is no risk of HPA axis suppression when the steroid treatment has been given for less than 3 weeks, the dose administered is lower than 5 mg/day of prednisone or equivalent, or if used on alternate days. The axis is more clearly suppressed when the dose is in excess of 20 mg/day of prednisone and it has been used for more than 3 weeks or when the patient has iatrogenic Cushing's syndrome. To avoid complications, such as refractory hypotension or haemorrhage, patients with a high suspicion of suppressed HPA axis should follow a regime of parenteral hydrocortisone perioperatively. No regime has demonstrated superiority over others,[2,3,10,13] but, as a rule, patients should receive 50 mg of hydrocortisone intraoperatively, then every 8 hours for 48–72 hours postoperatively in patients undergoing major surgery.[12]

Classical disease-modifying drugs in the perioperative period

Methotrexate

Since 1991, several studies have been published in which the use of perioperative MTX was analysed.[11,14–19] Most of these studies were observational and retrospective in nature. A randomized unblinded prospective 1 year follow-up study in 338 RA patients undergoing orthopaedic surgery reported less infections in

patients who continued on MTX compared to those who stopped it (1% vs 25%; p<0.001) and did not present any RA flare, while 8% of those who stopped MTX flared.[16] A systematic review concluded that continuing MTX during the perioperative period is at least as safe as discontinuing it, but with better prognosis in terms of disease activity, in patients undergoing elective orthopaedic surgery.[20] There may be, however, two exceptions to this general recommendation: patients with renal failure and elderly patients, in whom haematological toxicity risk may be increased given the special conditions of surgery. In these cases, some authors recommend discontinuation of MTX a week before surgery and reintroduction 1–2 weeks after the intervention, depending on evolution.

Leflunomide

A randomized controlled trial showed that the risk of infectious complications associated with maintaining leflunomide was not different from that if the drug was discontinued.[21] This contradicted previous observational data suggesting increased infectious complications, compared to MTX, if the drug was continued perioperatively.[22] The strength of the evidence supports continuation of leflunomide perioperatively.

Sulfasalazine

Clinical data are lacking on the perioperative use of sulfasalazine. The half-life is 6–10 hours; elimination is primarily renal. There are no studies which provide definite answers as to whether and for how long the drug should be discontinued perioperatively. In a large study on postoperative infections with TNF antagonists, sulfasalazine use was shown to be a protective factor against infections, therefore providing indirect evidence for continuation.[23] Importantly, given that the glomerular filtration rate may be reduced after surgery in predisposed patients, withholding sulfasalazine at least on the day of surgery is reasonable.

Azathioprine

In a retrospective study of postoperative wound complications after orthopaedic surgery, azathioprine was not associated with delayed wound healing.[24] A retrospective study that evaluated the influence of immunosuppressive therapy on postoperative complications in patients with Crohn's disease undergoing abdominal surgery found that azathioprine was not associated with postoperative complications, including intraabdominal infections.[25] Given these findings, and the fact that azathioprine is administered early after kidney transplantation, this drug may be considered safe. Therefore, the drug needs to be withheld only on the day of surgery, when an empty stomach is required anyway.

Hydroxychloroquine

A study on risk factors for wound healing did not find any association between antimalarials and postoperative complications.[24] Bibbo et al. analysed the results of foot and ankle surgery in RA and did not find an increased risk of poor wound healing or postoperative infections associated with the use of hydroxychloroquine (for NSAIDs, steroids, MTX, or gold).[7]

Hydroxychloroquine was used in the past to prevent postoperative venous thromboembolism after various orthopaedic surgical procedures, and despite some controversy about its benefit, the drug was considered to be well tolerated, and haemorrhagic complications or impaired wound healing were not increased.[26]

Based upon a long elimination half-life of approximately 40–50 days, and a toxicity profile generally classified as low, the continuation of hydroxychloroquine before and after surgery is deemed reasonable.

Biological agents in the perioperative period

TNF antagonists

Many studies have analysed perioperative exposure to anti-TNF agents,[23,27–35] most of which are neither adequately designed nor powered to answer whether the number and nature of complications is increased by discontinuation of the TNF antagonist during the perioperative period. In the British Society for Rheumatology Biologics Register (BSRBR), over 1500 surgeries, including patients with RA who had received anti-TNF treatment at any time prior to surgery, were studied with respect to exposure 28 days preceding surgery and serious infections occurring within 30 days of surgery.[28] The rate of infections in the exposed group was 7%, equal to the rate of the comparison control group on non-biologic DMARDs, and higher than the rate in the group in which the TNF antagonist was stopped (5%). Although the risk association does not reach statistical significance, and many unmeasured confounders may be at play, the authors recommend caution. This abstract did not comment on the risk of perioperative RA flares in patients discontinuing anti-TNF therapy.

Guidelines on the use of anti-TNF give specific recommendations on the perioperative management of these agents, which are based on expert opinion but a low level of evidence. The British[36] and the Spanish guidelines[37] recommend suspension of anti-TNF 2–4 weeks prior to elective surgery, depending on the drug half-lives.

Rituximab

The experience on the perioperative use of rituximab is driven mainly by the transplant literature. Rituximab is used in the prevention of transplant rejection and, as such, it is administered in the 4 months previous to surgery.[38] No distinct complications have been attributed to rituximab in this case. In fact, complete clearance of rituximab takes longer than 2 months, and this would require a prolonged interval between previous exposure and surgery. The transplant literature suggests that there is no need to discontinue rituximab prior to surgery, although it would be advisable to wait at least 2 weeks after last dosing to avoid delayed infusion reactions.

Abatacept, tocilizumab, and newer TNF antagonists

There is insufficient evidence to guide the perioperative use of newer biologics, and the manufacturers do not provide any specific guidance on the matter. Recommendations should probably align with those of TNF antagonists.

Other considerations

NSAIDs

NSAIDs may prolong the bleeding time, which may result in greater blood loss. Aspirin's effect on platelets may be long lasting, and it is recommended to suspend it 5–7 days prior to surgery and recommence it 72–96 hours after surgery. Other NSAIDs have shorter effects, with no requirement to suspend dosing for longer than 2–5 days prior to surgery, depending on half-lives of the individual

Table 93.1 Summary of recommendations on the perioperative use of immunosuppressive drugs

Drug	Before surgery	Day of surgery	After surgery
Glucocorticoids	Inform the anaesthetist, surgeon, and intensivist Haemodynamic monitoring	Haemodynamic monitoring Use stress doses of hydrocortisone if volume-refractory hypotension	Haemodynamic monitoring Use stress doses of hydrocortisone if volume-refractory hypotension
If <3 weeks + <5 mg/day of prednisone or equivalent (or on alternate days):	No action	No action—fasting	Reintroduce at same dosing
If >20 mg/day of prednisone + >3 weeks or iatrogenic Cushing's syndrome	No action	50 mg of hydrocortisone parenteral intraoperatively[12]	50 mg of hydrocortisone every 8 hours for 48–72 hours[12]
If intermediate situations:	No action	Hydrocortisone 25–50 mg or no action (fasting)	Hydrocortisone 25–50 mg every 8 hours for 48 hours or simply reintroduce steroids
Methotrexate	If >65 years old or renal failure discontinue 1 week before surgery. Other situations—no action[20]	No action—fasting	If >65 years old or renal failure wait 1–2 weeks All others, reintroduce as soon as oral medication can be provided
Leflunomide	No action[21]	No action—fasting	Reintroduce as soon as oral medication can be provided
Sulfasalazine	No action[23]	No action—fasting	Reintroduce as soon as oral medication can be provided
Azathioprine	No action[25]	No action—fasting	Reintroduce as soon as oral medication can be provided
Hydroxychloroquine	No action[7,24]	No action—fasting	Reintroduce as soon as oral medication can be provided
TNF antagonists	Suspend 2–4 weeks[a] prior to surgery[36]	No action	Reintroduce after 1 week
Rituximab	Wait 2 weeks after last dosing	No action	Reintroduce after 1 week
Abatacept	Wait 4 weeks after last dosing	No action	Reintroduce after 1 week

[a]Etanercept and adalimumab 2 weeks, infliximab 4 weeks.

drugs. They can be reintroduced from 48 hours after surgery if needed.

Risk factors for infectious complications

When deciding a perioperative strategy it is important to take into account other factors, especially those associated with an increased risk of infections, such as age, diabetes, renal failure, or comorbidities such as lung disease.[28,39,40] There is no clear association between disease activity in RA, for instance, and surgical complications. Hämäläinen et al. in a case-control study for risk factors of postoperative problems (136 cases; 1:2 controls), did not find any association with disease duration, Steinbrocker status, erythrocyte sedimentation rate (ESR), or rheumatoid factor.[39] However, surgical factors and factors related to the admission itself were associated, such as a prolonged admission,[39] the day of admission (apparently the risk seems higher on specific days),[39] the ischaemic time,[39] and the type of surgery (greater risk of major complications in knee replacement and hand and wrist synovectomy).[39,41,42] A final but very important factor would be a history of previous postoperative infections.[4,39]

Conclusion

The surgical risk must be carefully weighed against benefits in all rheumatic patients, especially in those using immunosuppressive medications and suffering multiple comorbid conditions. Where the benefits appear to outweigh the risks, a comprehensive health status and medication checklist should be used to uncover reversible risk factors that require attention, and to plan medication around surgery. Recommendations on the perioperative use of immunosuppressive drugs are summarized in Table 93.1. The support of the treating rheumatologist during the perioperative period is essential.

Vaccination in immunocompromised adults

Sander van Assen and Marc Bijl

Introduction

The aim of vaccination is to prevent or mitigate diseases by artificially inducing immunity. **Active vaccination** triggers the immune system to provide (protective) humoral and cell-mediated immune responses against the vaccine-preventable disease, while **passive vaccination** refers to the administration of exogenously produced antibodies for protection.

Most vaccines confer protection by eliciting B-cell responses leading to the production of antibodies directed against infectious or toxic agents, but neutralizing immune effector responses can also be T-cell mediated. An adequately functioning immune system is required to respond with protective immunity following vaccination. Therefore, patients with a compromised immune system may not be able to elicit protective immune responses, although they are most in need of preventive measures against infections.

In patients with autoimmune inflammatory rheumatic diseases (AIIRD) an immunocompromised state can result from treatment with immunosuppressive agents, or from the AIIRD itself, e.g. functional asplenia, hypocomplementaemia, or the presence of damaged organs serving as a locus minoris resistentiae.

An important issue with regard to vaccination is safety, in particular in patients with autoimmune diseases. The antigenic stimulus of vaccination might trigger a broader non-specific response, potentially resulting in increased activity of the underlying autoimmune disease.

Epidemiology of vaccine-preventable infections in patients with AIIRD

Infection risk is increased in patients with AIIRD. Especially pulmonary infections occur more frequently, and the mortality and morbidity of these infections are increased. Vaccines are available against influenza, *Streptococcus pneumoniae*, and *Haemophilus influenzae* b (Hib), which cause the majority of pulmonary infections in the general population. Here we summarize the epidemiology of vaccine-preventable infections (VPI) in patients with AIIRD.

In patients with AIIRD the incidence of influenza is unknown; however, the risk of hospital admission for pneumonia or influenza has been demonstrated to be higher in older patients (≥65 years) with rheumatic diseases and vasculitis compared to the elderly population in general.[1] Comparisons of the incidence of *S. pneumoniae* infection between patients with AIIRD and the general population are lacking.[1] In an uncontrolled prospective cohort of 45 patients with systemic lupus erythematosus (SLE) treated with rituximab (RTX), cyclophosphamide, and methylprednisolone, one patient developed pneumococcal pneumonia and septicaemia.[1]

The incidence of herpes zoster (HZ) in rheumatoid arthritis (RA) ranges from 0.55 up to 11.1/1.000 patient-years (PY) in prospective cohort studies.[1] RA per se is a risk factor for HZ, as are the use of steroids (relative risk (RR) point estimates 1.41–2.52); antitumour necrosis factor alpha (TNFα), in particular infliximab and adalimumab (RR point estimates 1.38–2.44); and the combination of TNFα-blocking agents and steroids (RR estimate 2.44).[1] Non-biologic disease-modifying anti-rheumatic drugs (DMARDs), with or without steroids, also increase the risk (cyclophosphamide 4.2-fold, azathioprine 2.1-fold, leflunomide 1.4-fold, non-biologic DMARDs and steroids 2.39-fold).[1] However, combination therapy with etanercept and methotrexate (MTX) may not increase the risk for HZ.[1] In SLE, the risk of HZ is increased 5- to 16-fold compared to the general population. The incidence of HZ was 18.3/1.000 PY in SLE patients.[1] HZ risk correlates with the use of cyclophosphamide, azathioprine, and steroids in combination with other immunosuppressive drugs.[1] The risk may be lower for mycophenolic acid compared with cyclophosphamide (RR 0.36) A randomized controlled trial (RCT) showed that SLE patients treated with RTX, along with background immunosuppressives including steroids, developed HZ more often than the placebo groups.[1] No increase in incidence of HZ during flares of SLE has been demonstrated.[1] In granulomatosis with polyangiitis (GPA) patients treated with standard immunosuppressives with or without etanercept, the incidence of HZ was high compared with the general population

(45/1.000 PY vs 1.2–4.8/1.000 PY). A serum creatinine level of 1.5 mg/dL or more increased the risk of developing HZ by a factor of 6.3.[1] The incidence of HZ is also high in patients with polymyositis/dermatomyositis (PM/DM): 27.2/1.000 PY.[1]

Human papillomavirus (HPV) infection occurs more often in SLE patients compared with healthy controls (24.6% vs 10.4%), also with the high-risk subtype HPV-16 (4.7–53% vs 1.2–6.7%).[1] The cumulative prevalence rises from 13.1% at baseline (11.7% high-risk subtype) to 25.5% (21.4% high-risk subtype) after 3 years. The incidence of HPV infection was 17/1.000 patient-months. The most common newly acquired HPV subtype was HPV-16, followed by HPV-18, -56 and -58. Only 31.8% of all incident infections were cleared.[1] For SLE patients the risk factors for HPV infection are the same as those for the general population, in addition to anti-nuclear antibodies (ANA) in excess of 320.[1]

Efficacy of vaccination in patients with AIIRD

Since at least some VPI occur more often in patients with AIIRD, the efficacy of vaccination in these patients should be addressed. Preferably, studies evaluating the efficacy of vaccination should use clinical endpoints. Unfortunately, only one vaccination study meets this criterion. All other studies investigated vaccines by measuring the humoral and/or cell-mediated immune response as a surrogate, although correlate of protection is often lacking for these measures. For influenza a haemagglutination inhibition (HI) titre of 40 or more is considered protective; however, this has never been validated for AIIRD patients. For pneumococcal, HZ, and HPV vaccination a correlate of protection is unknown, therefore a rise in titre following vaccination is predominantly used to address the efficacy.

Influenza vaccine

A reduction in pneumonitis, acute bronchitis or viral infection was found in RA patients and SLE patients who received influenza vaccine compared to those who did not.[1] Other studies have shown similar efficacy of seasonal influenza vaccination in RA patients compared to healthy controls, based on a HI titre of 40 or more. In most studies neither DMARDs nor TNFα blocking treatment hampered the humoral response.[1] Two studies reported a modestly impaired response in anti-TNFα users, not resulting in a lower percentage of seroprotection.[1] In contrast to DMARDs and TNFα-blocking treatment, RTX severely hampers the immune response following influenza vaccination.[1] In the first 8–12 weeks after treatment with RTX no antibody response was induced; 6–10 months after RTX the antibody response was partially restored.[1]

A modestly reduced response to influenza vaccination in SLE patients but also comparable efficacy of subunit influenza vaccine have been found in SLE patients compared to healthy controls.[1] In most studies the use of immunosuppressive drugs did not affect the vaccination response[1]; however, a lower response to vaccination in SLE patients on azathioprine, steroids, and hydroxychloroquine[1] has also been observed. The vast majority of studies assessing the effect of disease activity on the humoral response following influenza vaccination in RA and SLE patients did not show a reduced response during active disease.[1] Also in patients with GPA and systemic sclerosis (SSc) similar responses

following influenza vaccination compared to healthy controls were found.[1]

Vaccination for the novel influenza A/H1N1v (A/California 7/2009) virus that emerged in Mexico in 2009 provided useful insight into vaccination responses in patients with AIIRD, because virtually no pre-existent immunity to the novel influenza strain was present. Seroprotection rates for patients with RA, SLE, AS, PsA, and DM were impaired compared to healthy controls following vaccination with a A/H1N1v-vaccine with and without adjuvants,[2–6] although one study in SLE patients did not show significant differences in response.[7] Biologics, B-cell depletion, DMARDs (except antimalarials and sulphasalazine) and lymphocytopenia negatively influenced the humoral response.[3–6] Interestingly, a second dose of vaccine 3–4 weeks after the first one could overcome the hampered response,[3,6] as has also been shown for seasonal influenza vaccination in SLE patients.[8]

Cellular immune responses following influenza vaccination have also been addressed in a limited number of studies. A small study on RA patients treated with RTX found no difference in interferon (IFN) γ production by CD4 cells following influenza vaccination compared to healthy controls.[9] Cell-mediated immune responses in patients with GPA are comparable to those in healthy controls.[10] However, in SLE patients cell-mediated responses to influenza vaccination are hampered, as demonstrated by IFNγ-ELISpot and intracellular cytokine staining.[11] This may have been caused by the concomitant use of immunosuppressive drugs. It should be emphasized that the exact contribution of cell-mediated immunity to protection against influenza following influenza vaccination remains unknown.

Pneumococcal vaccine

The efficacy of pneumococcal vaccination is difficult to determine, as no generally accepted response criteria have been defined. Moreover, different vaccines (polysaccharide and conjugate vaccine) are available containing antigens with different numbers of pneumococcal serotypes.

Unvaccinated RA patients treated with MTX have a RR of 9.7 for developing pneumonia compared to those vaccinated with 23-valent polysaccharide pneumococcal vaccine.[12] Compared to healthy controls, similar as well as lower humoral responses to pneumococcal vaccines have been demonstrated in RA patients.[1] MTX alone or combined with TNFα-blocking agents negatively influenced the response, whereas TNFα-blocking agents alone did not reduce efficacy of pneumococcal vaccination in most studies. This held true for 23-valent polysaccharide as well as 7-valent conjugate pneumococcal vaccine.[1,13,14] The same was found for psoriatic arthritis (PsA) and anklylosing spondylitis (AS) patients. However, the response to pneumococcal polysaccharide vaccine was markedly reduced in RA patients vaccinated 28 weeks after RTX administration.[1]

In SLE patients similar or reduced/low responses to pneumococcal vaccine have been found,[1] not influenced by the combined use of steroids and azathioprine or cyclophosphamide.[1] RA and SLE disease activity did not influence the efficacy of vaccination.[1]

Hepatitis B vaccine

A response to hepatitis B (HBV) vaccination could be demonstrated in the majority of patients with RA, SLE, AS, and Behçet's disease (BD), irrespective of the use of steroids or DMARDs.[1] In AS patients the use of TNFα-blocking agents severely hampered the response to

HBV vaccine.[1] Low patient numbers and the lack of appropriately controlled studies make firm conclusions impossible.

Tetanus toxoid vaccine

Tetanus toxoid vaccination seems to be efficacious in RA and SLE patients.[1] The use of steroids and DMARDs, but also RTX when administered 24 weeks before tetanus vaccination, did not reduce efficacy.[1] The efficacy of tetanus vaccination may be reduced during active disease in SLE patients, but not in RA patients.[1]

Haemophilus influenzae b (Hib) vaccine

Eighty-eight per cent of SLE patients developed a protective antibody titre against Hib, with a trend towards a lower response in those using immunosuppressive drugs.[1]

Box 94.1 EULAR recommendations for vaccination in adult patients with autoimmune inflammatory rheumatic diseases

1. The vaccination status should be assessed in the initial work-up of patients with AIIRD.

2. Vaccination in patients with AIIRD should ideally be administered during stable disease.

3. Live attenuated vaccines should be avoided whenever possible in immunosuppressed patients with AIIRD.

4. Vaccination in patients with AIIRD can be administered during the use of DMARDs and TNFα blocking agents, but should ideally be administered before starting B-cell-depleting biological therapy.

5. Influenza vaccination should be strongly considered for patients with AIIRD.

6. 23-valent polysaccharide pneumococcal vaccination should be strongly considered for patients with AIIRD.

7. Patients with AIIRD should receive tetanus toxoid vaccination in accordance to recommendations for the general population. In case of major and/or contaminated wounds in patients who received RTX within the last 24 weeks, passive immunization with tetanus Ig should be administered.

8. Herpes zoster vaccination may be considered in patients with AIIRD.

9. HPV vaccination should be considered in selected patients with AIIRD.

10. In hyposplenic/asplenic patients with AIIRD influenza, pneumococcal, *Haemophilus influenzae* b, and meningococcal C vaccinations are recommended.

11. Hepatitis A and/or B vaccination is only recommended in patients with AIIRD who are at risk.

12. AIIRD patients who plan to travel are recommended to receive their vaccinations according to general rules, except for live attenuated vaccines, which should be avoided whenever possible in immunosuppressed patients with AIIRD.

13. BCG vaccination is not recommended in patients with AIIRD.

Source: van Assen et al.[16]

Safety of vaccination in patients with AIIRD

In patients with AIIRD the antigenic stimulation applied by vaccination might theoretically lead to exacerbations of the underlying autoimmune disease. Few randomized trials have addressed the safety of vaccination in patients with AIIRD. However, several pre–post-vaccination studies are available that compare disease activity before and after vaccination, using every patient as their own control.

Influenza vaccine

Two controlled trials and several pre–post studies showed no increase in RA disease activity following influenza vaccination.[1] Similarly, SLE patients who are vaccinated against influenza do not develop more disease flares than unvaccinated patients in most studies, whereas a few uncontrolled studies reported mild flares (up to 35%) or renal flares with glomerulonephritis (1 of 29 SLE patients).[1] Also, in GPA patients receiving influenza vaccination a difference in the occurrence of disease flares was not found compared to GPA patients who did not receive influenza vaccination, and no flares were registered in SSc patients who received (virosomal) influenza vaccine.[1]

Vaccination of AIIRD patients with both the non-adjuvanted and adjuvanted 2009 pandemic influenza A/H1N1 vaccine also appeared safe. Flares of SLE occurred as often following vaccination as in a control population (11% vs 10.5%)[15] and no rise in disease activity scores following vaccination was found.[1,2,4,6,7] Moreover, the levels of autoantibodies remained unchanged.[1,15]

Pneumococcal vaccine

In pre–post vaccination studies in RA and SLE patients no increase in disease activity following pneumococcal vaccination was demonstrated.[1] Similarly, vaccination did not increase disease activity in PsA and Sjögren's syndrome (SjS).[1]

Hepatitis B vaccine

HBV vaccination did not lead to increased disease activity in 22 vaccinated RA patients compared to 22 unvaccinated patients,[1] and in 28 SLE patients no significant change was recorded in Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) score after each vaccine dose.[1] In a study of 13 BD patients, three developed oral aphthae following HBV vaccination but otherwise no increase in disease activity was observed.[1]

Recommendations

A European League Against Rheumatism (EULAR) task force was set up in the spring of 2009 to develop evidence-based recommendations for vaccination of adult patients with AIIRD. Thirteen recommendations were formulated (Box 94.1). The basis for the recommendations are the increased incidence of certain VPI in patients with AIIRD and the efficacy of most vaccines in patients with AIIRD, even when treated with immunomodulating agents (rituximab being an exception). The aforementioned data, suggesting that vaccination is safe in patients with AIIRD, were considered to be of great importance when formulating the recommendations.[16]

CHAPTER 95

Vaccination in immunocompromised children

Marloes Heijstek, Mario Abinun, and Nico Wulffraat

Introduction

Recommendations from the European League Against Rheumatism (EULAR) exist for the immunization of children with rheumatic diseases (Table 95.1).[1] These are also applicable to patients with autoinflammatory diseases, because of similarities in clinical presentation and medication use.

Several issues need consideration when vaccinating immunocompromised hosts:

- Efficacy refers to the capacity of vaccinations to prevent infections.
  - Often, antibody responses are taken as surrogate endpoints for efficacy.
  - The immunogenicity can be reduced due to the immunosuppressed status.
- Safety depends on the disease, the vaccine, and the degree of treatment-induced immunosuppression.
  - Safety is determined by the rate of adverse events and the effect of vaccinations on the underlying disease.
- A clear distinction must be made between live-attenuated vaccines and non-live (killed) composite vaccines.
  - In immunosuppressed hosts, the risk of live-attenuated vaccines reverting to the virulent form, or inducing complications similar to those seen in the naturally occurring disease, must be weighed against the risks of natural infection.

Immunosuppression in patients with rheumatic or autoinflammatory diseases

All patients on high-dose glucocorticoids, high-dose disease-modifying antirheumatic drugs (DMARDs), and/or biologicals are considered immunocompromised. The doses are deemed fully immunosuppressive are listed in Table 95.2.

Live-attenuated vaccines in immunocompromised patients

It is recommended to adhere to national vaccination guidelines for the live-attenuated vaccines, unless patients are immunosuppressed due to high-dose DMARDs, high-dose glucocorticoids, or biologicals, when it is recommended to withhold these vaccines. However, booster live-attenuated vaccines can be considered when essential on a case-by-case basis, carefully weighing the risk of infections versus the hypothetical risks of vaccine adverse effects (Table 95.1). This is supported by studies showing that live-attenuated booster vaccines were safe in patients on standard doses of methotrexate (MTX) and low-dose glucocorticoids. Boosters are considered safer then primary live-attenuated vaccines, as patients have already built up (protective) immunity. Therefore, primary live-attenuated vaccines theoretically have higher risk of reverting to the virulent form of the pathogen, thereby inducing infection. Fortunately, primary vaccines are mostly administered prior to onset of the disease. However, when this is not the case, live-attenuated vaccines should be withheld in patients on high-dose immunosuppressive drugs and biologicals.

Bacillus Calmette–Guérin vaccine

The Bacillus Calmette–Guérin (BCG) vaccination against tuberculosis is included in national immunization programmes of countries where tuberculosis is endemic. In juvenile patients on anti-TNFα treatment, severe tuberculosis infections have been reported. In patients living in endemic areas, BCG vaccination should be administered prior to initiating immunosuppressive drugs. BCG vaccination is contraindicated in patients with cellular immunodeficiency syndromes and in severely immunosuppressed patients.[1] It is recommended to withhold BCG vaccination during active Kawasaki disease, because local inflammation at the BCG vaccination site can occur in up to 50% of these patients.[2] The efficacy of BCG vaccination in immunocompromised patients is unknown.

Table 95.1 Recommendations for vaccination of paediatric patients with rheumatic diseases

Recommendation	Grade[d] (A–D)
Live-attenuated vaccines	
Adhere to national vaccination guidelines[a] for live-attenuated vaccines unless patients are on high-dose DMARDs,[b] high-dose glucocorticoids,[b] or biologicals	C
Withhold live-attenuated vaccines in patients on high-dose DMARDs,[b] high-dose glucocorticoids,[b] or biologicals. However, essential booster vaccinations can be considered on a case-by-case basis weighing the risk of infections vs the hypothetical risk of vaccine-induced adverse events	D
Booster vaccinations against VZV, MMR, and YFV can be considered in patients on methotrexate <15 mg/m^2 per week or low-dose glucocorticoids	C
Assess VZV infection and vaccination history, especially in patients anticipating high-dose immunosuppressive therapy[b] or biologicals. In case of a negative history, VZV vaccine should be considered, ideally before initiating immunosuppressive therapy[c]	D
Non-live vaccines	
When indicated according to national guidelines,[a] non-live vaccines can be administered even when using glucocorticoids, DMARDs or anti-TNFα therapy	C
Adhere to national vaccination guidelines[a] for vaccination against HVA, tetanus, diphtheria, pertussis, Hib, pneumococci, and meningococci	B/C
Adhere to national vaccination guidelines[a] for vaccination against HVA, poliovirus, Japanese encephalitis, typhoid fever, rabies, cholera or tick-borne encephalitis	D
Consider annual influenza vaccination in all immunocompromised patients	D
When vaccinations against Hib, pneumococci and meningococci are not included in national vaccination programmes,[a] these vaccinations are recommended for patients with complement deficiency or functional asplenia. These vaccinations can be considered in patients on high-dose immunosuppressive drugs[b] or biologics prior to commencing therapy[c]	D
Adhere to national vaccination guidelines[a] for vaccination against HPV. Given the higher risk of HPV infection in female SLE patients, these patients should be advised to be vaccinated in the adolescence	D
Immunosuppressive drugs	
Measure pathogen-specific antibody concentrations after vaccination in patients on high dose glucocorticoids[b] or rituximab. This can also be considered in patients on anti-TNFα treatment	C
Measure pneumococcal strain-specific antibody concentrations after the pneumococcal polysaccharide vaccine in patients on methotrexate at time of vaccination	C
Vaccinate prior to commencing rituximab whenever possible	C
In patients with a contaminated wound, administer tetanus immunoglobulin if treated with rituximab in the past 6 months	D

DMARDs, disease-modifying anti-rheumatic drugs; Hib, *Haemophilus influenzae* type B; HVA, hepatitis A virus; HVB, hepatitis B virus; HPV, human papillomavirus; MMR, measles, mumps, rubella; SLE, systemic lupus erythematosus; TNF, tumour necrosis factor; VZV, varicella zoster virus; YFV, yellow fever virus

[a]National vaccination guidelines worldwide can be found via http://apps.who.int/immunization_monitoring/en/globalsummary/scheduleselect.cfm

[b]High-dose DMARDs are defined as intravenous pulse therapy, ciclosporin >2.5 mg/kg per day, sulphasalazine >40 mg/kg per day or 2 g/day, azathioprine >3 mg/kg, cyclophosphamide orally >2.0 mg/kg per day, leflunomide >0.5 mg/kg per day, or 6-mercaptopurine >1.5 mg/kg per day. High-dose glucocorticoids are dosages ≥2 mg/kg or ≥20 mg/day for ≥2 weeks.

[c]Generally 2–4 weeks is recommended before immunosuppressive therapy is commenced.

[d]The grade of recommendation is based on the level of evidence. Grade A recommendations are based on the highest level of evidence (meta-analysis of randomized controlled trials); grade D recommendations are based on consensus.

Adapted from Heijstek et al.[1]

Measles, mumps, rubella vaccine

The measles, mumps, rubella (MMR) vaccination is included in national immunization programmes worldwide. It is safe and efficacious when patients are not immunosuppressed by treatment. MMR booster vaccination does not aggravate JIA disease and has good immunogenicity, even in patients on standard dose MTX or low dose glucocorticoids.[3,4-4a] In these patients MMR booster vaccination can be considered.

Varicella zoster virus vaccine

Several countries have included varicella zoster virus (VZV) vaccination in their immunization programme. Case reports exist of severe disseminated primary VZV or zoster infections in patients on anti-TNFα therapy or MTX. Therefore, it is recommended to assess VZV infection and vaccination history, especially in patients anticipating high-dose immunosuppressive therapy or biologicals. In case of a negative history for VZV infection or vaccination,

Table 95.2 Immunosuppressive doses of anti-rheumatic drugs

Drug	Dose considered fully immunosuppressive
Glucocorticoids	>2 mg/kg or a total dose >20 mg/day during at least 2 weeks
Disease-modifying anti-rheumatic drugs (at a dose above the standard dosages)	
Methotrexate	15 mg/m^2 per week
Ciclosporin	2.5 mg/kg per day
Sulphasalazine	40 mg/kg per day up to 2 g/day
Azathioprine	1–3 mg/kg per day
Cyclophosphamide	0.5–2.0 mg/kg per day
Leflunomide	0.25–0.5 mg/kg per day
6-Mercaptopurine	1.5 mg/kg per day
Intravenous pulse therapy	
Methylprednisolone	Any
Cyclophosphamide	Any
Biologicals	Any

vaccination should be considered before initiation of immunosuppressive therapy.

The VZV vaccine is safe and efficacious when patients are not immunosuppressed by treatment.[1] Booster vaccinations against VZV can be considered in patients on MTX less than 15 mg/m^2 per week or low-dose glucocorticoids,[5] as the vaccine is at least relatively immunogenic.[5,6] A mild self-limiting varicella-like rash can occur, whereas severe adverse effects such as generalized varicella infection or disease flares are highly uncommon.

Yellow fever virus and oral poliovirus vaccine

It is recommended to follow national vaccination guidelines and to withhold the yellow fever virus (YFV) and oral poliovirus vaccine in patients on high-dose glucocorticoids, high-dose DMARDs, or biologicals. No information exists on these vaccines in juvenile patients. In adults with rheumatic diseases on various immunosuppressive drugs, including biologicals, YFV booster does not cause severe adverse events and has good immunogenicity.[1] Thus, booster vaccinations against yellow fever can be considered in patients on MTX less than 15 mg/m^2 per week or low-dose glucocorticoids.

Non-live composite vaccines in immunocompromised patients

Non-live composite vaccines administered through national vaccination programmes are safe and immunogenic in juvenile patients with rheumatic or autoinflammatory diseases even when using glucocorticoids, DMARDs, and/or anti-TNFα therapy (Table 95.1).[7–9]

Human papillomavirus vaccine

As patients with systemic lupus erythematosus (SLE) have higher risk of persistent human papillomavirus (HPV) infections,

premalignant lesions, and cervical cancer than healthy subjects, they should be vaccinated before they become sexually active.[10,10a] In all other patients, it is recommended to adhere to national vaccination guidelines.

Seasonal influenza virus vaccine

Seasonal influenza virus vaccination is recommended for children at high risk for influenza complications. Older patients with rheumatic diseases have an increased risk for influenza with a beneficial effect of vaccination, but it is unknown whether juvenile patients are at higher risk of (complicated) influenza infections.

Seasonal influenza vaccination is safe and immunogenic, even in patients on glucocorticoids or DMARDs.[11–14] Anti-TNFα treatment can suppress the antibody response, although this does not result in lower protection rates. Based on the potential increased risk of (complicated) influenza infections and the safety and immunogenicity of non-live influenza vaccines, annual influenza vaccination should be considered in immunocompromised patients.

Meningococcal, pneumococcal, and *Haemophilus influenzae* type b vaccine

Patients with SLE and JIA with functional asplenia or complement deficiencies (C3, C5–9) are at increased risk for infections with encapsulated bacteria such as meningococci, pneumococci, and *Haemophilus influenzae* type b (Hib). In countries where these vaccinations are not routinely administered, they are recommended for these patients. Immunocompromised patients travelling into countries where the meningococcal vaccine is not routinely administered are at increased risk of meningococcal infection. Additionally, patients receiving anti-TNFα agents and IL-1 receptor blocking agents may have increased susceptibility to pneumococcal infections.[15] These vaccines should be considered in patients prior to therapy with high-dose immunosuppressive drugs or biologicals. The monovalent meningococcal conjugate vaccine against serogroup C and the 7-valent pneumococcal conjugate vaccine are safe and immunogenic in JIA patients.[16,17-17a] The immunogenicity may be reduced in patients on high dose immunosuppressive drugs or biologicals.

Effects of immunosuppressive drugs on the efficacy of vaccinations

Glucocorticoids

It is recommended to measure vaccine responses through pathogen-specific antibody concentrations in patients on high-dose glucocorticoids.[14] Low-dose glucocorticosteroids do not reduce serologic responses. Hence, measuring antibody concentrations after immunization is not required in patients on low-dose glucocorticoids.[11]

Disease-modifying anti-rheumatic drugs

Patients on a standard MTX dose (15 mg/week) can be safely vaccinated with non-live and live-attenuated vaccines.[3–5] The standard MTX dose does not reduce the immunogenicity of vaccines,[8,11,14] except for the pneumococcal polysaccharide vaccine (PPV), and possibly other polysaccharide vaccines.[1,14] It is recommended to measure pneumococcal serotype-specific antibody concentrations

after PPV in patients on MTX at time of vaccination. If responses are insufficient, conjugate vaccines should be considered, since these vaccines are more immunogenic in immunocompromised patients. Studies on other DMARDs are scarce and too diverse to draw conclusions.

Biologicals

Anti-TNFα treatment does not reduce the protection rate of non-live composite vaccines although it can lower the titre of vaccination-induced antibodies.[1,16] It is recommended to measure vaccine responses in patients on anti-TNFα treatment at time of vaccination.

Rituximab (anti-B cell monoclonal antibody) blunts the humoral immune response up to 6 months after treatment.[1,14] It is recommended to vaccinate prior to rituximab use or to measure vaccine responses in patients on rituximab at time of vaccination. Patients with a contaminated wound and treated with rituximab in the past 6 months should be given tetanus immunoglobulin.

As data on other biologicals are lacking, measuring established antibody concentrations after vaccination and withholding live-attenuated vaccines is prudent.

Conclusion

Patients with rheumatic or autoinflammatory diseases treated with high-dose glucocorticoids, high-dose DMARDs, or biologicals are immunocompromised. Vaccination is crucial in these patients, given their increased risks of infections.[1]

Generally, immunogenicity of vaccines is good with some exceptions:

◆ Responses are reduced in patients on high-dose glucocorticoids and rituximab.

◆ MTX reduces responses to (pneumococcal) polysaccharide vaccines.

◆ Anti-TNFα can lower vaccine-induced antibody concentrations.

Offering vaccination before immunosuppressive drugs and/or measuring antibodies after immunization is suggested.

Overall, vaccinations do not increase disease activity and do not cause severe adverse events. Non-live vaccines are safe, but it is recommended to withhold live-attenuated vaccines in patients on high-dose immunosuppressive drugs and biologicals. However, booster vaccinations can be considered when essential[18].

Principles of management of juvenile idiopathic arthritis

Nicolino Ruperto and Angelo Ravelli

Introduction

The management of juvenile idiopathic arthritis (JIA) is based on a combination of pharmacological interventions, physical and occupational therapy, and psychosocial support.[1,2] (Ravelli and Martini[2] is a key reference, providing a comprehensive review of the epidemiology, classification, clinical features, aetiopathogenesis, outcome, and management of JIA.) The goal of treatment should be to induce disease remission, to control pain, to facilitate normal nutrition and growth, to preserve physical and psychological well-being, and to prevent long-term damage related to the disease or its therapy. Although we still do not possess medications that are able to cure the disease, prognosis has greatly improved in the recent years owing to major progresses in therapy. These advances have increased the expectation for disease control.[3–6]

The optimal approach to the management of a child with JIA is based on a multidisciplinary team composed of a paediatric rheumatologist, specialist nurse, physical therapist, occupational therapist, and psychologist.[1] Patient and family education and integration of parents' and children's perception of the disease course and effectiveness of therapeutic interventions in the clinical assessment are important to facilitate adherence to the management programme and therapeutic benefit.[7]

Because JIA is not a single disease, treatment approaches must recognize the differences between subtypes.[8–10] However, a rational therapeutic strategy is hampered by the inability to identify early in the disease course which children will experience a benign and self-remitting course and which children will go on to have unremitting disease with substantial risk of joint destruction and serious functional impairment.

Results of therapeutic studies in adult patients with rheumatoid arthritis (RA) are not applicable to children with JIA not only because children cannot be considered as young adults, but also because childhood arthritis is different from adult-onset RA. Furthermore, the pharmacological issues and safety concerns relating to the use of medications in growing individual deserve special consideration.

Medical management of juvenile idiopathic arthritis

Non-steroidal anti-inflammatory drugs

Non-steroidal anti-inflammatory drugs (NSAIDs) have traditionally been the mainstay treatment for all forms of JIA. Their role remains important and most children are started on an NSAID. A 4–6 week trial of an individual NSAID is necessary to assess its efficacy. However, since NSAIDs are not disease modifying, they are used more to treat pain, stiffness, and the fever associated with systemic arthritis. Only a few NSAIDs are approved for use in children: the most commonly used are naproxen, ibuprofen, and indomethacin. They are usually well tolerated and side effects are less common than in adults. However, the parents and patients should be advised to take the medication with food to minimize the risk of gastric upset. The utility of antacids, histamine$_2$-receptor antagonists, misoprostol, and proton pump inhibitors for prophylaxis against serious NSAID-induced gastrointestinal complications in children with chronic arthritis is unclear. Experience with cyclooxygenase (COX)-2 inhibitors in the paediatric age range is scarce.[11,12] Meloxicam, an inhibitor of both COX-1 and COX-2, has proven to be effective and safe in children in a controlled trial.[11] The NSAIDs that are commonly used in JIA and their doses are presented in Table 96.1.

Corticosteroids

Intra-articular injections

Intra-articular corticosteroid (IAC) injections are widely used in the management of children with JIA to induce short-term relief of inflammation symptoms and functional improvement, and to obviate the need for regular systemic therapy.[13,14] Nowadays, it is thought that many paediatric rheumatologists are using IACs as their first approach in oligoarticular JIA. In children with this subtype, local IAC therapy has been shown to enable correction of joint contractures, prevention of leg-length discrepancy, discontinuation of oral medications, resolution of Baker's cysts, and improvement of tenosynovitis. However, the strategy of performing multiple

Table 96.1 Non-steroidal anti-inflammatory drugs commonly used in children with juvenile idiopathic arthritis

Chemical class/drug	Dose (mg/kg/day)	Maximum dose (mg/day)	Doses per day
Salicylate			
Aspirin	80–100 (<25 kg) 2500 mg/m^2 (>25 kg)	4900	2–4
Propionic acid derivatives			
Naproxen	10–20	1000	2
Ibuprofen	30–40	2400	3–4
Ketoprofen	2–4	300	3–4
Flurbiprofen	3–4	300	2–4
Oxaprozin	10–20	1200	1

Indomethacin	1.5–3	200	2–3
Tolmetin	20–30	1800	3–4
Sulindac	4–6	400	2
Diclofenac	2–3	150	3
Etodolac	10–20	1000	1
Oxicams			
Meloxicam	0.25	15	1
Piroxicam	0.2–0.3	20	1
Nabumetone	30	2000	1
Pyrazole derivative			
Celecoxib	>2 yr old, 10–25 kg: 100 >2 yr old, 25–50 kg: 200	200	2

IAC injections is used by some clinicians in children with polyarthritis to induce prompt remission of synovitis, while simultaneously initiating therapy with disease-modifying agents (DMARDs) and/or biological agents.[15,16] Multiple IAC injections are meant to have the potential advantage of avoiding many side effects of systemic corticosteroids and selectively targeting the inflamed joints. Triamcinolone hexacetonide, which is more effective and has a longer effect than other forms of injectable corticosteroids, is universally recognized among paediatric rheumatologists as the medication of choice for intra-articular administration in JIA. However, use of a more soluble agent for smaller or difficult-to-access joints has been advised to avoid local side effects related to extravasation of triamcinolone hexacetonide from the joint space.[13] The dosage regimen of corticosteroid preparations currently used at the authors' centre is reported in Table 96.2.

Systemic corticosteroids

Patients whose disease is not well controlled by a course of NSAIDs or IAC therapy and an appropriate programme of physical therapy are candidates to receive more aggressive interventions. Moderate or high-dose systemic corticosteroid therapy is usually reserved to the management of the extra-articular manifestations of systemic JIA.[17] These include high fever unresponsive to NSAIDs; severe

anaemia, myocarditis, or pericarditis; and macrophage activation syndrome. Intravenous methylprednisolone (30 mg/kg per day to a maximum of 1 g/day on 1–3 consecutive days) is effective in controlling systemic and articular features of the disease, but its effect is often short-lived. In the other subtypes of JIA, corticosteroids should be used very selectively because their potential deleterious effects, especially on bone and growth, might outweigh any benefits to articular disease. A course of low-dose prednisone could be considered for reduction of pain and stiffness in patients with severe polyarthritis who are unresponsive to other therapies or who are awaiting the full therapeutic effect of a disease-modifying agent. There is no evidence that systemic corticosteroids are disease modifying in childhood arthritis.

Methotrexate

Methotrexate (MTX) has become the second-line agent of choice for children with persistently active arthritis because of its effectiveness and acceptable toxic effects.[18,19] Improvement in patients is usually seen after 6–12 weeks. The efficacy of this drug was established in a controlled trial in 1992 at a dose of 10 mg/m^2 per week given orally.[20] A subsequent randomized study has shown that MTX exerts its maximum therapeutic effect with parenteral administration of 15 mg/m^2 per week. There was no additional advantage in giving higher doses up to 30 mg/m^2 per week.[21] The greatest efficacy of MTX has been seen in patients with extended oligoarthritis, whereas the systemic-onset subtype may be the least responsive. The observation of a decrease in the rate of radiographic progression in two small uncontrolled studies has suggested that MTX may possess a disease-modifying effect.[22,23] It is not clear when a patient can stop taking MTX after the achievement of clinical remission because the disease will flare in up to 60% of patients after discontinuing the drug. Recently, a 12 month

Table 96.2 Type and dose of corticosteroid preparations used for intra-articular injections at the authors' centre

Joint	Corticosteroid	Dose
Shoulder	TH	1 mg/kg (max 40 mg)
Elbow	TH	0.75 mg/kg (max 30 mg)
Wrist	TH	0.25–0.5 mg/kg[a] (max 20 mg)
Hand (metacarpophalangeal and interphalangeal)	MP	5–10 mg[a]
Hip	TH	1 mg/kg (max 40 mg)
Knee	TH	1 mg/kg (max 40 mg)
Ankle	TH	0.75 mg/kg (max 30 mg)
Subtalar and intertarsal	MP	20–40 mg[a]
Foot (metatarsophalangeal and interphalangeal)	MP	5–20 mg[a]
Tendon sheaths	MP	20–40 mg%[a]

TH, triamcinolone hexacetonide; MP, methylprednisolone acetate.
[a]Depending on the child's size.

vs 6 month withdrawal of MTX was not found to reduce the relapse rate in JIA patients in remission.[24] Tests to monitor complete blood counts, liver enzymes, and renal function are recommended during MTX administration, although the optimal frequency of testing is unclear.[25] The supplementation of folic or folinic acid may help prevent the occurrence of liver enzyme abnormalities, oral ulcerations, and nausea. Leflunomide is an alternative option for patients unresponsive or intolerant to MTX.[26] However, experience with this drug in childhood arthritis is still scarce. Because leflunomide is teratogenic, young females of childbearing potential must have a negative pregnancy test before starting this medication and must practice appropriate contraception.

Sulfasalazine

Some studies have shown that sulfasalazine is able to improve arthritis in the late-onset oligoarticular group and in patients with juvenile spondyloarthropathies.[27,28] However, adverse reactions were frequently reported, especially rashes, gastrointestinal symptoms, and leucopenia, and led to discontinuation of the drug in a sizable proportion of patients. Administration of this medication in systemic arthritis is considered contraindicated, owing to the marked severity of side effects seen in patients with this JIA subset.

Ciclosporin

There are no controlled studies of ciclosporin in JIA. Small series have shown that this medication can be effective in patients refractory to MTX.[29] In systemic JIA, ciclosporin may be more beneficial for control of fever than for the treatment of arthritis and may enable corticosteroid dose reduction and may be distinctly efficacious in the management of macrophage activation syndrome.[30,31]

Combination therapies

Encouraging results have been reported in a small uncontrolled study of combination therapy with MTX and ciclosporin in patients refractory to MTX monotherapy.[32] A recent randomized trial has provided evidence that synthetic DMARDs in combination (MTX, sulfasalazine, and hydroxychloroquine) may be superior than MTX treatment alone in polyarticular JIA.[33]

Thalidomide

Thalidomide has been found to be effective in treatment-resistant systemic arthritis, both for systemic features and arthritis.[34] No significant adverse effects were noticed. However, use of this medication requires careful surveillance of the teratogenic effect and the development of peripheral neuropathy.

Autologous stem cell transplantation

Complete drug-free remission was achieved in around half of patients with long-standing and unresponsive systemic and polyarticular JIA who underwent autologous stem cell transplantation (ASCT).[35] However, since several issues remain open regarding the ASCT protocol, it should still be regarded as an experimental procedure for patients with very severe and unremitting disease. In the very rare patients who develop amyloidosis, alkylating agents such as chlorambucil may be beneficial.

Biologicals

The greatest advance in the treatment of JIA has been the introduction of biologic response modifiers, which offer a very effective therapeutic option for the treatment of patients who are resistant to conventional anti-rheumatic medications, namely MTX.[36] The development of these medications has been made possible by the advances in the understanding of the immune system, which have shed light on pathways involved in inflammation and self-tolerance and provided new targets for treatment of rheumatologic conditions. Biological agents have been designed to target key cytokines implicated in JIA, including tumour necrosis factor (TNF)α, interleukin (IL)-1, and IL-6 as well as signalling molecules involved in the regulation of B-cell and T-cell responses.

The efficacy of three anti-TNF agents (etanercept, infliximab, and adalimumab) and of the inhibitor of T-lymphocyte activation abatacept has been shown in the polyarticular form of the disease.[37–40] Anti-IL-1 (anakinra and canakinumab) and anti-IL-6 (tocilizumab) treatments have been found to be efficacious in systemic JIA, a disease that responds less well to anti-TNF drugs.[41–46] Biological medications are often used early in the course of JIA and are an effective treatment for arthritis, extra-articular manifestations of systemic disease, and uveitis. As seen for MTX, many patients experience a flare of symptoms after discontinuation of biological therapy.[47] Patients with JIA may, therefore, need to receive many years of biological therapy. Although the experience gained so far has shown that biological agents are overall safe in children with chronic arthritis, use of these medications in the paediatric population raises questions about risk of infections (particularly opportunistic infections and tuberculosis), response to vaccination, development of autoimmune phenomena, and long-term effects on immune surveillance and possible risk of malignancy.[48,49] Additional data concerning long-term safety of these drugs will be provided by the large-scale pharmacovigilance studies that are under way. The use of biologics in combination may be associated with increased infection risk and is not recommended. Details relating to biological therapies and the management of macrophage activation syndrome, a serious and potentially fatal complication seen most commonly in systemic JIA, are given in other chapters.

Treatment of problems associated with juvenile idiopathic arthritis

Iridocyclitis

In iridocyclitis, early diagnosis is fundamental for the success of therapy. The initial approach consists of glucocorticoid and mydriatic eye drops. In patients with disease resistant to topical therapy, systemic corticosteroid administration or subtenon injection of corticosteroids, or both, may be necessary. In disease not controlled by these interventions, several immunosuppressive medications have been considered effective, including MTX, ciclosporin, and alkylating agents. However, no controlled trials have been done. The efficacy of etanercept is controversial, whereas infliximab has been anecdotally reported to be of benefit.[50] A recent study has suggested that adalimumab is more efficacious than infliximab in maintaining remission of chronic childhood uveitis.[51] In a small case series, abatacept treatment was found to lead to sustained improvement in severe anti-TNFα-resistant JIA-related uveitis.[52]

Growth retardation and osteoporosis

Some studies have shown that human recombinant growth hormone could be beneficial in treatment of severe growth retardation in JIA.[53,54] The administration of oral alendronate has been associated with an increase in bone mineral density in paediatric

patients with diffuse connective tissue diseases, including JIA, who had a low bone mass or fragility fractures.[55] However, the potential long-term toxic effects of bisphosphonates on the growing skeleton remains a matter of concern.[56] Oral calcium supplementation was found to have only a marginal effect on bone mineral density in children with JIA who were not receiving corticosteroids.[57]

Physical and occupational therapy

Physiotherapy and occupational therapy are important components of the therapeutic approach to any patients with JIA.[58] Physical therapy in children with arthritis should be performed by a therapist specifically knowledgeable in paediatrics and experienced in the treatment of JIA. The aim of physical therapy is to keep or restore joint function and alignment as much as possible and achieve a normal pattern of mobility. Orthotic devices can be very useful in selected patients. Children with persistent flexion contractures may require serial night splinting or even serial casting to help correction. Due to improvement in pharmacological management and earlier disease control, serious functional disability and joint deformities are becoming less frequent. There is, therefore, an increasing need for physiotherapists to focus on broader issues, such as fitness, stamina, and bone strength.

An important aim of the management is to foster the normal psychosocial and social development of the child and to tackle possible difficulties caused by the disease or its consequences on family life. Participation in peer-group activities and regular attendance to school (including, whenever possible, the physical education programme) should be strongly encouraged. Children should be left largely free to establish their own level of activity, including the choice of the sport they wish to practice. Swimming and cycling, which do not put substantial weight on joints, are suitable sport activities. Appropriate attention to psychosocial issues, with the possible help of a paediatric psychologist, can potentially have a positive impact on the well-being of the child. Overprotection of the ill child and neglect of siblings is a common parental reaction, but should be avoided by early intervention. Education and counselling of the child with chronic arthritis and the parents about the present state of knowledge regarding outcome and therapy should be provided by the physician at the time of the first visit and repeated, as needed, during the subsequent clinical course.

Role of nurses

Nurses may play an important role in educating patients and parents on several issues, including handling and administration of traditional anti-rheumatic drugs and the newer biologicals, adverse effects of medications and monitoring of toxicity, importance of compliance with physicians' prescriptions, cautions and risks related to immunization, harmful impact of alcohol and smoking on health, and need to avoid pregnancy while taking medications with teratogenic potential. The European League Against Rheumatism (EULAR) recommendations for vaccination in paediatric patients with rheumatic diseases have been published recently.[59]

Role of surgical treatment

In selected situations, surgical approaches to irreversible joint contractures, dislocations, or joint replacement may be indicated.

However, nowadays the role of orthopaedic surgery in the management of JIA is much more limited than in the past. The long-term outcome of children with joint disease is not altered by prophylactic synovectomy. However, this surgical intervention may be useful to prolong the duration of remission of synovitis in a frequently relapsing joint. Care must be taken to prevent a postsurgical contracture. Arthroscopic surgery greatly reduces the morbidity associated with synovectomy.

Transition to adult care

The transition to adult care is a process that should start when a child reaches adolescence.[60] However, preparation of the child and family should be initiated as soon as the diagnosis is made and updated as the child matures. A successful transition requires an accurate planning and the coordinated participation of the patient, the family, and the paediatric and adult services. Adolescents should be encouraged gradually to take control of their disease management. Particular attention should be paid to fostering independent living skills and self-advocacy. Training in self-management, communication, and decision-making, conducted individually or in group sessions, may be helpful. Vocational evaluation and advice is welcome. The overall goal of transition is to help the adolescent or young adult to become more independent in managing healthcare needs and to assume adult roles such as a student, worker, parent, and partner.

American College of Rheumatology recommendations for the treatment of juvenile idiopathic arthritis

In 2011, the American College of Rheumatology (ACR) issued a set of recommendations aimed to assist physicians in selecting the safest and most effective treatment of JIA,[61] which were developed applying the Research and Development/University of California at Los Angeles (RAND/UCLA) Appropriateness Method and following the principles of the Appraisal of Guidelines for Research and Evaluation instrument (AGREE, at www.agreecollaboration. org). This process was based on a step-up approach, which mandates the subsequent administration of medications with greater potency once the previous treatment has failed. Instead of considering all International Leagues of Associations of Rheumatology (ILAR) categories of JIA individually, children with JIA were grouped into distinct 'treatment groups'. Recommendations were proposed for five treatment groups and were tailored according to the level of disease activity and the presence of features of poor prognosis specific for each treatment group. Three levels of disease activity were defined: low, moderate, and high. The state of inactive disease/clinical remission was not considered. Tapering or discontinuation of medications for patients with inactive disease was also not considered. In addition to the recommendations regarding treatment effectiveness, a guidance for the safety monitoring of the medications used in JIA is provided. A summary of the ACR recommendations for the treatment of JIA is presented in Box 96.1. Currently, the recommendations for systemic JIA are being revised to take into account the recently published trials on tocilizumab and canakinumab.[45,46]

Box 96.1 Summary of the American College of Rheumatology recommendations for the treatment of juvenile idiopathic arthritis

General recommendations that apply to all treatment groups

Intra-articular corticosteroids

- Recommended for active arthritis regardless of concurrent therapy or JIA treatment group
- Triamcinolone hexacetonide is the preferred injectable corticosteroid preparation
- A duration of clinical response to intra-articular corticosteroids of less than 4 months may imply a need for escalation of systemic therapy
- Intra-articular corticosteroid injection(s) that result in clinical improvement of arthritis for more than 4 months may be repeated, as needed

Methotrexate with TNFα inhibitors

- Continuing methotrexate when initiating etanercept or adalimumab is recommended for patients who had a partial previous clinical response to methotrexate
- Continuing methotrexate when initiating etanercept or adalimumab is uncertain for patients who had a poor previous clinical response to methotrexate
- It is assumed that methotrexate be continued when initiating infliximab

History of arthritis of four or fewer joints

NSAID monotherapy (without intra-articular corticosteroids)

- Patients with low disease activity, without joint contracture, and without poor prognostic features
- Continuation of NSAID monotherapy for more than 2 months is inappropriate for patients with active arthritis, irrespective of poor prognostic features

Intra-articular corticosteroids (with or without additional therapy)

- All patients with active arthritis

Methotrexate

- As initial treatment for patients with high disease activity and poor prognostic features
- Following initial intra-articular corticosteroid injection(s), patients with high disease activity without poor prognostic features and patients with moderate disease activity and poor prognostic features
- Following repeated intra-articular corticosteroid injection(s), patients with moderate disease activity without prognostic features, and patients with low disease activity and poor prognostic features

Sulfasalazine

- Following intra-articular corticosteroid injection(s) or an adequate trial of NSAIDs, patients with enthesitis-related arthritis

and moderate or high disease activity, irrespective of poor prognostic features

TNFα inhibitors

- Patients who have received intra-articular corticosteroid injection(s) and 3 months of methotrexate and have moderate or high disease activity and poor prognostic features
- Patients who have received intra-articular corticosteroid injection(s) and 6 months of methotrexate and have high disease activity without poor prognostic features
- Patients with enthesitis-related arthritis who have received intra-articular corticosteroid injection(s) and sulfasalazine and have moderate or high disease activity, irrespective of poor prognostic features

History of arthritis of five or more joints

NSAID monotherapy (without intra-articular corticosteroids)

- Uncertain as initial therapy
- Continuation of NSAID monotherapy for more than 2 months is inappropriate for patients with active arthritis, irrespective of poor prognostic features

Methotrexate

- As initial treatment for patients with high disease activity, irrespective of poor prognostic features, and patients with moderate disease activity and poor prognostic features
- Following approximately 1 month of NSAIDs, patients with low disease activity and poor prognostic features
- Following 1–2 months of NSAIDs, patients with moderate disease activity without poor prognostic features

Leflunomide

- Recommended as potential alternative to methotrexate

TNFα inhibitors

- Patients who have received 3 months of methotrexate or leflunomide and have moderate or high disease activity, irrespective of poor prognostic features
- Patients who have received 6 months of methotrexate or leflunomide and have low disease activity, irrespective of poor prognostic features

Switching from one TNF inhibitor to another

- Patients who have received the current TNFα inhibitor for 4 months and have moderate or high disease activity, irrespective of poor prognostic features

Abatacept

- Patients who have received a TNFα inhibitor for 4 months and have high disease activity, irrespective of poor prognostic features, or moderate disease activity and poor prognostic features

- Patients who have received more than one TNFα inhibitor sequentially and have moderate or high disease activity, irrespective of poor prognostic features, or low disease activity and poor prognostic features

Switching from abatacept to a TNFα inhibitor

- Patients who have received abatacept for 3 months and have high disease activity and poor prognostic features
- Patients who have received abatacept for 6 months and have moderate or high disease activity, irrespective of poor prognostic features

Rituximab

- Patients (particularly if rheumatoid factor-positive) who have received a TNFα inhibitor and abatacept sequentially and have high disease activity, irrespective of poor prognostic features, or moderate disease activity and poor prognostic features

Active sacroiliac arthritis

TNFα inhibitors

- Patients who have received an adequate trial of NSAIDs and have high disease activity and poor prognostic features
- Patients who have received 3 months of methotrexate and have high disease activity, irrespective of poor prognostic features, or moderate disease activity and features of poor prognosis
- Patients who have received 6 months of methotrexate and have moderate disease activity without poor prognostic features
- Patients who have received 3 months of sulfasalazine and have moderate or high disease activity, irrespective of poor prognostic features
- Patients who have received 6 months of sulfasalazine and have low disease activity and poor prognostic features

Systemic arthritis with active systemic features (and without active arthritis)

NSAID monotherapy

- Appropriate during the clinical evaluation of possible systemic arthritis
- Uncertain as initial or continued therapy for patients with active fever
- Inappropriate for patients with active fever and physician global assessment ≥ 7 out of 10
- Inappropriate for a duration greater than 1 month in patients with active fever

Systemic corticosteroids (with or without additional therapy)

- Patients with active fever and physician global assessment ≥7 out of 10
- Following up to 2 weeks of NSAIDs, all patients with fever

Anakinra

- All patients with active fever and poor prognostic features, irrespective of current therapy

- All patients with sustained or newly-developed fever while receiving corticosteroids

Methotrexate

- Inappropriate

Systemic arthritis with active arthritis (and without active systemic features)

NSAID monotherapy (with or without intra-articular corticosteroids)

- Patients with low disease activity without poor prognostic features
- Continuation of NSAID monotherapy for more than 1 month uncertain for patients with any level of disease activity, irrespective of poor prognostic features

Methotrexate

- All patients with active arthritis following one month or less of NSAID monotherapy (with or without intra-articular corticosteroids), irrespective of poor prognostic features

Anakinra

- Patients who have received methotrexate and have moderate or high disease activity, irrespective of poor prognostic features
- Patients who have received methotrexate and a TNFα inhibitor or methotrexate and abatacept and have moderate or high disease activity, irrespective of poor prognostic features

TNFα inhibitors

- Patients who have received methotrexate for 3 months or anakinra and have moderate or high disease activity, irrespective of poor prognostic features

Abatacept

- Patients who have received methotrexate and a TNFα inhibitor and have high disease activity, irrespective of poor prognostic features, or moderate disease activity and poor prognostic features

Calcineurin inhibitors

- Inappropriate

See Beukelman et al.[59] for the definitions of treatment groups, levels of disease activity, and poor prognostic features.

Recommendations provided for patients with systemic JIA do not to apply in case of clinical and laboratory evidence of macrophage activation syndrome or other severe complications, such as serositis, that require specific changes in therapy.

Recommendations for systemic JIA do not incorporate recent data relating to use of the IL-6 inhibitor tocilizumab or the IL-1 inhibitors canakinumab or rilonacept, which were not available at the time when the recommendations were developed.

British Society for Paediatric and Adolescent Rheumatology Standards of Care for children and young people with juvenile idiopathic arthritis

The development of the standards of care by the British Society for Paediatric and Adolescent Rheumatology (BSPAR) was inspired by the belief that all children with JIA have the right to equitable access to the highest quality of care, regardless of their geographic location, and that their care should be based on current evidence and be delivered by experienced multidisciplinary teams. The aim of the standards is to help these teams to improve the service they provide by formulating a statement of the minimum set of standards of care for children, adolescents, and young adults with JIA.[62] Of the 27 standards that were promulgated, the following 4 were highlighted as fundamental:

◆ encouragement of patients with JIA and their families to participate in the management of their disease

◆ providing an adequate training to all professionals likely to come into contact with a patient with JIA

◆ pursuing a holistic approach with focus on functional and psychosocial issues in addition to control of disease activity

◆ development of clinical networks for paediatric rheumatology.

Another major area of concern was the delay in access to specialist care. The BSPAR standards recommend that all patients with suspected JIA be seen by a paediatric rheumatologist within 10 weeks of onset of symptoms and within 4 weeks of the referral. This advice is aimed to increase the awareness of JIA, facilitate its early recognition by physicians, and urge referral to specialist teams. Ensuring early diagnosis to all children with JIA is a challenging task, as in many parts of the world specialist teams are rare. However, even where they exist, delay in diagnosis or access is still common.[63]

Other important recommendations incorporated in the BSPAR standards are that children with incident or suspected JIA be managed by a paediatric rheumatology multidisciplinary team, that JIA patients have prompt access to the drugs required to control their disease, that monitoring of therapy be conducted according to established guidelines, that 'tight' disease control be implemented in patients with active disease, that ophthalmologic assessment be made according to current guidelines, and that all young people with JIA have a planned and coordinated transition from the paediatric to the adult service. Beside the standards of care, the BSPAR outlined the optimal structure of the paediatric rheumatology multidisciplinary team, which should include a 'core multidisciplinary team', composed of members required by every JIA patients (e.g. paediatric rheumatologist, paediatric rheumatology nurse specialist, ophthalmologist, paediatric physiotherapist), and an 'extended multidisciplinary team', composed of members required if clinically indicated (e.g. play therapist, orthodontist, orthopaedic surgeon). In an editorial and a letter commenting the standards, it was argued that the goal of achievement of inactive disease and remission was not clearly formulated. Considering that therapeutic approaches and medications are now available to make disease remission an attainable objective for many, if not most, patients with JIA, it has been suggested that the standards be revised to include as overriding goal the achievement of clinical remission or, at least, minimal disease activity.[64,65]

CHAPTER 97

Anti-rheumatic drugs in pregnancy and lactation

Tarnya Marshall and Rita Abdulkader

Introduction

Autoimmune diseases affect males and females at childbearing ages. With the introduction of new agents, early aggressive disease control is possible early, but the influence on fertility, safety during pregnancy, and lactation are not yet fully understood.

The assessment of safety of drugs in pregnancy and during lactation relies on a limited body of evidence, based mainly on observational studies and case reports. Although studies in animals help inform experience, some drug effects prove to be species specific and extrapolation of this data to humans may be inappropriate. Additionally, when interpreting the effect of a drug and reports of adverse effects, two factors should be remembered:

◆ When the outcome of pregnancy exposed to a particular drug is considered, there is no 'normal' control group for comparison, and congenital malformation and other pregnancy-related complications could occur in the' normal' population.

◆ The effect of the underlying disease and its severity on the outcome of pregnancy need to be appreciated. This is usually difficult to predict and at times is not well described.

Although many women with autoimmune diseases notice improvement in their symptoms during pregnancy, some experience no improvement at all and some will have disease flares requiring treatment which may influence pregnancy outcomes. In general, if the disease control is achieved prior to pregnancy, this continues throughout pregnancy in most women provided they are compliant with appropriate treatment.[1]

Postpartum, however, autoimmune diseases tend to flare: for example 90% of rheumatoid arthritis (RA) patients will suffer a flare of their disease within 3 months of delivery,[2] requiring treatment that might affect the nursing infant.

In light of these issues, discussion should be undertaken early so that conception is planned. Patients of childbearing age should be counselled at drug initiation of the potential effects of their treatment on fertility and on the outcome of pregnancy if inadvertent exposure occurs.

The physician and patient should ideally plan future pregnancies, so that remission of the disease has been achieved where possible, that treatments compatible with pregnancy have been initiated, and that others with known risks to the fetus have been discontinued.

The decision to continue or stop any drugs in these patients should be taken on a case by case basis, after balancing the benefits of controlling active disease in the mother and the outcome of the pregnancy against possible risks to the fetus posed by the exposure to any drug.

Clearly, there is always a risk of an unplanned pregnancy resulting in inadvertent exposure to drugs. When this occurs, there should be a new literature review to establish emerging data, and discussion involving an obstetrician and the patient about the risks to the pregnancy. Further information can be sought about teratogenicity risk from the UK Teratology Information Services when drug exposure has occurred. Termination of pregnancy is not always indicated; however, close monitoring with screening for deformities is advisable in cases where the teratogenic risk of the key drugs is not clearly established or where there is significant risk.[3]

Non-steroidal anti-inflammatory drugs

Pregnancy

Population-based cohort studies show that the use of non-steroidal anti-inflammatory drugs (NSAIDs) in early pregnancy does not increase the risk of congenital deformities,[3] despite some reports of increased risk of cardiac septal defects, gastroschisis, and oral cleft associated with their use.[1,3] Additionally, there have been reports of increased risk of miscarriages in women taking NSAIDs, especially when these were used around the time of conception.[4,5]

The experience in women taking selective inhibitors of cyclooxygenase-2, however, has not been reported[3,4] and avoidance during pregnancy is recommended.[6]

Other than low-dose aspirin(<100 mg daily), the use of NSAIDs in late pregnancy was found to cause significant adverse effects in the fetus.[5] Administration of these drugs at this stage could lead to constriction and premature closure of the ductus arteriosus with reports of resulting pulmonary hypertension in the infant. NSAIDs may also impair renal function in the fetus, leading to reduced urine output and oligohydroamnios. These effects are evident from week 20 of pregnancy.[3,5] Additionally, there are reports of increased susceptibility to bleeding in newborns exposed to some NSAIDs

and high-dose aspirin late in pregnancy, including central nervous system haemorrhage.[5] Current advice, therefore, is to discontinue NSAIDs by week 32 of pregnancy. Before this their use is relatively safe, especially if agents with a short half-life are used and with the lowest effective doses.[3,5]

There are reports of epidural haematomas in mothers undergoing epidural anaesthesia while taking low-dose aspirin. Some experts advise cessation of treatment a week before a planned delivery, but the individual risks should be assessed and aspirin continued if the risks of stopping aspirin, such as in anti-phospholipid syndrome, outweigh the risks of bleeding complications.[5]

Lactation

Aspirin should be avoided in breastfeeding women because of the risk of Reye's syndrome;[6] however, if continuing treatment is considered essential, then caution should be exercised especially with doses above 100 mg.[5] Other NSAIDs are considered compatible with breastfeeding.[2]

When prescribing NSAIDs for nursing mothers, drugs with a long half-life should be avoided,[2] and mothers should be advised to take the drug at or shortly after breastfeeding to reduce the exposure of the infant to these drugs.[2,5] Ibuprofen in particular is preferred because of its short half-life and very low excretion in breast milk.[2,4]

Fertility

The effects of NSAIDs on fertility are uncertain. Their use has been implicated in reports of impaired fertility in women[4]; this is theoretically related to the role of cyclooxygenase enzymes in the rupture of the luteinized follicle.[3,4] However, the prevalence and significance of the luteinized unruptured follicle syndrome (LUFS) in women using NSAIDS remains to be established.[3]

Women attempting to conceive should preferably use NSAIDS intermittently and infrequently. Discontinuation of treatment should be considered in a woman who has had difficulty conceiving.[3,4]

Corticosteroids

Pregnancy

Placental transfer of corticosteroids varies according to their structure, leading to differences in fetal exposure to these drugs. Non-fluorinated corticosteroids such as prednisolone and methylprednisolone are subject to extensive metabolism by the placenta, resulting in only 10% of the maternal dose reaching the fetus.[5,7] On the other hand, fluorinated corticosteroids such as betamethasone and dexamethasone are less metabolized in the placenta, allowing significant effects on the fetus. When corticosteroids are used for maternal indications, non-fluorinated agents should be used to minimize unnecessary in-utero exposure.

In addition to those side effects encountered in non-pregnant patients, there are also pregnancy-related side effects, such as an increased risk of premature rupture of the membranes.[5,7] Although the use of corticosteroids does not cause an increased frequency of infections in newborn babies, prolonged high doses (>15 mg prednisolone) may lead to an increased risk of intrauterine infection.[3,5]

The use of corticosteroids in pregnancy is not associated with major teratogenic effect. Only rarely are cataract and adrenal suppression reported in infants exposed to high-dose corticosteroids.[5]

However, there has been concern about a small increase in the risk of cleft palate/cleft lip with corticosteroid use in the first trimester. This concern was raised by a meta-analysis which reported a 3.3-fold increase in the odds ratio of cleft lip and/or palate after first-trimester exposure to corticosteroids.[8] This was not supported by subsequent studies. At worst, therefore, the risk would increase the incidence from 1/1000 in the general population to 3/1000.[4]

There is conflicting evidence regarding the relationship between administration of corticosteroids during pregnancy and low birthweight. The difficulty arises from separating the complications of the underlying maternal disease requiring treatment, and the effects of the drugs.[3,5] A dose of 5–15 mg of prednisolone daily does not seem to increase the risk of intrauterine growth restriction.[3]

On balance, when steroids are needed, the lowest effective dose should be administered especially during early pregnancy. The mother should be monitored closely for side effects of treatment, and consideration should be given to adding calcium and vitamin D supplements if corticosteroid treatment throughout pregnancy is required.

Finally, a stress dose should be considered in cases of acute illness and in the peripartum period.[3]

Lactation

There is no evidence that the small amounts of corticosteroids excreted in breast milk have an adverse effect on the nursing infant. Therefore they are considered compatible with breastfeeding.[2,5]

In patients taking high doses of corticosteroids, a period of 4 hours between administration and breast feeding is recommended to minimize the infant's exposure to these drugs.[5,7]

As in pregnancy, consideration should be given to calcium and vitamin D supplements.

Fertility

There are no reports of corticosteroids having an adverse effect on fertility.[7]

Hydroxychloroquine

Hydroxychloroquine is an anti-malarial drug with mild disease-modifying actions in RA and causes a reduction in systemic lupus erythematosus (SLE) of fatigue, skin, arthralgia, and mucous membrane symptoms.

Pregnancy

Although hydroxychloroquine crosses the placenta, there is no evidence of toxicity in the fetus at the doses used in treating rheumatic diseases. Although the drug manufacturer advises against treatment with hydroxychloroquine during pregnancy in the summary of product characteristics (SPC), this is not borne out in clinical practice. In animal studies, ototoxicity and retinal pigmentation have been described but these have not been reported in human pregnancies when children were followed up to 26 months of age.[4,9]

Successful pregnancy outcome in SLE is dependent on tight disease control, and several studies have shown that discontinuing treatment in pregnant lupus patients is detrimental to disease control, with an increase in disease flares reported. In those patients

who continue hydroxychloroquine, lower maintenance doses of prednisolone are required.[10]

Lactation

Although hydroxychloroquine is excreted in breast milk, levels are very low and are not thought to be sufficient to cause infant toxicity. Guidance from national bodies is conflicting, with the American Academy of Paediatrics[11] advocating continuing therapy, whereas British Society for Rheumatology (BSR) guidance advocates stopping treatment.[6,12]

Risk and benefits of treatment should be discussed with the patient, and if they wish to continue breastfeeding this should be done with caution, recognizing that autoimmune disease often flares postpartum.

Fertility

There are no reports of adverse effects on fertility.

Sulfasalazine

Most of the evidence available for sulfasalazine in pregnancy and lactation is derived from studies in patients with inflammatory bowel disease.

Pregnancy

Sulfasalazine is known to inhibit the absorption and metabolism of folic acid. Therefore, adequate folate supplements should be given to the expectant mother before and during pregnancy. Although sulfasalazine crosses the placental barrier, it seems to have little effect on the fetus.[13] It is advised, however, that the dose used does not exceed 2 g/day during pregnancy.[5]

There have been scattered case reports of congenital malformation in children of mothers taking sulfasalazine during pregnancy, but the direct association with sulfasalazine remains to be established.[13,14] Additionally, a case of fetal haemolytic anaemia has been described, in which intrauterine blood transfusion was required.[15] However, the majority of published data has found no association with congenital malformations, or increased risk of kernicterus in full-term newborn infants.[16–18]

Lactation

Sulfasalazine use is considered safe in nursing mothers,[1,11] despite its excretion at low levels in breast milk. There appears no link with kernicterus in full-term infants.[16] Caution is advised, however, in premature babies and those deficient in glucose-6-phosphate dehydrogenase (G6PD).[6] There is one case report of bloody diarrhoea in an infant breastfed by a mother prescribed sulfasalazine in whom no other cause could be found.[19]

Fertility

Sulfasalazine use results in reversible infertility in men due to oligospermia, reduced sperm motility, and increased abnormal sperm forms.

A drug-free period of 3 months is recommended prior to conception as it may take up to 2.5 months for normal spermatogenesis and therefore fertility to return.[20,21] Additionally, there may be an increased risk of congenital abnormalities in the offspring of these men during this period.[22]

Methotrexate

Pregnancy

The majority of data is from patients treated with high-dose methotrexate for malignancy; much less is known about pregnancy in women taking low doses. In high doses, methotrexate is known to be teratogenic and as a result, it is sensible to advise against pregnancy in patients on lower doses.

Studies in animals showed that methotrexate is embryotoxic. Exposure to methotrexate during the first trimester is associated with increased risk of fetal death, and a risk of major congenital anomalies, including craniofacial and limb defects; severe neurological anomalies such as anencephaly, hydrocephaly, and meningomyelocele; and growth retardation.[3,23]

Methotrexate is retained in tissue for months after administration and should therefore be discontinued at least 3 months before attempting conception.[6] The manufacturer takes a more cautious opinion and advises a 6 month interval. Women should continue folic acid supplements prior to and during pregnancy.

Lactation

Methotrexate should be avoided during breastfeeding. It is present in breast milk, and may accumulate in the infant tissues.[11]

Fertility

Methotrexate does not appear to affect female fertility. In men, a reversible effect on fertility has been described,[24] although this may have been due to the effect of other coprescribed medicines.[25] It remains to be established whether methotrexate in men is teratogenic, so current advice is to stop treatment for at least 3 months prior to conception.[6]

Leflunomide

Pregnancy

Leflunomide is contraindicated in pregnancy as animal studies have shown marked teratogenicity. In rats, skeletal and central nervous system deformities, in addition to low birthweight and increased death rate after birth, are reported in pregnancies with leflunomide exposure.[4] Data for safety in human pregnancies is restricted mostly to case reports. Although no fetal abnormalities have been described, the current recommendation on the basis of animal studies is to avoid treatment in pregnancy.

Leflunomide's active metabolite A77 1726 is slowly eliminated and levels can be detected in plasma for up to 2 years after the last dose.[1] Patients who wish to consider a pregnancy should be advised to stop leflunomide for at least 2 years before conception, although a washout procedure can be undertaken to accelerate elimination using agents such as colestyramine or activated charcoal. This requires 11 days of colestyramine, an unpalatable agent, in a dosage of 8 g three times a day, or charcoal at a dose of 50 g four times a day. With either procedure, the active metabolite concentration should be measured on two occasions 14 days apart, and its concentration should be less than 20 μg/litre before attempting conception by men or women.[6] The washout procedure is also advised in the event of unplanned pregnancy in women prescribed leflunomide. For women using oral contraception and requiring washout, it should be pointed out that the absorption of oestrogen and

progesterone may also be affected, and that additional contraceptive methods are required.[26,27]

Lactation

The effects of leflunomide on the nursing infant are not known; it is therefore contraindicated during lactation.

Fertility

There are no known adverse effects of leflunomide on fertility in women; in men it may cause a reversible reduction in sperm count. Men taking leflunomide are advised that reliable contraception should be used, and that a washout procedure as outlined above should be performed 3 months before conception.

Azathioprine

Azathioprine is a prodrug. It is metabolized in the liver to 6-mercaptopurine, its active metabolite.

Pregnancy

Animal studies have shown potential teratogenicity, but there is no recurrent pattern of congenital anomalies reported in humans.[4] Most of the available data are derived from transplant patients and those with inflammatory bowel disease. Although an increased risk of intrauterine growth restriction and preterm delivery are reported, these could be related to disease severity rather than an effect of the drug.[4] Azathioprine and its metabolites are found in low concentrations in fetal blood after administration to the mother. The fetal liver is deficient in inosinate pyrophosphorylase, the enzyme required to convert azathioprine to its active metabolite; this may shield the fetus from harmful effects.[7,28] A decision to continue treatment during pregnancy should follow a careful assessment of risk vs benefit and a discussion with the patient.

In mothers continuing treatment, it is best to restrict the dose to 2 mg/kg or less to avoid haematopoietic suppression in the newborn.[3]

Lactation

Azathioprine is present in breast milk in low concentrations but it does not cause harm in the neonate and is therefore considered safe during lactation.[1] In one study there was no increased risk of infection in the breastfed offspring of mothers taking azathioprine and all children had mental and physical progress suitable for age in early childhood.[29]

Fertility

Azathioprine does not affect fertility in men or women. There is no convincing evidence of teratogenicity in men who father children during treatment.[30]

Mycophenolate mofetil

Mycophenolate mofetil is metabolized to mycophenolic acid. Most of the available data in pregnancy are derived from its use in organ transplant patients.

Pregnancy

Evidence from case reports and animal models suggests that mycophenolate mofetil is teratogenic, and it is therefore contraindicated in pregnancy and patients should stop treatment at least 6 weeks prior to conception.

Exposure to mycophenolate mofetil during pregnancy may result in low birthweight, premature birth, and an increased incidence of birth defects.[1] The most observed deformities involve the mouth (microtia, cleft lip and palate, micrognathia), ear (auditory canal atresia), fingers (short fingers and hypoplastic nails), and eyes (hypertelorism, ocular coloboma).There are also reports of renal, central nervous system, diaphragmatic, and cardiovascular malformations.

A distinctive phenotype has been described with in-utero exposure to mycophenolate mofetil: EMFO tetrada (ear, mouth, finger, ocular/organ malformations).[31]

Breastfeeding

Animal studies confirm that mycophenolate mofetil is excreted in breast milk. It should therefore be avoided in breastfeeding mothers.[6]

Fertility

Mycophenolate mofetil is not associated with reduced fertility in either men or women and does not adversely affect spermatogenesis. Drug company files (Roche Pharma, safety update) reported the outcome of 45 pregnancies where paternal mycophenolate mofetil exposure occurred. In this series, six cases of fetal malformations were described: foot, mouth, bladder, and chromosomal. Although the association with treatment is difficult to confirm, the incidence of abnormalities is high and the current advice for men is to stop mycophenolate mofetil for at least 3 months prior to conception.[5]

Ciclosporin

The data for the safety of ciclosporin in pregnancy and lactation are mainly derived from the transplant literature.

Ciclosporin passes the placental barrier, but its use has not been shown to increase the incidence of birth defects in exposed infants. This is supported by data from the United States National Transplantation Pregnancy Registry.[32] A meta-analysis reporting 410 pregnancies with history of exposure to ciclosporin also found no increase in risk of congenital malformations. The odds ratio for low birthweight and prematurity did not achieve statistical significance; however, they are reported at a rate of 56.3%. It is difficult to ascertain if this rate is related to the underlying disease or the influence of the drug.[5,33]

Ciclosporin could therefore be continued during pregnancy, preferably at the lowest effective dose, if the benefit of continuing the drug outweighs the risks. Maternal blood pressure and renal function should be even more closely monitored than usual during pregnancy. Where ciclosporin can be stopped, advice is to discontinue therapy at least 6 weeks prior to conception.[1]

Lactation

Ciclosporin is present in breast milk; there are reports of patients continuing treatment while nursing with no significant adverse effects.[2] However, there are insufficient safety data and the consensus is that breastfeeding should be avoided in women taking ciclosporin.[11]

Fertility

There are no reports of adverse effects on fertility in women.

Although ciclosporin has been shown to cause reversible impairment of testicular function and reduced fertility in rats,[34,35] this has not been observed in men.[36] However, unexplained infertility may warrant a break from therapy if clinically appropriate. There are no reports of male-mediated teratogenicity relating to the use of ciclosporin, and the decision to continue treatment while attempting conception should be tailored to the individual patient.

Cyclophosphamide

Cyclophosphamide is absolutely contraindicated in the first trimester of pregnancy; women should use a reliable contraceptive method during treatment and for 3 months afterwards.

Cyclophosphamide teratogenicity has been demonstrated in animal studies and observed in human pregnancies.[5] Although the administration of cyclophosphamide in the first trimester does not always result in fetal anomalies,[5] significant birth defects are observed with its use, including craniofacial, distal limb, ear, and visceral malformations, in addition to growth retardation.[5,7]

Cyclophosphamide use after the first trimester should only be considered if there is a significant risk to the life of the expectant mother from the underlying disease.[4,7] Although it is not associated with structural defects in the fetus, it may result in adverse effect on the infant's later neurological development, and may also cause growth delay and bone marrow suppression.[5] The outcome of these pregnancies is likely to be poor for the fetus, possibly reflecting the severity of the underlying maternal disease.[4]

Lactation

Cyclophosphamide is excreted in breast milk; therefore women receiving treatment should avoid breastfeeding during and for 36 hours after treatment.[6,11]

Fertility

There are isolated reports of birth defects in the babies born to fathers treated with cyclophosphamide. A causative relationship has not been proven, but men should be advised to avoid conception during treatment and for 3 months after.[1,5]

Cyclophosophamide has toxic effects on reproduction in men and women. These are present with both oral and intravenous administration. In women there is a risk of up to 40% of permanent amenorrhoea due to cyclophosphamide treatment. This risk is mainly related to cumulative dose and the age of the patient, being lowest below the age of 25, and highest above the age of 31.[5] In one study, permanent amenorrhoea was observed in 12% of women who were treated with 7 doses of cyclophosphamide (0.5–1.0 g/m^2 body surface area) increasing to 39% of women treated with 15 doses. There was also a significant increase in the incidence of amenorrhoea with age independent of the dose prescribed.[37] In men, on the other hand, the risk of infertility is unpredictable and can occur at any age, and at any dose.[5]

If time allows, men and women should be offered fertility preservation measures, such as cryopreservation and sperm banking. Additionally, the use of gonadotropin-releasing hormone agonists (GnRHa) in women may help protect the ovarian function; although the evidence for its use is still developing, it is unlikely to be associated with harm and, in our opinion, should be considered

in patients below 40 years of age should a future pregnancy be desirable.[38,39]

Gold

Gold compounds should be avoided during pregnancy as they cross the placenta and have been detected in fetal tissues.[6,7] Gold is also excreted in breast milk and is absorbed by the nursing infant; it should be therefore avoided in breastfeeding mothers.[6]

Penicillamine

Penicillamine is teratogenic in animal studies. Serious connective tissue abnormalities are reported in babies exposed to penicillamine in utero. It should be avoided in pregnant and breastfeeding patients.[6,7]

Biological agents

The data regarding biological treatment in pregnancy and lactation are limited as these are relatively new agents. Placental transfer differs between agents and depends on the molecular structure of the drug. For example, monoclonal antibodies are transferred by the placenta increasingly in the second and third trimesters, whereas fusion proteins have much less placental transfer, which in turn is minimal for agents that do not contain the fragment crystallizable region (Fc) of the immunoglobulin.[40]

The safety of biologics in pregnancy is collected via national registries and case reports, and as tumour necrosis factor alpha (TNFα) inhibitors were developed ahead of newer agents, more data is available for their safety. The need for ongoing treatment with biologic agents during pregnancy should be assessed on an individual basis following discussion with the patient.

TNFα inhibitors

Experience with TNFα inhibitors in pregnancy is limited. The data come from case reports, small case series, some controlled studies, and drug registries.

The BSR guidelines advise precaution in pregnancy for both men and women.[41] Therapy should only be continued if the risk of stopping is perceived to be high. In those cases where treatment is continued, monoclonal antibodies should be stopped by week 30, due to significant transplacental transfer. The long-term effects of in-utero exposure remain to be established.[40]

There is some controversy around the association of TNFα inhibitor use with VACTER (vertebral, anal, cardiac, tracheal, oesophageal, renal) anomalies. This was reported by one study which found an increase in congenital VACTER spectrum in women treated with infliximab or etanercept in early pregnancy.[42] Due to flaws in methodology and design, most experts agree that no association could be deducted from this study between TNFα inhibitors and fetal abnormalities. The lack of association with birth defects is also borne out in the literature of TNFα inhibitors in patients with inflammatory bowel disease.[43,44]

Despite the lack of evidence for teratogenicity with the use of these treatments, there may be an increased risk of miscarriage and fetal loss. Whether this is the effect of TNFα inhibitors or the underlying disease process remains unclear. Some studies showed no difference in miscarriage in pregnancies with history of exposure to TNFα inhibitors comparing to non-exposed pregnancies.[3]

However, the British Society for Rheumatology Biologics Register (BSRBR) has reported the outcome of 130 pregnancies in patients exposed to TNFα inhibitor treatment before or at conception. An increased rate of spontaneous abortion was noted among patients who received TNFα treatment. These women have severe disease to be able to access biological therapy, as defined by NICE, but levels of disease activity have not to date been reported in this cohort of women and this may be a confounding factor.[45]

Fertility

TNFα inhibitors have not been shown so far to have any adverse effects on fertility or male-mediated teratogenicity.

Etanercept

Etanercept is recombinant human TNF receptor (p75) Fc fusion protein.

Manufacturer advice

The manufacturer advises discontinuing etanercept at least 3 weeks before conception, and to avoid breastfeeding during treatment.

Pregnancy

Etanercept is not teratogenic in animals. Very low levels of etanercept cross the placenta, possibly due to the low affinity of etanercept to neonatal IgG transporter (FcRn).[40]

As discussed earlier, the suggestion of an association with VACTER anomalies with etanercept has been given little weight so far.

Lactation

Etanercept is present in breast milk in low levels. It is unlikely to have significant effects on the nursing infant. However, the current advice from the manufacturer is to avoid breastfeeding while receiving treatment.[40,46]

Adalimumab

Manufacturer advice

The manufacturer advises avoiding treatment during pregnancy and lactation, and discontinuing treatment for up to 5 months before conception in women and before commencing breastfeeding.

Pregnancy

In animals, it does not seem that adalimumab results in birth defects. Cases of successful human pregnancies while exposed to adalimumab were reported with no harmful effects on the fetus.[28]

Breastfeeding

There is insufficient data about the safety of the administration of adalimumab while breastfeeding. It is not also known if adalimumab is absorbed by the nursing infant after ingestion. The manufacturer advises discontinuation of treatment for at least 5 months before commencing breastfeeding.

Fertility

No adverse effects were reported.

Infliximab

Infliximab is a chimeric IgG1 monoclonal antibody to TNFα.

Pregnancy

The current advice from the manufacturer is to stop treatment 6 months before conception. If continuing treatment is deemed necessary, ongoing treatment is not recommended beyond the latter part of the second trimester.

Infliximab does not appear to cause congenital malformation in the fetus. It does not actively cross the placenta during the first trimester, but it is transferred during late second and third trimester. It is detectable in newborn serum for a few months after delivery.[40]

The limited available data does not show an association with increased infection risk. However concern has been raised about live vaccinations in young children, which should be delayed at least 6 months after delivery, if treatment was continued during pregnancy.[47] There is one case report of fatal disseminated Bacille Calmette–Guérin (BCG) infection after BCG vaccination in a 4.5 month old baby exposed to infliximab in utero throughout pregnancy.[48]

Lactation

Infliximab is present in breast milk. Case reports of patients continuing treatment while on infliximab revealed no adverse effect, however. The manufacturer advises no breastfeeding for 6 months after discontinuation.

Certulizumab

Certulizumab is a Fab fragment of an anti-TNFα monoclonal antibody.

Pregnancy

The current advice from the manufacturer is not to use certulizumab during pregnancy, and to use contraception up to 5 months after the last dose.

Data about the use in pregnancy is limited to few case reports with favourable outcomes.[40] There is no evidence of teratogenic effect in animal studies. Additionally, no transfer across the placenta was noted in rats. Unlike whole IgG antibodies, certulizumb lacks the Fc region necessary for active transfer across the placenta. Theoretically, certulizumab may have advantages over other TNFα inhibitors because of this, although this is an area for further research.[28,40]

Lactation

It is not known if certulizumab is excreted in breast milk, and breastfeeding should therefore be avoided in women receiving treatment.

Fertility

The manufacturer reports a trend on reduced sperm count with effect on motility in rodents with no effect on fertility. The significance of this in humans is still to be established.

Golimumab

The manufacturer advises adequate contraception and avoiding breastfeeding for 6 months after the last dose.

Pregnancy

No harm has been demonstrated in animal studies. There is limited data in humans and use during pregnancy should be considered only if essential.[6]

Lactation

Golimumab is present in milk in animal studies, although this is yet to be established in women. The manufacturer advises avoiding breastfeeding for 6 months after the last dose.

Fertility

No data available.

Rituximab

Rituximab is a monoclonal B-cell-depleting antibody.

Pregnancy

The manufacturer advises avoiding pregnancy and breastfeeding for 12 months after treatment as rituximab crosses the placenta. Animal studies revealed no evidence of teratogenicity, but experience in human pregnancies is limited. The effects of exposure early in the pregnancy are not yet clear. Case reports have shown that exposure during the second and third trimester resulted in serum levels of rituximab similar to the mother's, and was associated with B-cell depletion in the newborn.[40] Spontaneous recovery of B-cell numbers was complete within 6 months.[3] The long-term effects of this early B-cell depletion are not known.

Rituximab should, therefore, be avoided during pregnancy unless benefit to the mother outweighs possible risks to the baby, otherwise contraception should be recommended up to 12 months after the last dose.[6]

Lactation

Rituximab is excreted in animal milk. Breastfeeding should be avoided for 12 months after treatment, as advised by the manufacturer.

Abatacept

Abatacept is a CTLA4 and human immunoglobulin fusion protein which acts as a selective costimulation modulator inhibiting the activation of T cells.

Pregnancy

There are insufficient data about the use of abatacept in human pregnancies. In animal studies there is no evidence of teratogenicity. Limited changes in the immune function were noted in rats at 11 times a human dose of 10 mg/kg.[49] Current advice is to avoid unless treatment is essential[6]; patients should be advised to use contraception up to 14 weeks after the last dose (manufacturer's advice).

Lactation

It is not clear if abatacept is excreted in human milk. The current advice from the manufacturer is to discontinue treatment 14 weeks before breastfeeding.

Fertility

No adverse effects on fertility are noted in animal studies; there are no available data in humans.

Anakinra

Anakinra is the recombinant form of the human interleukin-1 receptor (IL-1R) antagonist.

There are insufficient data about safety in human pregnancy, although there is no evidence of harm in animal studies. Current advice is to avoid treatment during pregnancy. Additionally, patients should be advised to use contraception during treatment.

Lactation

It is yet to be established if anakinra is excreted in human milk, and breastfeeding should be avoided during treatment.

Tocilizumab

Tocilizumab is an interlukin-6 receptor (IL-6R) monoclonal antibody.

Pregnancy

The manufacturer advises stopping treatment 3 months before conception. The *British National Formulary* (BNF), however, advises 6 months before conception.

Animal studies revealed increased risk of spontaneous abortions and fetal death at a high dose. There is some emerging data about the safety of tocilizumab in human pregnancy, but these are still insufficient to recommend its safety.

Lactation

It remains to be established if tocilizumab is excreted in breast milk and there are insufficient safety data in breastfed infants to date.

CHAPTER 98

Septic arthritis in adults

Laura McGregor, Monica N. Gupta, and Max Field

Infections in native joints

Epidemiology

The sudden onset of monoarthritis in a synovial joint can arise from a variety of causes (Table 98.1) but the most likely is trauma or inflammation. Acute joint pain and swelling should always be regarded as a significant clinical event because joint infection has a high morbidity[1] and 11% mortality.[2] The incidence of septic arthritis (SA) in Europe is estimated to be 4–10 per 100 000 patient years per year.[3] However, these figures may be an underestimate because many analyses fail to take account of patients with negative microbiology in whom SA is suspected. The recent rising incidence may be due to an ageing population, increased use of immunosuppressant therapy, and increased surgical intervention. Five-year survival is poor irrespective of whether bacteria are isolated from synovial fluid or not, with over 30% mortality in each group.[4]

Risk factors

Although children are susceptible, SA occurs at any age. Adult patients, especially those with underlying joint disease, including osteoarthritis (OA) and in particular rheumatoid arthritis (RA), are at greater risk. Social deprivation[2] and increasing age are also risk factors. Currently 17% of the United Kingdom population is over 65 years of age, a figure due to rise to 23% by 2035,[5] suggesting that SA incidence is likely to increase. Elderly patients are also more likely to have undergone joint replacement surgery, and by 2010 an estimated 6% of the United Kingdom population will have undergone arthroplasty.[6] The elderly population are also more likely to have comorbidities that predispose to SA, including diabetes mellitus, malignancy, and renal disease (especially haemodialysis patients). In addition, recurrent infections of respiratory or urinary tracts or in cutaneous ulceration all confer an increased risk, which might explain the increased predisposition in more impoverished populations. Intravenous drug users are also predisposed to SA, often in unusual sites of infection and with atypical organisms.[3] The increasingly widespread use of biological therapies for inflammatory rheumatic and bowel diseases has also led to an increased SA incidence. Patients with RA receiving anti-tumour necrosis factor (TNF) therapy for less than 1-year have a twofold increase in risk compared with patients treated with disease-modifying anti-rheumatic drugs (DMARDs) alone.[7] However, RA patients needing anti-TNF therapy typically have longer disease duration, more severe disease, and more joint replacements, and are therefore already in a high-risk group.

Pathopysiology

Mechanisms behind SA pathogenesis are unclear but clues can be found in patients and animal models. Native joint infections usually follow bacterial colonization in a primary source, spread via the bloodstream.[1] SA develops in up to 90% of mice after intravenous

Table 98.1 Differential diagnosis of acute pain in a single joint

Common	Acute monoarthritis of systemic disease
Septic arthritis	Systemic lupus erythematosus
Crystal arthropathies	Vasculitides (ANCA positive and negative)
Reactive arthritides	Henoch–Schönlein purpura
Lyme disease	Behçet's disease
Plant thorn synovitis	Bacterial endocarditis
Other infections (mycobacterial, viral)	Familial Mediterranean fever
Trauma	**Bone disease**
Loose bodies	Paget's disease
Stress fracture	Osteomyelitis
Ischaemic necrosis	Osteogenic/osteoid tumours
Haemarthrosis	Metastatic disease
Acute monoarthritis of polyarthritis	**Monoarthritis of non-inflammatory disease**
Psoriatic arthritis	Osteoarthritis
Rheumatoid arthritis	Charcot joint
Juvenile inflammatory arthritides	Storage diseases (haemochromatosis)

ANCA, anti-neutrophil cytoplasmic antibodies.

injection of staphylococci[8] or streptococci,[9] supporting this hypothesis, but these models are complicated by high mortality from infection. In humans, inflammatory cytokines are found in SA synovial fluids,[10] and metalloproteinases have also been found. This implies that cytokine production could activate intra-articular enzymes leading to joint damage after infection.

Pathogenesis of SA is probably multifactorial, depending on interactions between bacteria and their ability to bind to synovial tissues, evade the immune response and stimulate joint damage. *Staphylococcus aureus* has a variety of receptors (microbial surface components recognizing adhesive matrix molecules, MSCRAMMs) that mediate attachment to joint tissues or implanted devices.[11] Cell-surface alpha-haemolysin on staphylococci adheres to host cell-surface membranes and produces pores in them, leading to cell death.[12] Some proteins facilitate bacterial entry into osteoblasts, implying a potential role in osteomyelitis, and others could be implicated in apoptosis via a host caspase-dependant mechanism, thereby accelerating joint destruction.[13] Injection of bacteria genetically altered to be deficient in staphylococcal protein A (SPA) in the mouse model results in less severe SA than that following injection of wild-type bacteria.[11] The mechanism remains unclear but because SPA binds IgG, interferes with complement binding, and restricts bacterial opsonization and phagocytosis, altered clearance of bacteria deficient in SPA may explain the lesser degree of articular damage. Similarly, variations in sialic acid content in streptococcal cell-wall polysaccharides may explain different degrees of joint damage in mice after injection of different strains of streptococci. Bacterial cell-wall antigens in *Neisseria gonorrhoeae* can also inactivate complement, enable survival inside neutrophils[14] and adversely affect immune-mediated removal of Gram-negative bacteria. Neisseria also have endotoxin activity, which may be a 'virulence factor' activating mediators of joint destruction.

Host factors are also important in SA. MHC class II antigens bind to staphylococcal exotoxin TSST-1 and activate T cells by linking with the T-cell receptor beta chain. Injection of staphylococci producing TSST-1 induce synovitis with clonal T-cell expansion, expression of the interleukin (IL)-2 receptor, and production of gamma-interferon (IFNγ) in synovial T cells,[15] whereas injection of bacteria lacking TSST-1 causes synovial inflammation less frequently.[16] Other mechanisms behind bacterial interaction with host cells may involve Toll-like receptors (TLRs). Peptidoglycans in Gram-positive bacteria interact with macrophage TLR-2 increasing intracellular NFκB production, which increases IL-1 and TNFα synthesis,[17] which in turn can stimulate metalloproteinase production.

The roles of proinflammatory cytokines and those that control inflammation in SA are not clear from experiments in animal models. Administration of IFNγ, which upregulates macrophage activation, worsens arthritis in both mouse models,[18,19] confirming a role for T cells. Infected murine synovial tissue T cells contain messenger RNA for IL-4 and IL-10, which downregulate the immune response, but their role in human disease remains uncertain. Removal of IL-10 worsens the clinical and histological features of SA,[20,21] implying IL-10 may control inflammation after infection. The role for IL-4 is less clear. In the streptococcal model IL-4 deficiency worsens arthritis,[22] whereas in the staphylococcal model IL-4 gene deletion limits arthritis development.[23]

The role of macrophage-derived cytokines, particularly TNFα, is in augmenting a wide variety of cellular and humoral host responses to infection. TNFα can also directly restrict growth of intracellular bacteria. Removal of TNFα leads to accelerated growth of *Listeria monocytogenes* in infected tissue following enteric infection.[24] In septic shock in animals, neutralization of TNFα before inoculation of bacteria led to reduced mortality. However, in human clinical trials in septic shock an increase in mortality was noted. The role for TNFα in the pathogenesis of RA is increasingly apparent. Patients with RA are susceptible to native joint SA, possibly because of increased vascular flow to synovial tissues, previous damage to the joint, or DMARD therapy to control arthritis. Since licensing of TNF blockade as an RA treatment, nearly 20% of patients on these treatments have suffered serious infections,[25] often without an apparent 'septic' response. In a recently published British Society of Rheumatology Biologics Registry retrospective analysis[7] of patients receiving anti-TNF, a twofold increase of RA patients developing SA was shown compared to DMARDs alone. The risk appears greatest within the first year of treatment and falls in later years, suggesting a possible differing role for TNFα in response to early and late infections, but this has yet to be characterized.

Currently, there is no consistent information from animal models to explain the role of TNFα and IL-1. Neutralizing TNFα and IL-1 in a rabbit *S. aureus* model of SA before inoculation prevented arthritis development; whereas inactivation 24 hours after inoculation treatment was ineffective.[26] This suggests that macrophage-derived cytokines may be implicated in microbial clearance, as well as synovitis in SA. However, in mice with TNFα and IL-1 receptor genes both deleted, staphylococcal inoculation led to more aggressive joint disease,[23,26] possibly by allowing more bacteria access to the joints. In the streptococcal model, TNFα was not implicated but limitation of IL-1β and IL-6 production 1 hour after bacterial inoculation reduced joint destruction,[27] and this effect could be overcome by injecting exogenous IL-1β and IL-6. This suggests that IL-1 and IL-6 overproduction by monocytes and macrophages is also implicated in the pathogenesis of early joint damage.

The reasons for conflicting results in different models remain unclear and there may be no unifying hypothesis. However, interactions between different bacteria and host blood vessels, mononuclear phagocytic system, and inflamed synovium are clearly important. Equally, cytokines from T cells and macrophages are probably implicated, but, as their roles can vary during different phases of infection, their effects in the in-vivo models will need more detailed study if mechanisms of inflammation in joint infection are to be accurately elucidated.

Clinical features

History

Patients usually complain of an acutely painful single swollen joint, but up to 20% of patients have identifiable polyarticular infection (Table 98.2) The history should include the patient's age and occupation, together with a social history to include use of illicit drugs. To further differentiate causes of acute joint pain a history of prescribed medications, as well as information concerning sexual and travel history, should be obtained. Pain and joint stiffness, its temporal pattern, aggravating and relieving factors should also be sought. A systemic enquiry can help to aid the diagnosis, and specific enquiries regarding purulent sputum, dysuria, penile/vaginal discharge, leg ulceration, or recent joint surgery should be made. History of fever occurs in 50–57%,[2,28] and sweats/rigors are reported in only 30%, and these are therefore not essential for

Table 98.2 Joints most frequently affected in septic arthritis

Site	USA[1,a]	France[47,a]	Scotland[2,b]	Saudi Arabia[48,b]
Knee	68%	33%	56%	50%
Hip	9%	22%	16%	25%
Polyarticular	19%	11%	15%	8%
Shoulder	15%	12%	4%	16%
Wrist	15%	NR	4%	NR
Ankle	7%	NR	2%	NR
Elbow	10%	NR	2%	NR
Sternoclavicular	NR	NR	2%	NR
Sacro-iliac	NR	11%	NR	NR

NR, not recorded.

diagnosis. Immunosuppressive therapy for any disease may mask typical features of inflammation, so a high index of suspicion is required.

Examination

The Regional Examination of the Musculoskeletal System (REMS; see Chapter 6) may be used to identify articular abnormalities. Physicians should look, feel, and move the joint to assess function, comparing the affected joint and normal side for evidence of more widespread disease. Examination of the acutely swollen joint will show signs of inflammation (pain, erythema, swelling, heat, and disability). The presence of synovial swelling and/or effusion, joint instability, limited movement, and deformity necessitate investigation. Local periarticular tenderness without joint swelling could indicate enthesitis, tendinitis, or bursitis, or possibly primary bone disease. In those patients with an inflammatory polyarthritis, the affected septic joints are likely to have signs out of keeping with global underlying disease activity. Large joints are the most commonly affected (Table 98.2).

Untreated *Neisseria gonorrhoeae* infection can also lead to a destructive arthritis, but can be asymptomatic. It should be suspected in sexually active patients presenting with migratory arthralgias, tenosynovitis, and skin rashes with vesicles.

Investigations

Prompt aseptic synovial aspiration is of paramount importance in diagnosis and treatment of SA and should take place prior to antibiotic administration (Figure 98.1). Although individual hospital admission policies may differ, many uncomplicated patients with SA can be managed in a rheumatology setting without recourse to surgical intervention. However, a suspected infected prosthetic joint should be referred to the orthopaedic surgical team for aspiration in theatre.[29]

Synovial fluid is usually cloudy with a high white cell count (WCC). Immediate microscopy is recommended to identify cell types, Gram stain for bacteria, and polarized light microscopy for uric acid or calcium pyrophosphate dihydrate disease (CPPD) crystals.[29] Causative organisms are seen in up to 57% of synovial fluid.[3] The value of performing quantitative WCC in synovial fluid aspirated from native joints is debated as it lacks the sensitivity to

differentiate between infection and inflammation.[30] Low synovial fluid glucose, high lactate,[31] and procalcitonin are reported in SA. Evidence that these can separate infectious from inflammatory arthritis is lacking, and so they are not performed in routine practice. Neisseria organisms are fastidious with low yields from culture, but polymerase chain reaction (PCR) can detect Neisseria-specific DNA. Arthroscopic synovial biopsy is rarely necessary, but in tuberculosis may be required for diagnosis. Bone biopsy may be needed to identify causative organisms in non-resolving osteomyelitis.

Blood cultures should be performed routinely, prior to antibiotic therapy. The commonest joint infections result from haematogenous spread, and in some cases blood cultures may identify bacteria when synovial fluid cultures do not. At presentation, erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are almost invariably raised, with CRP being the more discriminatory.[32] The WCC is normal at presentation in 37% of SA patients, but in those with RA this figure rises to 50%. Impaired renal and liver function predicts a poorer outcome.[2] Evaluation of potential distant sites of infection should be determined by clinical presentation, including chest radiograph, urine cultures, and swabs from skin ulcers as well as oral, anal, and genital sites in patients with suspected Neisseria infection.

A range of imaging studies can assist in diagnosis of an acute monoarthritis but only a few are salient for SA. Plain radiographs show soft tissue swelling and previous joint damage from whatever cause, but often show no evidence of the joint destruction that may be apparent later. In anaerobic infections (the least common cause of SA), gas may be seen in the joint cavity. Nevertheless, radiographs can be helpful in providing evidence of an alternative diagnosis such as chondrocalcinosis. The quickest way to localize synovitis and to target aspiration is ultrasound, which can also discriminate between joint effusion, and more superficial cellulitis, bursitis or tenosynovitis. MRI (Figure 98.2a) can also assist in distinguishing between potential differential diagnoses and is helpful in demonstrating additional osteomyelitis (Figure 98.2c). Radionucleotide scans (Figure 98.2b) will not be able to differentiate between infection and inflammation, but labelled white call scans can identify areas of infection when the primary source of infection is uncertain.

Suspected SA

When there is a clinical suggestion of SA from the patients' history and examination, but routine investigations fail to isolate any bacteria, the other immediate investigations (as outlined above) are equally likely to be abnormal and outcomes (including mortality) are identical when compared patients with bacterial proven SA.[33] Long-term mortality outcomes are also similar between patients with bacteria-proven and suspected SA.[4] Hence, absence of systemic symptoms and normal microbiological investigations should never negate a strong clinical suspicion.

Organisms

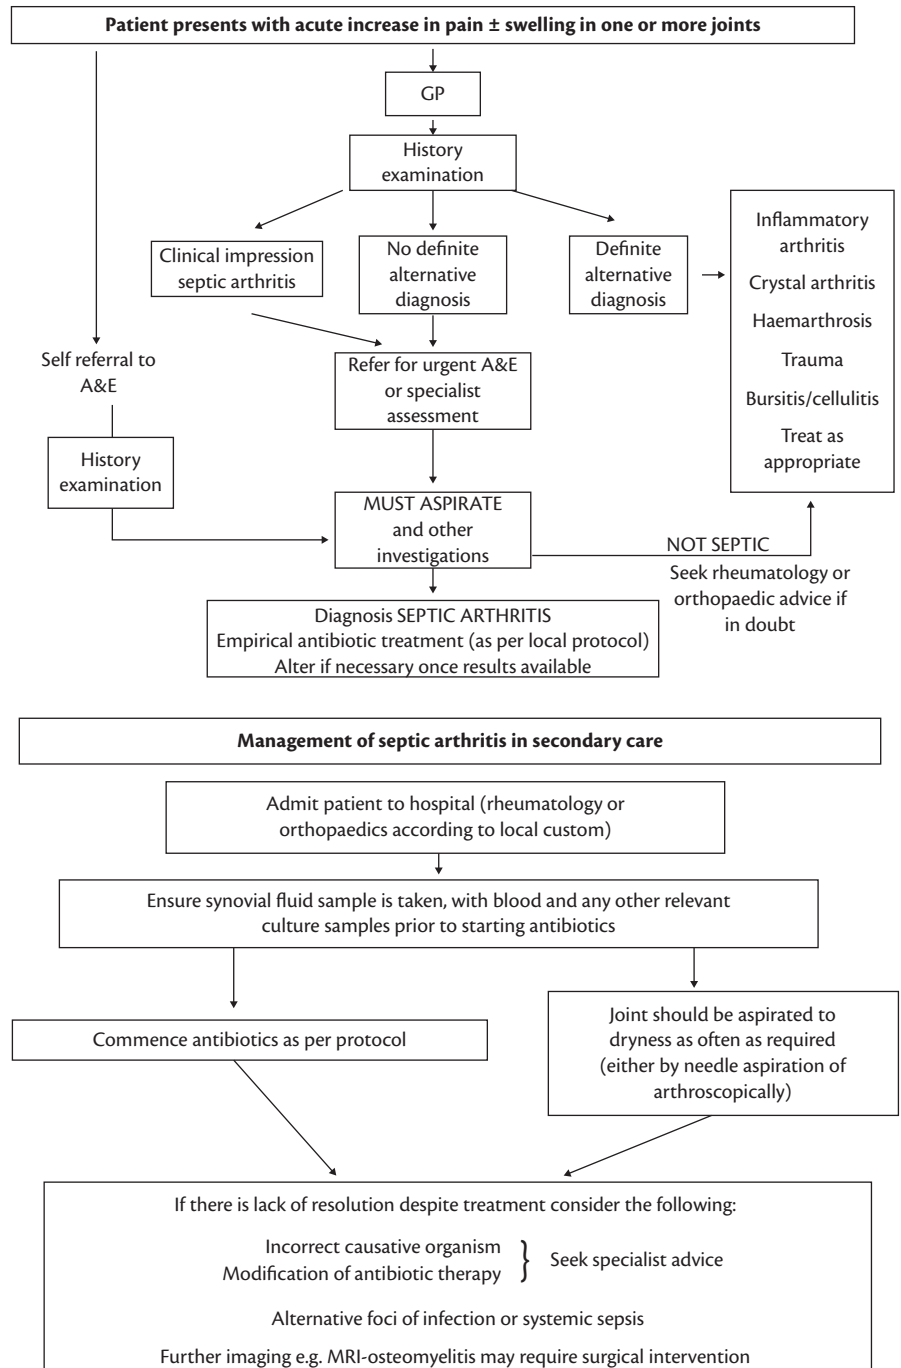
The most commonly detected organisms in SA (Table 98.3) include staphylococci, streptococci, and Gram-negative bacteria.[2] Infection with multiple organisms is increasingly recognized.[2] *S. aureus* is the prominent organism in retrospective and prospective published series with prevalence in SA remaining unchanged for many years.[34] In addition to an increasing resistance to penicillin G noted in the 1970s, the prevalence of methicillin-resistant *S. aureus* (MRSA) detection is rising.[33] In the past, isolates of coagulase-negative


Fig. 98.1 British Society of Rheumatology (BSR) guidelines for management of the acutely hot swollen joint.

staphylococci, commonly *S. epidermidis*, were regarded as contaminants, but frequent detection in patients following recent joint surgery has raised awareness of this organism's significance.[33] Analysis of streptococci implicated in SA shows that group A (the most pathogenic) account for around 40%, group B for 30%, and group G for the remainder. Most patients with streptococcal SA were aged 50 years or older and often had comorbidities: autoimmune disease, chronic wounds, diabetes mellitus, and neoplasia. *S. pneumoniae* is alpha-haemolytic and is an important cause of pneumonia but is an uncommon pathogen in streptococcal SA.[34,35]

Gram-negative bacteria, especially those belonging to the family Enterobacteriaceae, are an increasing cause of bone and joint infections.[35] Elderly patients and those with urinary tract infections and chronic illness (particularly diabetes mellitus, sickle cell anaemia, neoplasia, connective tissue disease, and after renal transplantation) were found to be most susceptible.

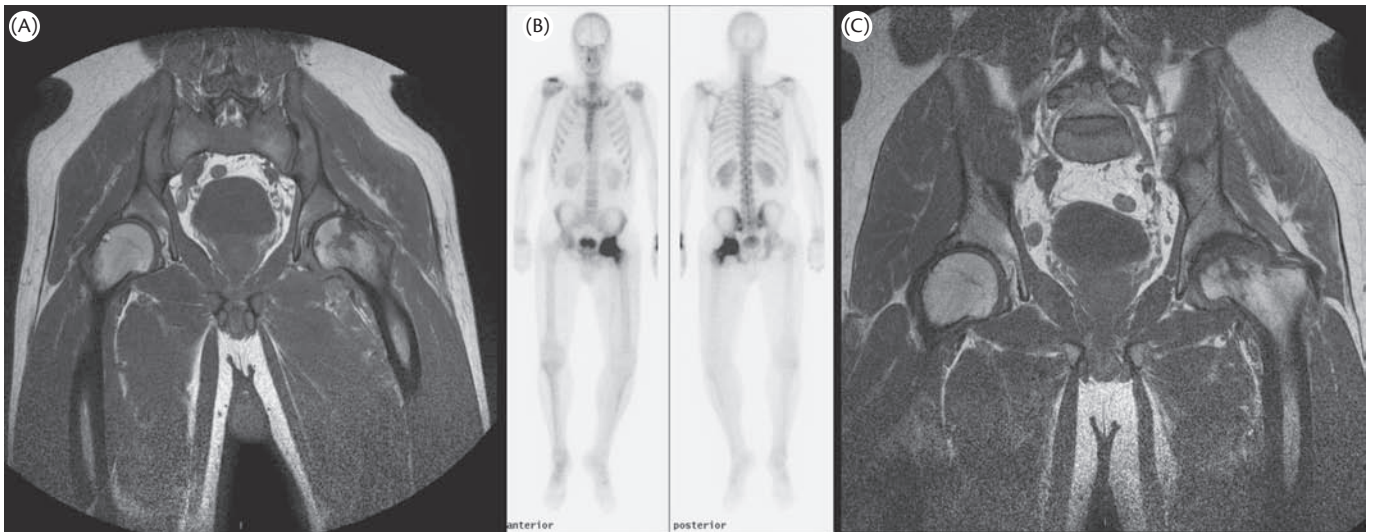
Anaerobes including bacteroides, *Propionibacterium acnes*, and some anaerobic Gram-positive cocci are isolated in less than 7% of cases of SA, often in combination with aerobes. Free gas in the joint on plain radiograph, or foul-smelling synovial fluid could suggest an anaerobic infection. Synovial fluid should be cultured for at least 2 weeks because of the slow growth of these organisms. Sensitivity testing is mandatory because many species are multidrug resistant.


Fig. 98.2 Evolution of an infected left hip joint despite antibiotic therapy: (A) Initial MRI scan of an infected left hip at day 3 showing destruction of the femoral head. (B) Technetium isotope bone scan at day 3 showing uptake of radioactivity in the left hip joint. (C) MRI scan at week 8 showing further destruction of left femoral head and acetabulum.
Figures provided by Dr D. Colville, Department of Nuclear Medicine, Glasgow Royal Infirmary.

N. gonorrhoeae was isolated from the synovial fluid in 12% of SA cases seen in aboriginal Australians,[36] a much higher percentage than that reported recently in European studies (Table 98.3). Infection can be asymptomatic, but should be suspected in sexually active patients presenting with migratory arthralgias, tenosynovitis, and skin rashes with vesicles.

Mycobacteria and fungi rarely cause SA. Special microbiological techniques are required to enable confirmation and a high index of suspicion is necessary in potentially infected individuals.

Treatment

The BSR, British Health Professionals in Rheumatology (BHPR), and British Orthopaedic Association (BOA) guidelines published in 2006 (Figure 98.1) provide a framework on which to base treatment.[29] Prompt treatment is required to reduce the associated morbidity and mortality. Joints should be aspirated to dryness, with repeated aspirations necessary if effusions reaccumulates. Surgical intervention in uncomplicated cases does not appear to confer benefit compared with repeated aseptic joint aspiration. Antibiotic therapy should be guided by local prescribing protocols, and instituted before culture results are available, but preferably after joint aspiration. Individual patient risk factors and the likelihood of a causative organism should help to determine an appropriate antibiotic until culture and sensitivity results are known (Table 98.4). Although there is no evidence to support the route or treatment duration of antibiotics in patients with SA, the general consensus is that at least 2 weeks of parenteral therapy followed by 4 weeks of oral therapy is required. Monitoring for signs and symptoms of sepsis or shock should be undertaken and treated appropriately. Orthopaedic intervention with arthroscopy and wash out of the affected joint may be required if signs do not settle with conservative measures.[29] Physiotherapy in the recovery period is important in order to maintain function.

Table 98.3 Bacteria isolated (%) from patients with proven septic arthritis

Table 98.4 Summary of United Kingdom recommendations for initial antibiotic use in suspected septic arthritis after obtaining bacterial culture (dependent on local protocols)

Clinical situation	Suggested antibiotic
No risk of atypical organisms	IV flucloxacillin. Local policy may add IV gentamycin or oral fusidic acid
No risk of atypical organisms but penicillin allergic	Clindamycin or 2nd/3rd generation cephalosporin
High risk of Gram-negative infection (elderly ±UTIs or recent bowel surgery)	2nd/3rd generation cephalosporin (flucloxacillin may be in local policy)
Discuss with microbiologist	MRSA risk (recent in-patient, nursing home resident, leg ulcers, etc.)
Vancomycin together with 2nd/3rd generation cephalosporin	Discuss with microbiologist
Possible gonococcus or meningococcus	Ceftriaxone or similar (depends on local policy)
Patient needing intensive care or high-risk IV drug users	Discuss with microbiologist

IV, intravenous; MRSA, methicillin-resistant Staphylococcus aureus; UTI, urinary tract infection.
Adapted from Matthews et al.[29]

Corticosteroids and bisphosphonates

Suppression of an excessive immune response with corticosteroids could be a more effective treatment regimen for *S. aureus* SA than use of antibiotics alone. Tarkowski and colleagues showed that, in mice treated with intraperitoneal cloxacillin together with intraperitoneal corticosteroid, the prevalence, severity, and mortality associated with SA induced by *S. aureus* inoculation was significantly reduced compared with mice treated with intraperitoneal cloxacillin alone.[37]

A randomized double-blind, placebo-controlled trial assessed dexamethasone treatment for SA in 123 children, given in parallel with standard antibiotic treatment, reduced duration of infection and subsequent joint damage when compared to antibiotics alone.[38] However, there are no studies in the adult population—a potential subject for further clinical trials.

The addition of bisphosphonates to an intraperitoneal treatment regimen of corticosteroids and antibiotics seems to add further clinical benefit in the staphylococcus animal model. This finding could be due to a decrease in osteoclast activity and a consequent reduction in skeletal destruction, and again may warrant further study in the human population.[39]

Infections in prosthetic joints

Prosthetic joints have brought relief to many millions of patients since the middle of the 20th century. Infection in primary joint replacements, is fortunately rare (1–3%), but in patients with RA and following an infected first replacement the frequency is higher. BSR/BOA guidelines suggest that suspected prosthetic joint infection should be referred to orthopaedic surgery for treatment.[29] Increased risks for prosthetic joint infection include infection at a distant site, the presence of a malignancy, a history of joint arthroplasty, other comorbid conditions (RA, diabetes mellitus), simultaneous bilateral joint replacement, and an operative time in excess of 2.5 hours.[40]

Contamination during implantation is considered to result in early (up to 3 months) or delayed up to 24 months) infections, but those after 24 months (late) probably result from joint infection via the blood stream as with native joint infection. Patients usually present with local pain at rest and on movement. Examination of infected joints may show a sinus, indicating a need for prosthesis removal. However, signs of inflammation may be found in early or delayed infections but are less likely in late infections.

ESR can be high for months and the CRP for up to 3 weeks following routine arthroplasty and so are of limited value during acute infections. Nevertheless, in delayed joint prosthesis infection, an elevated CRP and ESR have a high sensitivity (88% and 75% respectively) compared to 45% for high WCC. Low inflammatory markers at presentation have a good negative-predictive value.

Radiographs in infected prosthetic joints may show loosening (Figure 98.3a), subperiosteal bone growth, and rarely transcortical sinus tracts. Bone scans using technetium-99 m-labelled methylene diphosphonate can be positive for up to 12 months after replacement surgery[41] but are useful in patients with suspected delayed infection (Figure 98.3b). CT and MRI are of limited value because of the metal in the joints. However, indium-labelled white cell scans can be helpful (Figure 98.3c), especially when compared to the marrow-suppressed signal from the same scan which confirms the uptake in the femoral component (Figure 98.3d).

Joint aspiration may help differentiate infection from joint loosening. Gram-stained smear of synovial fluid has high specificity (>97%) but low sensitivity (<20%).[42] Synovial fluid WCC in excess of 1700/mm^3 and neutrophils greater than 65% has a 97% sensitivity,[43] but these figures are reduced in patients with inflammatory arthritis. *S. aureus* accounts for most early and recurrent infections, but delayed infections often result from skin contaminants like coagulase-negative staphylococci. If surgery is required, best microbiological results are obtained if three samples of tissue from the joint capsule, synovial lining, bone–cement interface, and samples from purulent material or sequestra are taken.[40] Ideally, antimicrobial therapy should be stopped for at least 2 weeks before revision surgery, and perioperative antibiotics should be withheld until all tissue cultures have been obtained. If this approach is followed and at leaat one out of three specimens show bacterial growth then the probability of prosthetic joint infection is over 94%.[42]

A variety of factors affect interactions between hosts and joint implants. Fibronectin-binding proteins on staphylococci enhance bacterial adherence to joint prostheses, limiting efficient bacterial removal. *S. epidermidis* can degrade polysaccharides and form an exopolysaccharide glycocalyx on artificial surfaces which protect bacteria from phagocytosis.[44] The heat resulting from bone cement mixing around the shafts of prostheses can cause bone necrosis,
Fig. 98.3 Infected femoral component of a left knee prosthesis: (A) Routine radiograph showing area of loosening round the femoral and tibial components of the prosthesis. (B) Technetium isotope bone scan showing increased uptake in the femoral and tibial components. (C) Indium-labelled white cell scan showing increased uptake around the femoral component and in the local bone marrow. (D) Simultaneous technetium scan shows bone marrow uptake in both components confirming that a concentration of radioactivity in the white cell scan (C) is the result of the focus of infection in the femoral component.
Figures provided by Dr D. Colville, Department of Nuclear Medicine, Glasgow Royal Infirmary.

providing a nidus for infection, and bone cement itself can inhibit neutrophil and complement functions, as can the implant itself.

As in native joint infection, not all patients with infected prosthetic joints require joint removal. Patients with joint pain and swelling of less than 3 weeks with a stable prosthesis may not need surgery but may be candidates for antibiotics and implant retention, possibly with debridement.[45] Equally, long-term antibiotic treatment may be necessary for patients if risks of surgery are too great. However, late infections require most patients to undergo a two-stage process, removing infected prosthesis, debriding of infected bone, and stabilizing the joint with an antibiotic-impregnated spacer. After 6 weeks of intravenous antibiotics (according to local protocols) and reimplantation of a second implant the success rate can be as high as 90%.[46]

Prevention of prosthetic joint infections

Preoperative evaluation of a patient for occult infection, such as periodontal disease or bacteriuria, is warranted, and any infection should be successfully treated before proceeding to joint replacement. Perioperative antibiotic prophylaxis significantly reduces rates of early joint infection after initial replacement. The role of antibiotic prophylaxis to prevent late prosthetic joint infection during procedures that lead to transient bacteraemia is more controversial. The incidence of late infection in prosthetic joints because of procedure-related bacteraemia is 10–100 cases per 100 000 patients per year. The cost of providing antibiotic prophylaxis to all patients with prosthetic joints is not inconsiderable and its efficacy is unknown. Similarly, the effect of more intensive therapy in treating infected prosthetic joints in RA patients is also unknown and until long-term studies from the British Society for Rheumatology Rheumatoid Arthritis Register (BSRBR) of biological and routine DMARD treatments are available, patients should be counselled on risks and benefits of antibiotic prophylaxis.

Conclusion

In an acute monoarthritis with classical symptoms of acute inflammation, SA should be considered as the most likely diagnosis, and should be treated immediately after appropriate investigations, particularly culture of synovial fluid, blood, and any possible sites of infection. Treatment for native joint infection outlined in BSR and BOA guidelines includes repeated aspiration to dryness and intravenous antibiotics to cover common organisms, but locally derived antibiotic guidelines should be used in each case. Lack of bacterial culture results in a patient with suspected SA should not delay treatment, as outcomes are no different from those in bacteria-proven SA. Treatment of infected prosthetic joint infection should always be referred to orthopaedic surgeons for investigation and treatment, which may include removal of the infected prosthesis as well as long-term intravenous antibiotic therapy.

CHAPTER 99

Bone and joint infections in children

Priya Sukhtankar, Julia Clark, and Saul N. Faust

Introduction

This chapter describes the range of paediatric bone and joint infections, focusing on osteomyelitis (OM), both acute and chronic; septic arthritis (SA); and tuberculous osteomyelitis. In addition, special situations such as immunodeficiency, complications of surgery, children with sickle cell disease, and infections caused by multiresistant organisms and hospital-acquired infections are discussed.

Bone and joint infections are relatively uncommon in children, and may be challenging to diagnose and treat. While laboratory investigations and imaging aid diagnosis, clinical signs are vital in informing the diagnosis and management of children of different ages with bone and joint infections. This chapter discusses the features suggestive of OM/SA in children of different ages, and investigations to aid diagnosis.

The involvement of multidisciplinary medical and surgical teams is essential to provide optimal care. Bone biopsy of infected joints may be indicated to identify organisms, although it may not always be technically possible or feasible due to lack of resources.

Certain laboratory tests have more relevance than others, and normal values should be interpreted with caution. Conventional microscopy and culture of bone and joint samples or blood cultures from children with OM/SA has a diagnostic yield as low as 12% in many western European paediatric populations including the United Kingdom, but rates of up to 50% have been reported in selected case series. Newer specific molecular tests appear to be useful in achieving a microbiological diagnosis.

The use of imaging varies with the suspected site of infection, the age of the child, and the resources available locally. Importantly, radiological features of infection may not be present in early disease.

The clinical course and prognosis depends on the causative organism, the mode of infection, and risk factors of the patient. However, more favourable outcomes occur with early diagnosis and prompt treatment with appropriate antimicrobial therapy. Complications of OM and SA in children vary according to age and depend on the extent of disease.

Epidemiology

The incidence of osteomyelitis (OM) and SA in children in the United Kingdom was estimated to be 2.9 new cases per 100 000 in 2001,[1,2] but is currently the subject of a national clinical study. Unpublished data from Southampton, Newcastle, and South London show an admission rate of between 0.048 and 0.07 per 1000 child years in all children from 0 to 18 years. In high-risk groups and in tropical countries the incidence is significantly higher, particularly of chronic osteoarticular infection (OAI). In sub-Saharan Africa HIV-positive and malnourished children are at increased risk of SA and OM due to immunocompromise.[3] This region also has a high incidence of sickle cell disease, which increases the risk of OAI.

Half of children with acute OM are 0–5 years old. Boys are approximately twice as likely to be affected by OM or SA as girls, although there is no gender predilection in the first year of life.[4] There no longer appears to be a link with social deprivation in resource-rich countries.[1]

Bone and joint infections are the second most common infections children with sickle cell disease after pneumonia and pneumococcal septicaemia.[5] This is discussed further under aetiology and pathophysiology.

Tuberculous SA and osteomyelitis are increasing, especially in countries where HIV is highly endemic. In the United Kingdom this tends to be a disease of immigrant populations from countries where the prevalence of tuberculosis (TB) is high, for example the Indian subcontinent.[6] These infections represent 1–2% of all TB, and 10–20% of all extrapulmonary disease. Tuberculous bone and joint disease mainly affects adolescents. Only 50% of these will have concurrent pulmonary TB. TB typically involves synovial joints and spine; osteomyelitis of long bones is less common.[7,8] Tuberculous infection of the spine (Pott's disease) accounts for up to 50% of tuberculous OM/SA.

Definitions

Osteomyelitis is inflammation of bone, usually due to bacterial infection, but occasionally due to fungal infection. It can be broadly divided into three groups:

- **Acute or haematogenous osteomyelitis (AHOM)**: this is the most common form of osteomyelitis in infants and young children. Organisms are seeded to the bone or joint via the circulation during an episode of bacteraemia. Children with sickle cell

disease and immunodeficiency such as chronic granulomatous disease are at increased risk.

◆ **Subacute or focal osteomyelitis**: this generally occurs in older children, often secondary to penetrating injury or surgical-site infection. Organisms are directly inoculated to the site of infection via puncture wound, or from adjacent infection.

◆ **Chronic osteomyelitis**: this occurs if osteomyelitis is left untreated or partially treated and can lead to abscess formation, pathological fracture, and sequestration. It is most common following focal osteomyelitis owing to its insidious course in resource-rich countries. In resource-poor countries, or where access to health care is not readily available, it follows AHOM and is more common.[9]

The clinical course of these types of infections depends on the age of the child, additional pathology and the causative organism.

◆ **SA** is infection within a joint, either due to haematogenous spread, extension of osteomyelitis into the adjacent joint, or direct inoculation of the joint itself.

◆ **Tuberculous osteomyelitis** is infection of a long bone, or spine with *Mycobacterium tuberculosis*. There is caseation and granuloma formation. This infection almost always involves the adjacent joint, causing tuberculous SA.

◆ **Osteoarticular infection (OAI)**: in this chapter the term refers to either OM and/or SA.

◆ **Discitis (diskitis)** is specifically infection and/or inflammation of an intervertebral disc.

Pathophysiology and aetiology

Acute (haematogenous) osteomyelitis

Organisms enter bone via the nutrient artery. There is some evidence based on clinical observation that infection of the bone is associated with microtrauma of the growth plate. This is supported by experiments using animal models.[10,11] A subclinical nidus of necrotic bone may form where infection can become established.

If osteomyelitis remains untreated inflammatory exudate spreads from infected region into haversian canals and canals of Volkmann towards the periosteum. This compresses blood supply further, resulting in bone necrosis, which goes on to form a sequestrum and/or sinus.

The metaphyseal region of long bones is most commonly affected as this has rich blood supply and bacteria are deposited in tight capillary loops where blood flow is slow. Once adhesion has occurred the bacteria proliferate into vascular tunnels. They can then invade metaphyseal cartilage. Metaphyseal capillaries also have very low numbers of phagocytic cells in the endothelium and therefore have limited protection against bacterial organisms.

In older children the growth plate acts as a barrier to extension of infection as blood vessels do not cross this layer of cartilage. Importantly, neonates have transphyseal vessels that traverse the growth plate into the epiphysis, which can lead to more extensive infection with more likely spread into the adjacent joint.[11] In adolescents, where the physis has ossified, the barrier also disappears, allowing extension and contiguous SA.

Subacute or focal osteomyelitis

Organisms usually enter the bone or joint directly from a puncture wound, such as an animal bite, or ingrowing toenail. These infections often present insidiously with localized inflammation, and are more likely to become chronic if unrecognized or misdiagnosed as soft tissue infection.

Surgical-site infection is caused by a similar range of organisms to acute haematogenous osteomyelitis. External fixation of fractures is a significant risk factor.[12,13] Resistant organisms are likely to be hospital-acquired, and can be persistent and difficult to treat where indwelling metalwork,[14] or devices such as bone-implanted hearing aids,[15] are present.

Chronic osteomyelitis

This occurs if the initial infection is left untreated (or is partially untreated), and was common in the preantibiotic era. If treatment is not initiated, abscess formation, and chronic suppuration with a leaking sinus can occur. This can lead to lifelong deformity, or may necessitate amputation.[16]

Septic arthritis

Infection of the joint can occur secondary to direct haematogenous seeding of bacteria to the joint, or as an extension of OM.[17] Notably SA occurs in up to 76% of neonates with bone infection.[18,19] If osteomyelitis extends into the adjacent joint it is likely to cause significant damage to the growth plate.

Organisms

Many organisms cause bone and joint infections (Table 99.1), in particular those mentioned in this section.

Staphylococcus aureus

The most common OAI-causing organism worldwide is *Staphylococcus aureus*, which has specific binding factors for fibronectin and laminin. Strains causing osteomyelitis have also been found to express adhesins for collagen and bind to bone and connective tissue.[20]

In the United Kingdom the majority of infections caused by *S. aureus* are meticillin-sensitive (MSSA). However, in other countries (such as the United States), community as well as hospital-acquired infections may be meticillin resistant (MRSA).[21] If there is a history of travel to countries where community-acquired MRSA (CA-MRSA) is common this should be considered and antibiotic therapy adapted accordingly. Patients with CA-MRSA OM/SA are also at increased risk of deep vein thrombosis (DVT).[21,22]

Panton–Valentine leucocidin (PVL) producing strains of *S. aureus* are relatively uncommon in OM/SA in the United Kingdom and also tend to be associated with acquisition of infection in other countries such as the United States. Around 60% of PVL *S. aureus* is MSSA.[23] However, if PVL is suspected it is important to request additional testing. Expression of PVL is associated with depletion of leucocytes, tissue necrosis, severe systemic illness, and destructive bone disease.[24]

Risk factors for PVL *S. aureus* include communities living in close contact, contact sports, and previous history of skin abscesses. MRSA and PVL-producing strains have been noted to cause higher fever and more significantly raised inflammatory markers than non-PVL-producing MSSA.[25]

Kingella kingae

Kingella kingae is a facultative anaerobic Gram-negative organism that has been recognized as an important pathogen in OM

Table 99.1 Microorganisms causing osteoarticular infections in children in the United Kingdom

Organism frequency
Common
Staphylococcus aureus (MSSA), 44–80%
Kingella kingae, 14–50% (increased <36 months)
Rare
Meticillin-resistant *S aureus*, (MRSA) 40–50% in USA, rare in UK
Panton Valentine Leucocidin (PVL) MSSA
Group A *Streptococcus* (GAS)
Group B *Streptococcus* (GBS), *Escherichia coli* (neonate)
Non-typeable *Haemophilus* spp. (incidence unknown), *Haemophilus influenzae* type b (non-immunized or immunodeficient)
Streptococcus pneumoniae, Coagulase-negative *staphylococcus* (CoNS) (subacute)
Very rare at any age (increased in immunodeficiency and where specific risk factors occur)
Pseudomonas aeruginosa (usually inoculation injuries and therefore >1 year old)
Neisseria gonorrhea, *Neisseria menigitidis* (neonate, adolescent)
Mycobacterium tuberculosis (older children as OAI develops 2 years from primary infection)
Salmonella spp. (sickle cell disease) Non-tuberculous mycobacteria (associated with defects of IFNg/IL12 pathway)
Klebsiella spp. *Bartonella henselae*, *Fusobacterium spp.* (often multifocal)
Aspergillus spp., *Candida albicans* (neonate, damaged bone, CGD)
Nocardia asteroides, *Serratia* spp. (CGD)
Age-specific organisms
Neonate:
GBS, MSSA *E coli* and other gram-negatives, *Candida albicans*
<2 years:
MSSA, *K kingae*, *S pneumoniae*, *H influenzae* type b Non-typeable *Haemophilus* spp., *E coli*, MSSA PVL
2–5 years:
MSSA, *K kingae*, GAS, *S pneumoniae*, *H influenzae* type b, Non-typeable *Haemophilus* spp., *Pseudomonas* spp., Coagulase negative staphylococcus (subacute) MSSA PVL>5 years
MSSA,MSSA PVL, MRSA

Adapted from Managing bone and joint infection in children, Faust et al, Archives of Disease in Childhood, 2012 Jun;97(6):545–53.

and SA in young children for the last two decades. One study has suggested that *K. kingae* is more likely to be detected if bone and joint aspirates are cultured in broth,[26] although this has not been replicated elsewhere and has not been the case in clinical practice in the United Kingdom. New molecular methods including specific targeted polymerase chain reaction (PCR) are more likely to demonstrate the organism.[27] Often carried in the nasopharynx, the major clinical manifestation in children is in bone and joint disease, although it also causes endocarditis and has been described as a causative agent in brain abscesses.

Streptococci

Streptococcus pneumoniae is a less common cause of OM/SA in children, despite being a relatively common cause of bacteraemia. When seen it is mainly in infants and in immunocompromised children.

Group A β-haemolytic streptococci more commonly cause bone and joint infections. This is a common cause of skin and soft tissue infections, particularly following chickenpox.

Haemophilus influenzae

Haemophilus influenzae was a major cause of OM and SA in children prior to the introduction of the *H. influenza* type B (Hib) vaccination in the late 1980s and early 1990s. It should be considered in unvaccinated and immunocompromised children.

Pseudomonas aeruginosa

This is an uncommon cause of osteomyelitis in general. However, it is an important cause of subacute focal osteomyelitis of the foot, and usually involves a puncture wound such as stubbed toe or blister. Puncture wounds through a shoe are a particular risk factor.[28–30] Cases of acute haematogenous spread of *P. aeruginosa* are also reported.

Mycobacterium tuberculosis

Mycobacterium tuberculosis is an increasingly important pathogen worldwide. Fifty percent of children with TB present with no active pulmonary focus. In children pulmonary TB may be 'silent' with no signs or symptoms.[31] Initial infection can be missed, and subsequent bone and joint infection may not become apparent until several years later. Fifty percent have spinal involvement and the remainder have infection of long bones and synovial joints.

Spread of *M. tuberculosis* to osteoarticular sites is usually haematogenous. Occasionally there is direct contamination of a joint, or spread from an adjacent lymph node. Tuberculous osteomyelitis is usually characterized by necrotizing (caseating) granulomatous inflammation. Weightbearing joints are most commonly

involved. In the spine the lower thoracic and lumbar vertebrae usually involved and spread occurs into adjacent discs and vertebrae, although there may be 'skip' lesions.

The organism usually enters the spine via arterioles supplying the anterior end plate and then spreads posteriorly. Spread to the intervertebral disc occurs late in the disease.[32] Pott's disease is vertebral osteomyelitis with paravertebral abscess, frequently associated with extensive bone destruction. Spinal tuberculosis is most common in adolescents and can present with vertebral collapse. Gibbus deformity occurs when there are multiple levels of collapse late in the disease.[33] Tuberculous dactylitis is largely a disease of young children (<10 years) and may remain unrecognized for long periods of time. It usually affects the hands, but can also affect the feet.[34] Extrapulmonary TB is more common in children who are coinfected with HIV, and also shows some female preponderance.[35]

Anaerobes

Anaerobic OAI is uncommon. However, in cases where there has been preceding history of trauma or surgery disrupting blood supply to the affected area, or in the skull where there has been mastoiditis or chronic otitis media, this should be considered. Anaerobes usually enter the site by direct contamination rather than via the haematogenous route.

Propionibacterium acnes is an aerotolerant anaerobe that causes postoperative infection, particularly following spinal surgery with metalwork. *Fusobacterium necrophorum* is an obligate anaerobe causing complicated mastoiditis with osteomyelitis.[36]

There are several case reports of non-tuberculous mycobacterial osteomyelitis, in both immunocompetent and immunocompromised children.[37–39]

Fungi

OAI caused by fungal infection, including yeasts and moulds, is extremely rare in immunocompetent hosts, although cases are documented in adults.[40] It affects children with neutropenia, chronic granulomatous disease, and premature and low-birthweight neonates. Fungaemia occurs most commonly in the intensive care setting.[41]

Candida species are the most common yeasts to cause systemic fungal infection, of which *C. albicans* is most common. Non-albicans candida species include *C. glabrata, C. kruseii*, and *C. parapsilosis.* These may be more virulent organisms than *C. albicans* and have different antifungal susceptibilities and resistance.

Aspergillus is the most common moulds implicated. Pathogenic species in humans include *A. fumigatus, A. flavus*, and *A. niger.* The most common sites of aspergillus OM are the spine, ribs, small bones, and chest wall.[42]

Other filamentous fungi found to cause opportunistic infection in immunocompromised patients are mucor, rhizopus, and fusarium.

Cryptococcus is a yeast found in soil, and has been described in a number of cases of fungal OAI. This organism is a cause of fungal meningitis in patients with HIV infection, but is occasionally seen as a cause of OAI in immunocompetent individuals.[43]

Special groups

Neonates

Neonates are more likely to have multifocal OM and to develop SA as infection spreads via transphyseal vessels. This is usually caused by haematogenous spread. Group B streptococcus is the most common organism and MSSA is also common. Coagulase-negative staphylococcus can also cause bacteraemia and seed to neonatal bones and joints. This organism should always be considered when indwelling central catheters are present.

Neonates are also more likely to develop fungal OM and SA, most commonly secondary to disseminated candidiasis. Risk factors for neonatal systemic fungal infection and subsequent OAI are prematurity, indwelling catheters, prolonged antibiotic use, and immune deficiency. Some 1–2% of infants with disseminated candidiasis will develop OM/SA. Infants less than 6 months old account for 85% of all paediatric fungal arthritis, which is most commonly caused by *C. albicans* or *C. parapsilosis.* Use of prophylactic fluconazole in neonatal intensive care units is changing the patterns of infection and susceptibility.[41]

Sickle cell disease

Sickle cell disease (SCD) is a most common genetic disease in defined areas of Africa and in migrant populations, affecting approximately 12 000 people in the United Kingdom. In 1999 the number of babies born with SCD in the United Kingdom was estimated to be 0.28 in 1000 per year.[44] In parts of sub-Saharan Africa the incidence is estimated at 3% of live births.[45]

Children with SCD, and to a lesser extent other haemoglobinopathies, are at increased risk of bone and joint infection. This may be difficult to distinguish clinically from ischaemic disease such as necrosis of the femoral head due to the SCD itself, and from sickle cell crisis. The increased risk of bone and joint infection is due to bone ischaemia, and small areas of necrotic bone allow a nidus of infection to form.

In sub-Saharan Africa 90% of children with SCD die before diagnosis, and the most common cause of death is sepsis.[46] In the United Kingdom at-risk infants are screened for SCD and will start penicillin prophylaxis once a diagnosis is made. In addition, Hib and conjugate pneumococcal vaccination reduce the risk of sepsis.

Non-typhoid salmonella bacteraemia is much more common in the SCD population. This can be attributed to impaired liver and splenic function, areas of devitalization of the bowel allowing translocation, and impairment of opsonization and phagocytosis. However, the reasons for salmonella bacteraemia in SCD are not fully understood.[47,48]

OM and SA in these patients is more likely to be caused by salmonella as a result of the increased risk of bacteraemia,[49] although MSSA infection remains an important cause.[50,51] The most commonly affected sites are long bones, in particular the tibia and humerus. Children with SCD are at greater risk of recurrence of OM/SA and treatment may be more challenging.

Immunocompromise

In immunosuppressed children MSSA remains the most common organism. However, if there is poor response to conventional therapy it is important to consider fungal infections such as *C. albicans, Aspergillus* , and less common organisms such as non-tuberculous mycobacteria, *Nocardia asteroides*, and anaerobes. Infection in immunocompromised children is more likely to be disseminated. OAI may be the first presentation and immunocompromise should be considered if there are atypical organisms, fungi, or multifocal or disseminated disease.

Children with acute leukaemia frequently present with bone pain. Once these patients have started chemotherapy they are at risk of neutropenia and thus at risk of infection. Bone and joint pain may

therefore indicate OAI, or relapse of malignancy.[52] Children presenting with febrile neutropenia are usually treated with empiric intravenous antibiotic therapy assuming bacterial infection, which is usually not found to be OAI, and a high index of clinical suspicion is often required to detect the source of infection if the febrile episode does not resolve as expected.

Chronic granulomatous disease (CGD) is a rare inherited deficiency of NADPH oxidase causing failure of phagocytic cells to produce oxidants. Children with this disease are therefore particularly susceptible to infection with catalase-positive organisms, non-tuberculous mycobacteria, *Nocardia asteroides*, serratia, aspergillus: 25% of children with CGD develop OAI.[53] Chest wall and vertebral spread may occur from contiguous pneumonia. Haematogenous spread also occurs to limb bones, and the osteomyelitis may be multifocal.

Clinical features

Classically the child with OAI presents with fever, pain at the affected site, and often bone or joint swelling. The child may be systemically unwell, especially in acute haematogenous OM.

Infants may present with a pseudoparalysis—refusal to move the affected limb. Where the lower limb is affected toddlers may refuse to walk. In SA the joint is held in a fixed position that maximizes the joint space and reduces pain. For example, the hip may be held flexed, abducted and externally rotated.

Pyrexia of unknown origin is a presenting feature. OAI should be considered in all children with persistent fever where no cause is found, even if there are no focal signs.

Focal osteomyelitis generally presents insidiously. There may be history of puncture wound, and localized tenderness and swelling in an otherwise well child. This may be difficult to distinguish from overlying soft tissue infection, but is more persistent.

Tuberculous OAI can be challenging to diagnose. These children may have a very long history of pain. In particular, spinal pain may have been present for months or years. Often there is faltering growth or weight loss.

Discitis often presents with an irritable child with no obvious cause. Babies and young children in nappies may become distressed during nappy changes as the spine is flexed.

See Table 99.2 for a summary of aetiology and clinical features.

Table 99.2 Summary of aetiology and clinical features

Age	Organisms	Clinical features
Neonates	GBS, *Escherichia coli*/Gram-negatives, MSSA, *Candida albicans*, coagulase-negative staphylococcus	Irritability, fever, widespread pain often difficult to localize on examination
		Pseudoparalysis, erythema, bone or limb swelling. Several sites may be involved Pseudoparalysis of arm, looking like a delayed-onset Erb's palsy, classic of late-onset GBS OM of humeral head
		Bone or joint infection should be considered if there is a positive blood culture
<2 years	MSSA, *Kingella kingae*, *Streptococcus pneumoniae*, *Haemophilus influenzae* type b, non-typeable haemophilus, *E. coli*, GAS (especially in children following chickenpox), MSSA PVL (uncommon in the UK), MRSA PVL (very rare in the UK)	**Acute haematogenous osteomyelitis:**
		Usually short history, with an ill child in pain
		Fever of unknown origin
		Fever and malaise are frequent with bacteraemia but may be absent
2–5 years	MSSA, *K. kingae*, GAS, *S. pneumoniae*, non-typeable haemophilus, MSSA PVL (uncommon in the UK), MRSA PVL (very rare in the UK)	Refusal to move the limb or to weightbear, limp, erythema, bone or limb swelling, local tenderness
		Septic arthritis:
>5 years	MSSA, MRSA PVL (uncommon in the UK), MRSA PVL (very rare in the UK), *K. kingae*, pseudomonas	Usually a unifocal hot, immobile, tender peripheral joint, with pain on passive joint movement
		May have no focal signs
		Fever of unknown origin
		Subacute or chronic osteomyelitis:
		Longer history, maybe weeks, with no systemic symptoms
		History of penetrating wound
		Often no fever
		Less acute local signs with limp, refusal to move the limb or weightbear
		Local bony swelling or tenderness
		If left untreated can form fistulas, have purulent discharge
Discitis	Usually no organism is isolated	**Insidious onset, with no systemic illness**
		Fever is uncommon
		Back pain, refusal to sit, stand, or walk
		Refusal to flex the spine, local tenderness, irritability on nappy changing in infants
		Constipation or abdominal pain

GAS, group A streptococcus; GBS, group B streptococcus; MRSA, meticillin-resistant *Staphylococcus aureus*; MSSA, meticillin-sensitive *Staphylococcus aureus*; PVL, Panton–Valentine leucocidin.

The differential diagnoses of OM/SA include:

- Trauma including non-accidental injury
- Soft tissue infections—cellulitis, fasciitis
- Malignancy—osteosarcoma, leukaemia, neuroblastoma
- Reactive arthritis—secondary to viral infection
- Haemarthrosis
- Henoch–Scho?nlein purpura
- Juvenile idiopathic arthritis—the commonest cause of monoarthritis in children
- Infarction/bone necrosis, especially in SCD
- Erb's palsy in neonates

Investigations and diagnosis

The clinical course and outcome of OAI is dependent on early treatment before tissue destruction can occur.[17] If clinical features suggest OM or SA, imaging and laboratory tests can confirm diagnosis and the extent of disease. They can then be used to monitor disease progression and resolution.

Laboratory tests

Initial tests when the child presents should include C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR). These are more reliably increased than white cell count but normal values do not absolutely exclude OM or SA.[54] Values of ESR greater than 20 mm/hour and CRP greater than 20 mg/litre are found in more than 90% of children with OM or SA. ESR tends to peak on day 3–5 of infection, whereas CRP increases more rapidly and peaks on day 2 of hospitalization. ESR lags behind resolution of disease, and takes 2–3 weeks of to return to normal, whereas CRP takes around 1 week.[55]

The Kocher criteria are used in the emergency setting to aid diagnosis of a septic hip in a child presenting with hip pain. The original study to develop these rules was based on SA of the hip specifically. Kocher's criteria use four independent predictive factors: history of fever above 38.3 °C, non-weightbearing, ESR 40 mm/hour or longer, and white blood cell count greater than 12×10^6/dL. If all four features are present the likelihood of SA of the hip is 93%.[56,57] If a CRP level above 20 mg/litre is included, the likelihood increases to 97%.[58]

More recently studies have shown that the severity of infection with MRSA is greater than with MSSA and that CRP and ESR are higher in MRSA infection than in MSSA infection.[59]

Blood culture should be performed in all children with suspected bone and joint infection, ideally before starting antibiotic therapy. Blood cultures have been reported to be positive in up to 60% of cases.[60] However, these are mostly selected case series and rates of positive blood culture in OM/SA in the United Kingdom and Europe are often much lower.[2]

Full blood count and film should also be performed, as the differential diagnosis of bone and joint pains will include leukaemia, particularly if the spine is involved.

Due to the non-specificity of symptoms in neonates and ability of bacteria to cause widespread infection, a full septic screen including urine microscopy and culture, chest radiograph, and lumbar puncture should be performed.

If TB is suspected a tuberculin skin test (TST) and interferon gamma release assay (IGRA) should be done. These have similar sensitivity in children.[61] Negative TST and/or IGRA do not rule out TB, but are useful tools to aid diagnosis where history is suggestive of exposure to *M. tuberculosis.*

Direct samples from the affected bone or joint are usually taken surgically if indicated (bone biopsy), or occasionally via interventional radiology. CT- or ultrasound-guided aspiration of joints allows for reliable samples of the affected area.

All samples should be sent for microscopy and culture, and histology. Culture of bone and joint aspirates is important, but sensitivity remains low, even when methods are optimized.

However, molecular techniques such as PCR are being increasingly used to identify organisms in culture-negative disease. DNA is extracted from tissue and incubated with primers for the constant regions of 16S RNA gene.[62] The bacterial specific sequences between these regions are then amplified and the bacteria can be identified by entering the sequence into a database.[60,63]

Real-time PCR has been particularly useful for identifying *K. kingae* infections, and is one of the reasons this organism has been more recently recognized as an important cause of OM/SA.[63] This method is also used to identify PVL-producing strains of *S. aureus* when clinically suspected, using a PCR target specific for these strains.[64]

Imaging

Plain radiographs may show periosteal elevation or lytic change if infection has been present for more than 10 days. This is not a sensitive test and it is particularly difficult to see changes in the pelvis, ribs, sternum, and spine. Plain radiographs of the affected joint are usually performed, for example, in the non-weightbearing toddler to exclude fracture.

MRI is the gold standard for imaging OM and SA due to its higher sensitivity and specificity, and also as it does not involve ionizing radiation.[65] T2-weighted images show increased bone marrow intensity corresponding with oedema. T1-weighted images show darker bone marrow. These changes are not specific, but can be interpreted in the context of suspected bone infection. If abscess is suspected this is best demonstrated with fat suppression on T1-weighted image with gadolinium enhancement.[66] However, MRI is not always be practical in the acute setting when younger children are likely to require a general anaesthetic for the procedure. MRI is particularly important in the diagnosis of skeletal TB, and in spinal and pelvic osteomyelitis and discitis. Sparing of the intervertebral disc on imaging early in the disease is suggestive of TB.[32,33]

CT shows soft tissue changes and necrotic bone, and may be easier to perform in young children where general anaesthetic is not available. CT is also useful for providing guidance to interventional radiologists and surgeons when taking aspirates from sites of bone or joint infection.

Ultrasound scan be useful in SA to assess deep effusion, subperiostial collection and abscess formation. Its main use is in neonates, and in guided aspiration of joints.[67]

Technetium radionuclide bone scan (^{99m}Tc) or bone scintigraphy has high sensitivity and specificity but is now used less often due to the radiation burden. This technique may also give false-negative results in infancy. Scintigraphy can be useful where multifocal infection is more common, such as in immunocompromised children or those with SCD.[68]

Management

There are no agreed national or international guidelines for the management of paediatric OAI, although recent pragmatic guidelines have been published in the United Kingdom.[2,69] Management is multidisciplinary including paediatricians, orthopaedic surgeons, radiologists, and microbiologists. There remains limited high-quality evidence to guide therapy, although large prospective trials are currently being considered. Until now established practice has been based on expert opinion and history.[70,71]

Key steps in the management involve an initial decision regarding whether surgical intervention for diagnosis and/or treatment is required or feasible, as well as the choice of empirical intravenous antibiotic agent. The choice of antimicrobial agent for ongoing care will be guided by microbiology results. Subsequently decisions must be made surrounding the overall length of therapy, and whether to switch from intravenous to oral antibiotic agents.

Surgery

There is little high-quality evidence on which to base surgical practice of OAI at present, and decisions are therefore based on expert orthopaedic opinion.

Where a soft tissue collection or bone abscess is apparent radiologically, surgical drainage is recommended.[72] Immobilization of any surgically treated limb is also advisable.[2]

If OM/SA is diagnosed early by MRI scan and medical treatment is initiated successfully, surgical intervention is usually not required. Treatment response can be assessed by monitoring CRP and ESR, and the clinical status of the child.[9] Surgical drainage in acute OM is indicated if there is poor response to antibiotics after 48–72 hours.[71]

If SA is suspected, guided aspiration prior to starting antibiotic therapy is advisable to identify the organism where logistically possible. Ideally this should be before antibiotic therapy is initiated, unless a delay of more than 4 hours is anticipated. Arthroscopic drainage or washout of the joint is also indicated to reduce destruction of the synovium and cartilage by inflammatory cells. In SA of the hip, the role of surgery is considered more definite. Capsulotomy to drain the joint, and where pus is not identified, drilling of the femoral head to decompress any osteomyelitis to prevent necrosis, are indicated.[20] If PVL MSSA or MRSA is suspected it, aspiration and washout are considered essential as these organisms can cause rapid tissue destruction.[16,17] Where the spine is involved, orthotic support may be indicated especially if there is evidence of collapse on imaging.

Antibiotic therapy

See Table 99.3 for summary.

Initial empirical therapy

Once the child is clinically stable, the important aspects of medical management are antibiotic therapy and analgesia. The majority of children with OM/SA do not present overtly septic or unwell, and do not usually require resuscitation outside the neonatal period. It takes time to identify causative organisms, therefore initial therapy will usually be empirical, and is always intravenous. This must be tailored to provide best cover for the most likely organisms. Treatment should be initiated as soon as a diagnosis of OAI is made, or immediately following surgery for diagnosis or treatment.

Table 99.3 Summary table of antibiotics by age group

Neonate (<3 months)	Benzyl penicillin and gentamicin
	Or cefotaxime
	Add amoxicillin if listeria suspected
	Oral switch to co-amoxiclav
3 months–5 years	Cefuroxime
	Oral switch to cefalexin or co-amoxiclav
>5 years	Flucloxacillin or clindamycin
	Consider ceftazidime or ciprofloxacin if pseudomonas suspected
	Oral switch to co-amoxiclav suspension or flucloxacillin or clindamycin tablets

In neonates (preterm or <3 months of age), initial empiric therapy is the same as for other neonatal sepsis, and practice varies between centres. For example, benzylpenicillin with gentamicin, or cefotaxime are often first line. These regimes cover group B streptococcus, MSSA, and Gram-negative organisms. Cefotaxime also has good penetration into the cerebrospinal fluid. Ampicillin or amoxicillin are added until *Listeria monocytogenes* meningitis is excluded. In view of the haematogenous aetiology of OM/SA in neonates and immature immune system, it is advisable to do a full septic screen including lumbar puncture in this group.

In children 3 months to 5 years old, initial therapy should have potent activity against MSSA although this age group is at most risk of *K. kingae* infection, probably secondary to pharyngeal colonization.[73] Cefuroxime provides good cover for this and for MSSA as well as for group A streptococcus, non-typeable haemophilus infections, and *H. influenzae* type B in any children incompletely immunized.

In children 6 years and older, MSSA is by far the most common organism and high-dose intravenous flucloxacillin is the usual antibiotic therapy of choice, or clindamycin if penicillin allergic. If there is poor response to treatment after 48–72 hours of treatment, or if MRSA or PVL is suspected, clindamycin or linezolid can be added as a second agent (but see below for treatment in confirmed PVL staphylococcal infections).[59,65,72]

In children with puncture wounds of the feet, such as a nail through a sports shoe, pseudomonas should also be covered. The wound should be irrigated and debrided if necessary to remove debris, and tetanus vaccination status checked.

Duration of intravenous therapy and oral switch

In recent years, many have advocated the reduction of risks associated with long-term intravenous therapy with early switch to oral therapy.[69,71,74] Small clinical studies have shown a similar cure rate between short courses of intravenous antibiotic therapy with oral continuation vs long-course intravenous therapy. In selected cases, acute SA has also been treated with a total course of 2 weeks of antibiotic therapy.[69,75]

Oral switch can be considered early after 48 hours if disease is uncomplicated osteomyelitis, and there is clinical improvement.[76] The child should be afebrile and able to take oral food and fluids.[74] CRP should also have fallen consistently.[9] Pragmatically this could be to one third of the original value or to less than 20 mg/mL. Conversely, if there is continued pyrexia and inflammatory markers

are not falling, intravenous therapy should be reviewed, and further imaging and surgical intervention considered as above.[2]

The decision of which agent to use when to switch to switching to oral therapy is also dependent on palatability and frequency of administration of the drug. Flucloxacillin and clindamycin suspensions are unpalatable and poorly tolerated, and adherence to these medications is poor.[77] They are therefore not a good first choice in young children who cannot take tablets, despite their excellent oral bioavailability and tissue penetration.[71]

Co-amoxiclav and cefalexin suspensions are generally well tolerated and these are good alternatives for oral switch in any children unable to take tablets. In older children who can take tablets, flucloxacillin or clindamycin can be continued orally.[77]

The total duration of intravenous antibiotic therapy required to effect complete cure is unknown, but most clinical practice is based on consideration of reduction of old textbook regimes of up to 6 weeks intravenous therapy for both uncomplicated and complex disease. Historic observational studies suggested a risk of relapse with antibiotic therapy of less than 3 weeks.[78,79]

In complicated disease—defined as where there is evidence of multifocal disease, significant bone destruction, abscess or pathological fracture, or immunocompromise[20]—the total duration of antibiotic therapy may be longer. Intravenous therapy may also be prolonged if the child is systemically unwell or unable to tolerate oral antibiotics. This group includes neonates, in whom oral antibiotics are unreliably absorbed, and intravenous therapy should be continued for 14–21 days.[20] Complex disease with significant collection may require up to 6 weeks intravenous antibiotics.

Where pseudomonas infection is suspected, anti-pseudomonal therapy should be initiated. Agents include ciprofloxacin and ceftazidime. Ciprofloxacin is has good oral availability, and can be used for oral switch. The wound should be irrigated and debrided if necessary to remove debris, and tetanus vaccination status checked.[28,80]

If PVL disease is suspected the latest Health Protection Agency guidelines should be used in the United Kingdom, and the case discussed with a specialist in infectious disease. This is a notifiable disease in the United Kingdom and contacts should be traced. It should be treated with flucloxacillin, if MSSA. If MRSA is confirmed, vancomycin or clindamycin may be used. Clindamycin, linezolid, or rifampicin inhibits protein synthesis and theoretically reduces toxin production. Addition of rifampicin to vancomycin therapy in MRSA OAI may also be advised by local microbiologists.[72]

Tuberculous osteomyelitis once confirmed should be treated according to National Institute for Health and Clinical Excellence (NICE) guidelines for *M. tuberculosis* infection. This is initially standard regimen of 4 months rifampicin, isoniazid, pyrazinamide, and ethambutol followed by 2 months rifampicin and isoniazid only. *M. tuberculosis* infections require close monitoring and repeat imaging is advised.

In immunocompromised children prolonged intravenous antibiotic therapy is indicated. These should be discussed with microbiology and paediatric infectious disease consultants. Many of these children will have been treated with antibiotics previously and may be colonized with resistant organisms.

If fungal osteomyelitis is suspected antifungal treatment is initiated, for example with amphotericin, caspofungin, posaconazole, or voriconazole. This should be discussed with specialist microbiologists or infectious disease paediatricians. There is limited evidence available regarding the treatment of these infections, which frequently require surgical debridement.[42] Fluconazole and amphotericin B remain commonly used both in neonates and in older children at risk of fungal infection. Liver and renal functions require monitoring with most antifungal therapy. Echinocandins such as caspofungin and micafungin are a newer class of antifungals that effectively treat yeast infections such as candida and are fungicidal for these. Voriconazole and pozaconazole are also being used in persistent fungal infections.

Children with SCD should be managed with adequate analgesia and hydration where necessary. Intravenous cephalosporin is usual as empirical therapy, although failure of ceftriaxone treatment for salmonella is reported. If salmonella infection is suspected, quinolones may be of use in susceptible organisms.

Children with discitis should be treated with empiric anti-staphylococcal antibiotic therapy as this reduces duration of symptoms.

Complications

Children who have had OM/SA should be followed carefully, as seemingly uncomplicated cases may have altered growth or occasionally develop deformity. Pathological fracture following chronic OM is a well-recognized complication.[81]

Necrosis of the affected epiphysis and limb-length discrepancy are also seen. This is more common where there is a delay in treatment, or in response to treatment and following MRSA infections.[82] Complication rates of treatment regimens themselves are unclear.

Spinal osteomyelitis, and in particular destructive tuberculous disease, can lead to neurological complications associated with vertebral collapse including hemiplegia. This is preventable with regular follow-up and orthotic and physiotherapy input.

Conclusion

OAI in children is an uncommon but important diagnosis. Clinical features may be non-specific and variable. Imaging techniques aid diagnosis, and MRI is the most effective of these. The causative organisms vary with age and risk factors.

Empirical antibiotic therapy should target the most likely causative organisms within these groups. Surgical input to obtain samples, or decompress or stabilize bones and joints is sometimes necessary, and orthopaedic opinion should be sought. Complications are rare when OAI is diagnosed and treated in the acute phase.

Case history 1: Osteomyelitis in a child over 6 years old.

A 6 year old boy presented with a one-day history of right knee pain. He had played football in the park the day before, and was otherwise usually fit and well with no significant past medical history. On arrival at the Emergency Department he had a temperature of 38.5 °C. Examination of his legs showed reduced flexion and rotation of the right hip, which was warm to touch.

Blood tests showed a white blood cell count of 12×10^9/dL and CRP of 52 g/dL. Ultrasound scan showed an effusion in the right hip. Blood cultures showed no growth at 48 hours. Arthroscopic washout of the hip was performed, obtaining turbid fluid. His unifocal SA was treated empirically with intravenous flucloxacillin for 1 week with resolution of pain and fever. He was discharged

with a further 3 weeks of oral co-amoxiclav, ensuring good drug adherence by using an oral antibiotic with good taste and suitable dose frequency regime.

Learning Points:

- Reduced range of movement, pain and fever suggest OAI.

- Knee pain may be referred pain from the hip.

- MSSA is the most likely organism, flucloxacillin is a good choice of intravenous antibiotic in this age group if there are no comorbidities.

Case history 2: Osteomyelitis in a younger child

A 5 year old boy presented to hospital with a 2 week history of left ankle pain. His mother thought he might have twisted it while playing. On examination he was reluctant to weight bear and the ankle was swollen and warm to touch. White blood cell count was 10×10^9/dL, and CRP was 25 mg/L.

Following normal ultrasound and plain radiographs, MRI of the ankle was performed and showed OM of the distal fibula, the report suggesting inflammation of 2–3 weeks duration. Blood cultures were negative but multiplex PCR subsequently confirmed *Kingella kingae* infection. He was treated with intravenous cefuroxime for 5 days, and discharged to complete 4 weeks cefalexin. Clinical symptoms resolved.

Learning points:

- Minor trauma is commonly present in the history, and may be a 'red herring'.

- Ultrasound scan and radiograph may appear normal and MRI can confirm diagnosis.

- Multiplex PCR is useful for the identification of *K. kingae*—which should be considered in all children up to 5 years.

Case history 3: Neonatal osteoarticular infection—beware limb pseudoparalysis

A 3 week old baby presented with a 3 day history of not moving the right leg. He was mottled and pyrexial, 38.5 °C at presentation. Full septic screen was performed that showed white blood cell count of 4×10^9/dL with neutrophil count of 2×10^9/dL. CRP was 77 g/dL. Lumbar puncture showed cerebrospinal fluid white cell count of less than 5/dL with normal protein and glucose 70% of plasma level (normal).

Clinical diagnosis of SA of the hip was made and washout performed. He was treated empirically with intravenous cefotaxime for 2 weeks initial period. As blood culture grew a fully sensitive group B streptococcus, treatment was changed to intravenous benzylpenicillin to complete a 6 week course of therapy.

Learning points:

- Pseudoparalysis in a neonate suggests OAI.

- Full septic screen is indicated in view of likely bacteraemia.

- Surgical washout is indicated in SA of the hip.

Case history 4: Tuberculous osteoarticular infection

A 14 year old Nepalese boy presented with a painful, discharging sinus on the anterior aspect of his left shoulder with reduced range of movement. He had been taking non-steroidal anti-infalammatory drugs (NSAIDs) for 6 weeks for pain and swelling. He was noted to be of short stature, below the 0.4th centile, and reported that he had had night sweats for some months. He also described worsening back pain for the last 2 years. Examination showed marked scoliosis.

White cell count was 12.2×10^9/dL, neutrophils 7×10^9/dL, CRP 43 g/dL and ESR 23 mm/hour. TST showed induration of 15 mm, IGRA was indeterminate. Culture of pus from the sinus showed no growth and acid-fast bacilli were not seen.

Technetium bone scan showed a lesion in the T12/L1 region of the spine, and in the left shoulder. MRI also showed multifocal spinal disease with collapse of the T12 vertebra. CT-guided biopsy of the spine was performed and culture grew a fully sensitive *M. tuberculosis*. Quadruple therapy of rifampicin, isoniazid, pyrazinamide, and ethambutol was started following the biopsy. This teenager also required a spinal brace and physiotherapy input before return to school and mobile activities.

Learning points:

- Tuberculous OAI may be chronic.

- Diagnosis may be challenging due to false-negative or equivocal IGRA or TST, and difficulty culturing the organism.

- Treatment is for at least 6 months and regular follow-up is required.

CHAPTER 100

Osteomyelitis

Jeremy Field and Neil Upadhyay

Epidemiology

The heterogeneity of osteomyelitis makes the true incidence in the United Kingdom unknown. Osteomyelitis resulting from bacteria spread via the bloodstream to bone is reported at between 10 and 100 per 100 000 in adults[1] and approximately 3 per 100 000 in children[2]; incidences in decline with rising living standards.

Osteomyelitis in adults more typically follows direct or contiguous spread of organisms to bone. Individuals sustaining open fractures, those who have undergone orthopaedic surgery, and those with systemic diseases such as diabetes, peripheral vascular disease, and rheumatoid arthritis have a greater prevalence of osteomyelitis than age- and sex- matched persons without such risk factors.[3–5]

Classification

Several classifications of osteomyelitis exist with none universally accepted. In general osteomyelitis is categorized as acute or chronic; the distinction is based on histological appearance rather than duration of infection. Acute osteomyelitis is defined by presence of inflammatory response cells. Persistent infection causes periosteal stripping, local ischaemia, and microvascular thrombosis. The result is tissue death. The presence of necrotic bone signals the end of the acute phase, independent of time.

The most accepted classification for osteomyelitis in adults is that of Cierny and Mader[6] (Table 100.1). It considers four anatomical stages of disease and emphasizes patient factors which influence both a hosts' response to infection and would-be treatments. Stages are interchangeable, altered by successful therapy, patient comorbidity optimization, or adjuvant treatments. Knowing the stage and host characteristic helps direct surgical treatment and correlates with prognosis.

Aetiopathogenesis

Bacterial inoculation of bone follows (1) haematogenous dissemination, (2) direct inoculation (open fracture, penetrating injury, surgery), or (3) contiguous spread from an adjacent infection (cellulitis, ulcer, infected prosthesis). Rarely adult osteomyelitis follows reactivation of earlier bone infection. The causative organism and pathogenesis will vary with patient age, immunosuppression, and mechanism of inoculation. All aetiological classes of osteomyelitis may progress to a chronic process.

Haematogenous osteomyelitis

The pathogenesis of haematogenous dissemination of microorganisms to bone varies with age. This reflects the differences in microbial causes for bacteraemia as a function of age.

Haematogenous spread to metaphyseal bone is the most common pathogenesis for osteomyelitis in healthy children. Their highly vascular bone with non-anastamosing capillary loops, prone to haemorrhage and infarction from minor trauma, can create a favourable environment for bacterial embolic settling. The growing ends of bone, in particular the distal femur and proximal tibia, are affected. In infants, concurrent septic arthritis is common; infection spreads from the metaphysis via transphyseal blood vessels to the epiphysis and then to the joint. At the age of 1 year the physis becomes avascular, limiting spread to the joint in older age groups.

Infection seeding to bone via the bloodstream is uncommon in healthy adults and unusual without an element of bone injury prior to inoculation. Adult patients with haematogenous osteomyelitis often have an underlying medical condition (Table 100.2). Osteomyelitis from haematogenous spread again typically affects metaphyseal bone but the metaphysis of long bones does not have the same predisposition for infection as seen in children; vertebrae and sternoclavicular and sacroiliac joints are often affected. Metaphyseal bone remains susceptible to infection since blood vessels make sharp angles that slow blood flow; this is particularly seen in venous sinusoids. The venous sinusoids additionally have reduced phagocytic activity, making them venerable to bacterial adherence and multiplication.

Haematogenous osteomyelitis is usually caused by a single pathogen. *Staphylococcus aureus* is far the commonest causative organism in children, accounting for more than 80% of cases. Groups A, C, and G β-haemolytic streptococcus and *Streptococcus pneumoniae* are also encountered in infants and children. *Haemophilus influenzae* is now not usually seen in the United Kingdom following introduction of conjugate Hib vaccination in childhood immunizations.[7] Group B streptococcal infection and enteric Gram-negative bacilli such as *E. coli* are seen in neonates.

In adults *S. aureus* is the common causative organism[8]; however, those with other medical comorbidities may have less common organisms isolated (Table 100.3). Staphylococcus species have numerous mechanisms to adhere to and invade into bone, and to survive within osteoblasts, allowing the bacteria to avoid contact with host defences and several antibiotic agents.[9]

Table 100.1 Cierney–Mader staging system. Patients' staging may be altered by successful therapy, host alteration, or treatment

Anatomical classification		Physiological classification	
Type I	Intramedullary osteomyelitis; nidus is endosteal, confined to intramedullary surfaces of bone, e.g. haematogenous osteomyelitis, infected fracture union following intramedullary nail stabilization	Normal physiological, metabolic and immunologic capabilities. Normal response to infection/surgery	Class A
Type II	Cortical bone osteomyelitis; infection limited to exterior of bone, e.g. infected fracture union with soft issue deficit; contiguous spread from decubitus or vascular ulcers	At risk of treatment failure due to local and systemic deficiencies predisposing to infection/poor wound healing (Table 100.2). Host reversal/optimization of comorbidities will improve outcomes to more closely parallel Class A patients	Class B
Type III	Cortical bone and marrow osteomyelitis; localized full thickness. Bone axially stable, e.g. infected fracture union following internal fixation	Poor physiological reserve. Morbidity of treatment greater than risk of disease or exceeds expected benefit. Palliative or non-curative therapy	Class C
Type IV	Circumferential involvement osteomyelitis; diffuse; axially unstable either before or after debridement, e.g. periprosthetic infections, infected non-unions		

There is increasing awareness of meticillin-resistant *S. aureus* (MRSA) in adults and this should be considered the infecting organism in high-risk patients (Box 100.1).

Direct inoculation and contiguous spread osteomyelitis

Infections following osteosynthesis or arthroplasty are rising in line with numbers performed. Rheumatoid arthritis has a higher incidence of delayed infection than osteoarthritis and is a significant factor in the late development of sepsis in arthroplasties.[10] Osteomyelitis from contiguous spread (overlying soft tissue infection or ulceration) is more common with diabetes and peripheral vascular disease becoming more prevalent.

Table 100.2 Systemic and local patient factors that affect the host's immunological, metabolic, and vascular response to an infecting organism

Systemic factors	Local factors
Diabetes mellitus	Arterial and venous insufficiency
Sickle cell disease	Chronic lymphoedema
Malignancy	Previous surgery
Extremes of age	Prosthetic material
Renal or hepatic failure	Extensive tissue scarring
Malnutrition	Neuropathy
Immune-modulating agents	Obesity
HIV/AIDS	Post-radiation fibrosis
Alcohol/parenteral drug abuse	
Chronic granulomatous disease	
Chronic hypoxia	

Chronic osteomyelitis is a progressive infection resulting in inflammatory destruction and necrosis of bone. It can become persistent as a result of inadvertent innate host immune responses to contain the infection, and bacterial adaptation regardless of patient's immune status. In an attempt to contain the infection host phagocytes generate toxic oxygen free radicals and release proteolytic enzymes which lyse surrounding tissue. Cytokines such as interleukin(IL)-1, IL-6, and tumour necrosis factor (TNF), released as part of the immune response, are potent osteolytic factors. In conjunction, some released metabolites such as prostaglandin E2 have the effect of decreasing the amount of bacterial inoculum required for infection.[11]

Chronic osteomyelitis is a biofilm infection.[12] Several bacteria (*S. aureus*, coagulase-negative staphylococci, and pseudomonas species), once attached to the surface of dead bone or prosthetic implants, produce a polysaccharide extracellular matrix within which colonies of microorganisms develop and mature. This biofilm microbial growth protects against natural host defences and antibiotic therapy. Although some antibiotics can penetrate the biofilm, the most effective treatment is surgical debridement.

Direct or contiguous infections tend to be localized and involve multiple organisms. *S aureus* predominates, but coagulase-negative staphylococci, pseudomonas species and enteric Gram-negative bacilli are all common,[13] especially in implant-related infections. Anaerobes such as clostridia may be involved following contaminated open fractures. *Pseudomonas aeruginosa* is the commonest infective organism from puncture wounds to the foot, particularly in diabetics.

Clinical features

In early stages of disease diagnosis is primarily clinical and often difficult, thus a raised index of suspicion is required particularly in certain patient groups (Table 100.2). History should identify conditions which predispose to infection, affect host response, and

Table 100.3 Potential aetiopathogen based on location of disease and patient characteristics

Location	Age/susceptibility factors	Organism
Haematogenous	Neonates	S. aureus, Group B streptococcus, enteric Gram-negative bacilli
	Children	S. aureus, Streptococcus pneumoniae, Group A,C, G, β-haemolytic streptococcus
	Adults	S. aureus (predominates unless comorbidities/post traumatic/ post surgery)
	Elderly	S. aureus, enteric Gram-negative bacilli
	Sickle cell disease	Salmonella, S. pneumoniae, Haemophilus influenzae
	Immunocompromised	S. aureus, fungi, Bartonella henselae, mycobacterium species
	IVDU	S. aureus, enteric Gram-negative bacilli, MRSA, PVL S. aureus
Post-traumatic	Open fractures	S. aureus, polymicrobial Gram-negative aerobic bacilli, anaerobes such as clostridia
Periprosthetic	Prosthesis	S. aureus, Staph. epidermidis, polymicrobial, streptococcus species, pseudomonas, enteric Gram-negative bacilli
Dependent areas	Decubitus ulcers	S. aureus, pseudomonas, streptococci, anaerobic bacteria
Vertebrae: 50% lumbar 35% thoracic 15% cervical	Elderly Urinary tract sepsis Immunocompromised IVDU	S. aureus (in all groups), enteric Gram-negative bacilli, pseudomonas, Mycobacterium tuberculosis (most common in thoracic spine), brucella (especially in S. America, Middle East, and Mediterranean), candida
Tarsal bones	Diabetes Peripheral vascular disease Puncture wound	S. aureus, Pseudomonas aeruginosa, streptococcus, enterococcus, coagulase-negative staphylococcus, enteric Gram-negative bacilli, anaerobes
Sternoclavicular joint	Indwelling devices	S. aureus
	IVDU	S. aureus, β-haemolytic streptococcus, enteric Gram-negative bacilli, P. aeruginosa, PVL S. aureus, MRSA
Anywhere	Human/animal bite	S. aureus, pasteurella, Eikenella corrodens
	HIV/AIDS	Aspergillus, Candida albicans, mycobacterium
Acute multifocal osteomyelitis	Skin disorders such as palmoplantar pustulosis	Negative bone cultures and spontaneous healing without specific treatment

IVDU, intravenous drug use; MRSA, methicillin-resistant *Staphylococcus aureus*; PVL, Panton-Valentine leukocidin Staphylococcus aureus.

Box 100.1 Factors associated with increased risk of MRSA infection

- History of hospitalization
- Surgery
- Dialysis
- Residence in long-term care facility
- Permanent indwelling catheter or percutaneous medical device
- Previous MRSA isolation from patient
- Intravenous drug user

---

ascertain the most likely aetiological organism based on presence or absence of certain risk factors (Box 100.1). Malignant and benign tumours, bone cysts, non-infected non-unions, and acute bone infarcts may present with similar symptoms to osteomyelitis.

Acute osteomyelitis, particularly in children, will present with systemic symptoms of bacteraemia as well as local tenderness, reluctance to use affected limb, increased swelling, temperature, and erythema surrounding the involved bone. Symptoms are a function of the host response to infection; thus in many adults with reduced immunity the response is variable and may, even in severe disease, be mild and difficult to localize.

Clinical manifestations of chronic osteomyelitis are often localized and, although they always involve surrounding soft tissues, can be subtle with minimal swelling, erythema, or raised temperature. Symptoms may follow an open injury, surgery, or skin ulcer. Infection could occur almost immediately, within days, or have a more insidious onset over weeks to months after injury, operation, or earlier infection. Patients may have indwelling prosthetic material and a history of preceding treatments to date. Longstanding poorly localized pain, deformity, axial instability, limb shortening, sinus tract, and chronic wounds overlying bone or surgical hardware may signify underlying infection. Bone may be seen or felt at the base of a deep ulcer or wound, a clinical finding highly predictive of underlying bone involvement.[14]

The arterial and venous system should be assessed and the limb examined for neuropathy.

Investigations

There are no specific blood tests to confirm osteomyelitis. In acute cases, acute-phase proteins such as white cell count, C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) will be raised but are often normal in chronic infection. If raised, monitoring CRP may help assess effectiveness of antibiotic therapy.[15] Doppler ultrasonography or angiography may be indicated if arterial or venous insufficiency is suspected.

Imaging

Anterior-posterior and lateral radiographs (including oblique views in the hand or foot) of the affected area should first be requested but may show no abnormality in early disease. It will take many days to weeks for radiographic findings such as periosteal reaction, periosteal lifting, cortical breaches, bone destruction, and involucrum to develop (Figures 100.1, Figure 100.2a). Initial radiographs will aid exclusion of differential diagnoses such as osteoporotic fracture or metastasis, identify implants, and complement later imaging tests. In chronic osteomyelitis osseous changes are apparent but some initial findings may also represent non-infective aetiologies such as bone healing following fracture or surgical sequelae; thus, further imaging may be required.

Fig. 100.1 Chronic osteomyelitis of femur. The inflammatory exudate (pus) spreads into the vascular channels raising the intraosseous pressure, slowing blood flow, and resulting in ischaemic necrosis of bone. The devascularized necrotic bone fragments may separate; these are known as sequestra (black arrow). New bone continues to form in response; the less dense area surrounding the sequestra (white arrow) is the involucrum.

CT is sensitive for bone destruction but again demonstrates little abnormality in early disease. CT is useful in chronic osteomyelitis prior to surgery for delineating bone disease.

MRI is highly sensitive and will detect early inflammatory changes of osteomyelitis within days of onset (Figure 100.2b).[16] Later in the disease it will demonstrate necrotic bone, abscess, sequestra and sinus formation, and define extent of tissue involvement. MRI has a low specificity differentiating osteomyelitis from other inflammatory conditions or normal postoperative changes, and may be limited from artefacts from metallic implants. It is therefore not helpful in assessing response to treatment.

Indium-111-labelled white cell scintigraphy can provide useful early information and is more specific than three-phase technetium-99m bone scan in identifying an area of infection. Isotope scanning is inferior to other forms of diagnostic imaging but may be useful in suspected prosthetic infections,[17] and can be used to evaluate response to treatment and confirm eradication of infection. Fluorodeoxyglucose positron emission tomography (FGD-PET) has been reported to have the highest diagnostic accuracy for confirming or excluding diagnosis of chronic osteomyelitis in the axial skeleton[18] but is not widely available.

Management of osteomyelitis

There are no set guidelines for antibiotic therapy. Each hospital has its own preferred regimes. Aetiological diagnosis is key since treatment success is directly related to knowledge of pathogen sensitivity.[19] Bacterial identification may come from multiple blood cultures, biopsy of affected area, or samples sent following surgical debridement. Cultured swabs or fluid from sinuses correlates poorly with underlying deep infective flora, and aspiration of deep fluid collections or percutaneous biopsies in chronic osteomyelitis may provide false-negative results since the organisms are distributed sparsely.[20] Most microbiological departments will only perform a standard microscopy, culture, and sensitivity (MC&S). If unusual pathogens are suspected from clinical history the microbiology department should be informed.

False-negative growth is common when empirical treatment is commenced prior to culture. In such situations histology will confirm the underlying infective process and exclude other pathological processes. The genome of many microorganisms is known and molecular detection methods such as polymerase chain reaction (PCR) can be used when standard methods do not confirm a causative organism. Mass spectrometry, pulsed field gel electrophoresis, and DNA pyrosequencing has improved pathogen detection and characterization and may well be the method of diagnosis in the future but is not universally accepted or available at present.[21,22]

Treatment of acute osteomyelitis

A combined focused antimicrobial and surgical approach should be considered in all cases of osteomyelitis; however, antimicrobial therapy alone may suffice for treatment of acute osteomyelitis in children and some adults diagnosed early. Patients with diabetic foot infections may require surgical debridement, but revascularization of the limb and appropriate antimicrobial therapy may be sufficient for healing to occur. Vertebral osteomyelitis without neurological symptoms is treated with antibiotic therapy alone. Empirical antibiotics can be commenced to cover clinically suspected pathogens after cultures are taken in acute cases (Table 100.4). Osteomyelitis

Fig. 100.2 This patient with type 1 diabetes presented with a 2 week history of swelling and erythema centred over third metacarpal of hand. He had sustained a penetrating injury several weeks prior that required no formal treatment. (a) Radiograph demonstrates periosteal reaction (black arrow) and lytic bone area (white arrow). (b) MRI (T2 fat-suppressed image) showing diffuse oedema within third metacarpal (white arrow) and swelling of surrounding tissue. A bone biopsy was taken which revealed *Staphylococcus aureus*. The patient was successfully treated with 14 days intravenous antibiotics followed by 28 days oral antibiotics.

Table 100.4 First-line intravenous/oral antibiotics for osteomyelitis in adults (comorbidities include diabetes, rheumatoid arthritis, immunocompromised, intravenous drug users)

Adults **without** comorbidities		Adults **with** comorbidities or vertebral osteomyelitis	
First-line IV/PO antibiotics	Penicillin allergy	First-line IV/PO antibiotics	Penicillin allergy or diabetic foot osteomyelitis
Samples to determine causative organism should be taken prior to commencement of antibiotics (multiple blood cultures/bone biopsy) In the absence of acute local or systemic upset there is no urgency to commence empiric antibiotic treatment		Multiple blood cultures should be taken prior to commencement of antibiotics	
Benzylpenicillin 2.4 g IV QDS *plus* Flucloxacillin 2 g IV QDS *plus* Sodium fusidate 500 mg[a] PO TDS *or* Rifampicin 600 mg[a] BD	Clindamycin 1.2 g IV QDS	Flucloxacillin 2 g IV QDS *plus* Sodium fusidate 500 mg[a] PO TDS *plus* Ciprofloxacin 750 mg PO BD	Clindamycin 1.2 g IV QDS[c] *plus* Ciprofloxacin 750 mg PO BD
If high risk for MRSA based on patient characteristics Teicoplanin 600 mg[b] IV OD after loading doses *plus* Fusidin 500 mg PO TDS *or* rifampacin 600 mg[a] BD			

BD, twice daily;IV, intravenous; PO, by mouth; QDS, four time a day; TDS, three times a day; MRSA, methicillin resistant *S. aureus*.
[a]Monitor liver function.
[b]Teicoplanin levels should be checked day 5: aim for serum levels 20–60 mg/litre.
[c]If concern about high levels of *Clostridium difficile* locally, consider teicoplanin.

arising from *Mycobacterium tuberculosis* is often successfully treated with multidrug antibiotic regimes but should be discussed with infectious disease or respiratory physicians (see Chapter 103) with surgery reserved for cases requiring bone stabilization or decompressive spinal surgery for neurological complications.

If appropriate, the limb should be elevated, splinted to rest the soft tissues, and comorbidities addressed. Targeted multidrug antibiotic therapy can be instituted once organisms and sensitivities are determined. There is no clarity on optimum duration of intravenous antibiotics. If the patient systemically improves, surrounding tissues settle and the causative organism identified with known sensitivities, antibiotic agents may be converted to oral. Two weeks of parenteral antibiotics followed by 4 weeks oral is often prescribed but this should be flexible depending on patient response to treatment. In some adults 72 hours of intravenous antibiotics may be appropriate, and often 24–48 hours is adequate in children, followed by the targeted oral agents.

Treatment of chronic osteomyelitis

Complex infections do not permit application of general algorithms and are best treated in dedicated centres. Treatment recommendations are based on expert opinion rather than randomized control trials. They broadly include limb salvage, amputation, and palliative treatment.

Patients require optimization of comorbidities. If indicated, vascular reconstruction prior to orthopaedic and plastic surgical intervention will prove beneficial in long-term results. If angioplasty or arterial bypass is performed surgical debridement should be delayed for up to 3 months to allow optimal reperfusion of tissues.

Limb salvage

Meticulous surgical debridement is required,[23] i.e. removal of the infected segment of bone, surrounding infected tissues or retained implants (such as plates, screws, and joint replacements). An oncologic approach—complete (i.e. wide) excision—is often adopted. Prosthetic material in situ should be considered colonized and a potential nidus for recurrence. That said, bones will heal in the presence of active infection provided stability is maintained. Well-fixed implants can be removed at a later stage.[24] Infected arthroplasties generally require immediate removal, commencement of treatments to eradicate infection, and staged revision. The exception is a stable implant and a known organism of lower virulence (such as coagulase-negative staphylococcus) in a patient with comorbidities that make further surgery high risk.

In patients with long-bone disease staged reconstruction may be required: In Cierny–Mader stage IV disease, and occasionally in stage III disease (Table 100.1), debridement results in a large bone and soft tissue defect. Appropriate management of this space is essential to prevent infection recurrence. Soft tissue and bone reconstruction should not be considered separate procedures, since complete and good-quality soft tissue cover is required to ensure survival of new callus formation.

Two methods widely used to bridge the bone defect are (1) insertion of a cancellous bone graft and (2) circular frame (Ilizarov/Taylor special frame) callus-distraction osteogenesis. The cancellous bone graft is a feasible method to bridge defects less than 6 cm in size, provided infection-free well-vascularized soft tissue cover is attainable and good contact between graft and living cancellous

bone is achieved.[25] This may be difficult to accomplish, thus the callus-distraction technique is the gold standard for bridging larger osseous defects provided there is sufficient bone to create a transport segment.[26] Bone is fractured at the proximal metaphysic (corticotomy) and the segment between the newly created metaphyseal fracture and defect is slowly transported through the defect left by debridement and later docked to the distal, disease-free bone. Growth of new bone (regenerated) follows the transported metaphyseal bone segment (Figure 100.3). The technique is labour intensive and requires extended periods of treatment (averaging 9 months). It can be combined with muscle flaps provided adequate preprocedure planning ensures that injury to the flap is avoided during bone transport.

In patients with comorbidities or those who will not tolerate prolonged reconstruction, acute shortening—i.e. removing osteomyelitis segment and immediately approximating the bone ends—is a reasonable option. The tibia can be shortened up to 4 cm, the femur 6 cm, and humerus 5 cm. An orthosis can later be prescribed to correct lower limb length discrepancy.

There is no consensus on optimum method of delivery or duration of antibiotics following surgery. Antibiotic-loaded spacers can be used on occasions to deliver high concentrations of antimicrobial therapy between reconstructive operations. Four to six weeks of parenteral therapy has become the standard.[27] The rationale behind this regime is recognition that bone takes 3–4 weeks to revascularize. Many centres will continue oral antibiotics for a further 6 weeks after parenteral therapy. In one-third of cases, no organisms are identified thus postoperative antibiotic regimes need to cover *S. aureus* and other probable pathogens based on patient characteristics (Table 100.3).

Amputation or palliative treatment

In a subgroup of patients with chronic infection and concomitant systemic disease, intervention will not alter prognosis. Persistent infection, pain, deformity, and even chronic suppuration are not absolute indications for treatment. These patients may benefit from amputation or disease-controlling measures such as limited debridements/evacuation of collections and long-term suppressive antibiotic therapy. Amputation does not guarantee eradication of infection.[28]

Prognosis

Prognosis depends on the number of risk factors, duration of infection before treatment, and the patient's overall health. The different aetiologies require differing medical and surgical strategies but early diagnosis and appropriate intervention in an otherwise well or fully optimized patient should lead to recovery.

Dedicated units treating complex chronic cases report 98% infection-free patients at 2 years, falling to 92% at 4 years and 90% at 8 years. Recurrence of disease may occur early (shortly after stopping antibiotics) or late. The tendency for infection to relapse sometimes years after apparently successful therapy suggests remission (or arrest) rather than cure of treated osteomyelitis. Outcome is related to host type. A review of 2207 patients treated over a 26 year period showed primary treatment to be successful in 96% of healthy patients (success defined as infection free at 2 year follow-up); this success rate fell to 73% in patients classed to have local and systemic comorbidities.
Fig. 100.3 The radiographs and illustration from left to right show the process of bone transport with use of a ring fixator to treat a bone defect following debridement of infected bone. (a) The 3 cm defect following debridement is seen (grey arrow). A corticotomy is made proximally at the metaphysis (grey striped arrow). (b) the segment between is transported down in the direction of black arrow to docking site of the distal tibia. The regenerate (grey crossed arrow) is what follows behind the corticotmy. (c) The same tibia following successful treatment (red arrows show remodelled segments).

Lyme borreliosis

Andreas Krause and Volker Fingerle

Definition

Lyme borreliosis (LB) is an infectious disease endemic in the northern hemisphere with a broad spectrum of clinical manifestations mainly affecting skin, joints and nervous system. The causative agent of LB, *Borrelia burgdorferi sensu lato*, is transmitted by hard ticks belonging to the *Ixodes ricinus/I. persulcatus* complex. Most cases heal completely, either spontaneously or after antibiotic therapy. Only rarely does the pathogen persist chronically or, by infection-triggered immunopathological mechanisms, does a chronic Lyme arthritis occur.

Epidemiology

LB occurs in a belt-like area between 40° and 60°N latitude around the world, corresponding to the abundance of vector-competent hard ticks, *I. persulcatus and I. scapularis* in North America, *I. ricinus* in Europe, and *I. persulcatus* in Asia. The highest incidences are reported from the north-eastern United States and central/eastern Europe (300 cases/100 000 or more). The rate appears to have increased significantly over the past 10–20 years, although this observation may be due mostly to increased awareness, advanced reporting, and improved diagnosis of the disease. Antibodies against *B. burgdorferi* can be detected in about 5–25% of healthy adults (rate of subsided infection or seroprevalence), depending among other things on age, region, and risk of exposure. The rate of infected ticks varies broadly but is usually 10–30%. The risk of being infected with *B. burgdorferi* by a tick bite varies considerably and is entirely dependent on the local tick infection rate and duration of the tick bite.[1,2]

Aetiology and pathogenesis

B. burgdorferi sensu lato refers to a heterogeneous group of highly mobile spirochaetes, of which at least five genospecies can cause LB in humans in Europe: *B. burgdorferi sensu stricto*, *B. garinii*, *B. afzelii*, *B. bavariensis*, and *B. spielmanii*. The pathogens differ, among other things, by their geographical distribution (in the United States, only *B. burgdorferi sensu stricto* has been found so far; Europe is dominated by *B. garinii* and *B. afzelii*), their adaptation to different hosts and, which is clinically significant, by the preferred affliction of different organ systems (organotropism). Although all five genospecies may be pathogens causing erythema migrans (EM),

B. burgdorferi sensu stricto preferably affects joints. Acrodermatitis chronica atrophicans (ACA) is, in the vast majority of cases, caused by *B. afzelii*, and *B. spielmanii* has been isolated only from skin so far. This organotropism of the pathogen is not absolute, but it at least partially explains the various clinical manifestations and different forms of disease.[3]

The pathogen is transmitted during the blood meal of infected ticks. In this, the tick and the borrelia both experience complex processes of adaptation until the pathogens may emigrate from the midgut of the ticks, invade the salivary glands, and finally infect the host via the saliva.[4] The best-studied example is the differential expression of the surface proteins (Osp) OspA and OspC of *B. burgdorferi*. OspA is the dominant surface protein in the tick that has not yet sucked, with which it anchors to the intestinal wall by a receptor that is primarily upregulated in the intestines of infected ticks. During the act of sucking, OspA is downregulated and OspC is upregulated, which allows borrelia to disseminate into the salivary glands. There, OspC binds the tick saliva protein Salp15 that, among other things, suppresses the antibody-mediated killing and the activation of CD4+ T cells in the host. Therefore, after the start of a tick bite it usually takes several hours until successful pathogen transmission can take place.[4,5]

In the skin, the spirochaetes spread locally at first, which is noticeable as the typical centrifugal expansion of the EM. Haematogenous and probably also lymphogenous spreading of the pathogens with colonization of various organs may occur even in the first days of the infection. Clinical manifestations of LB are thus the expression of a direct infection of the respective organ at first. The observation that on the one hand, infections can also be asymptomatic and that on the other hand, a few pathogens can cause a severe inflammatory reaction, demonstrates the importance of the host immune response and the pathogen–host interaction in the pathogenesis of the disease.

Relatively little is known about the natural course of borrelia infection in humans. In every phase of the infection or disease, spontaneous healing of the disease can occur even without antibiotic therapy. On the other hand, *B. burgdorferi* can persist in the host for many years despite an intense immune response. Among other things, the pathogen protects itself by escaping to immunologically privileged sites, complement resistance, and change in the antigen structure against the elimination by the immune system. It is possible that this pathogen persistence is not associated with symptoms in every case.[5]

B. burgdorferi has several mechanisms for spreading in the host after transmission and escaping attack by the immune system. These include the corkscrew-like motion (rotation around the longitudinal axis) by endoflagella; the expression of numerous proteins interacting with the extracellular matrix such as plasminogen-binding proteins, fibrinogen-binding protein BBK32, decorin-binding proteins A and B, integrin-binding protein p66, and the glycosaminoglycan-binding protein Bgp. Erp (OspE-related) and CRASP (complement regulator-acquiring surface proteins) that bind factor H and factor H-like protein I, inhibit complement activation depending on the species (*B. afzelii* is resistant to complement, *B. garinii* is sensitive to complement); and also the formation of the membrane attack complex as well as opsonization for complement-dependent phagocytosis and the mortification of the pathogens. The differential expression and true antigenic variation of surface proteins, especially of the *vlsE* gene products, impair an effective specific immune response.

The non-specific immune response is stimulated in particular by surface lipoproteins of *B. burgdorferi*. By binding to Toll-like receptors, especially TLR 2/1 and TLR 2/6 heterodimers, activation of macrophages and initiation of an inflammatory reaction with release of proinflammatory chemokines and interleukins including IL-17 occurs. At the same time, the specific humoral and cellular immune response is activated, which is characterized by a predominant Th1 response and a relatively slowly developing antibody formation.[5]

Adequate antibiotic therapy usually results in pathogen elimination and healing of the infection. Nevertheless, there are a few patients with Lyme arthritis who have lasting joint symptoms despite repeated antibiotic therapy. In the United States, this applies to an estimated 10% of patients; Europe does not have good epidemiological data for this. The immunopathogenesis of this so-called 'antibiotic-resistant' Lyme arthritis is still poorly understood. Available results argue against pathogen persistence as a cause, without being able to exclude it completely. Infection-triggered immunological mechanisms are suspected instead. The association of antibiotic-resistant cases with antibody formation against OspA and certain *HLA DRB1* alleles binding the OspA$_{163-175}$ peptide led to suspicions of an immunological cross-reaction, e.g. with homologous human LFA-1 structures as a cause. However, further studies could not confirm this autoimmune hypothesis and rather indicated that the prolonged immune response may be adequate and targeted against persistent antigens. Recent studies suggest that a Th17 response induced via NapA (neutrophil-activating protein A) could play a crucial role in the pathogenesis of Lyme arthritis. The question of which immunological mechanisms lead to chronic Lyme arthritis (which, ultimately, heals spontaneously within a few years) thus remains unclear.[5]

Clinical picture

The manifestations of the disease are individually variable and can heal spontaneously in every phase of the disease or can be brought to healing by appropriate antibiotic therapy.

Clinically proven is the division of LB into an early phase (early localized and early disseminated) and a late phase (persisting infection) with different clinical pictures and a varied response to antibiotic therapy (Table 101.1).[1,2,6,7]

The EM, by far the most common clinical manifestation of LB, starts with a latency of 2–30 (mean 7–14) days at the site of the tick bite as a reddish-livid, only rarely pruritic, painless erythema. The characteristic ring shape with a central papule (site of the tick bite) may develop over time by central healing. After dissemination of the pathogen, multiple EM or the borrelial lymphocytoma (lymphadenosis cutis benigna Bäfverstedt) may occur as further early skin manifestations. The late borreliosis of the skin, ACA, most frequently affects the extremities and starts as a bluish-livid inflammatory process of the skin with oedematous swelling. The atrophy of skin and subcutaneous fat tissue occurs only in the further course of the disease, which may last for many years. The ACA is often associated with arthropathies and polyneuropathies in the area of the affected skin.[2,67]

Early neuroborreliosis develops as the second most common manifestation of LB after an average incubation period of 3–6 weeks. The typical manifestation is the Garin–Bujadoux–Bannwarth meningoradiculoneuritis with nocturnally more pronounced pseudoradicular pain and cranial nerve pareses, most frequently affecting the facial nerve (one or both sides). Especially children show marked symptoms of meningitis. Late manifestations involving the central nervous system with myelitis, encephalitis, or encephalomyelitis are very rare but usually take a chronic course. Vasculitides in the area of the central nervous system are very rare.[1,2,8]

Lyme carditis is observed in less than 5% of patients and can lead to variable degrees of atrioventricular (AV) blocks with dizziness, palpitations, or syncopations. An involvement of other internal organs is possible but usually without clinical significance.[1,2,6]

Rheumatological symptoms may occur relatively early in the disease, i.e. within a few weeks after infection, as arthralgias, myalgias, or mild, transient arthritides of individual joints. However, the typical Lyme arthritis manifests itself in the late phase of the disease, i.e. several weeks to months after pathogen transmission.

The arthritis usually starts as a monoarthritis or oligoarthritis that is intermittent at first, later persistent. In 85% of these cases, at least one knee is affected. The ankle and elbow joints may be involved as well, while an affliction of the finger joints, especially in the form of a polyarthritis, is practically never observed. Also, an involvement of the sacroiliac joints or the spine does not occur in Lyme arthritis. Analysis of the synovia in acute arthritis shows significantly increased cell numbers of up to 50 000/μL with a predominance of neutrophils. Concomitant manifestations in the locomotor system are bursitides and tenosynovitides. Aside from the myalgias particularly observed in early phases, the late Lyme borreliosis can lead in rare cases to a manifest, proximally more pronounced myositis with muscle weakness and muscle atrophies.[1,2,6,7,9]

Diagnostics

The tentative diagnosis of LB is always made based on the clinical symptoms at first; laboratory diagnostics then serve to substantiate the diagnosis. Aside from the skin manifestations of LB, which can often be diagnosed clinically, the symptoms are often ambiguous and require the exclusion of differential diagnoses (Tables 101.2–101.4) For the diagnosis of neuroborreliosis, cerebrospinal fluid diagnostics with detection of pleocytosis and autochthonous antibody production should always be performed. Without direct pathogen detection in the joint, Lyme arthritis can be diagnosed with sufficient certainty only after appropriate differential diagnostics and under observation of the diagnostic criteria.

Table 101.1 Clinical manifestations in Lyme borreliosis

Organ system/stage of illness	Manifestations	Commentary
Non-specific symptoms		
Early stage	Malaise, headache, low fever, arthralgias, myalgias, swollen lymph nodes	May be severe, no respiratory or gastrointestinal symptoms
Late stage	See early stage	Mostly less pronounced
Skin		
Early stage	Erythema migrans	Expanding, not markedly elevated erythematous skin lesion (>5 cm largest diameter), with or without central clearing, distinct edge. 2–30 days after tick removal. Often seronegative. Multiple lesions (disseminated form) more often in the USA
	Borrelial lymphocytoma	Rare. Painless bluish-red node or plaque, predelection site: ear lobe or scrotum in children, on or near the nipple in adults
Late stage	ACA, not present in the USA	Mainly extensor site of extremities. After initial oedematous swelling, long standing red to bluish-red lesion, later on skin atrophy. Sometimes polyneuropathy, juxta-articular fibroid nodes and skin induration. Chronic course
Nervous system		
Early stage	Meningoradiculitis (Bannwarth syndrome; Europe), meningitis predominantly USA Rare: CNS manifestations, vasculitis	Bannwarth: painful radiculitis that typically exacerbates at night, cranial nerve pareses (mostly facial nerve). Signs of meningitis
Late stage	Meningitis, myelitis, encephalitis, encephalomyelitis, peripheral neuropathy	Very rare, chronic course. Mostly encephalitis and/or myelitis with spastic syndrome, spastic-atactic gait disorder, micturition. Encephalopathy with cognitive disturbance or isolated PNP described in the USA. In Europe PNP only in association with ACA
Heart		
Early stage	Myopericarditis	Rare, typically atrioventricular block of varying degree, usually total recovery
Late stage	Chronic cardiomyopathy, ventricular extrasystolia	Questionable, single cases
Musculoskeletal		
Early stage	Arthralgia, myalgia	Sometimes transient arthritis
Late stage	Arthritis, myositis, bursitis, enthesitis	Initially intermittent, later on persistent arthritis of large joints, mostly affecting the knee, no axial involvement, myositis rare
Other		
Early stage	Conjunctivitis, uveitis anterior und posterior, papillitis, episcleritis	Rare, chorioiditis characteristic, may result in persisting visual loss
	Hepatomegaly, hepatitis, splenomegaly	Usually not clinically relevant
Late stage	Vasculitis	Rare, may result in ischemia

ACA, acrodermatitis chronica atrophicans; CNS, central nervous system; PNP, polyneuropathy.

Detection of pathogens by culture and polymerase chain reaction

Suitable materials are skin biopsies, cerebrospinal fluid, synovial fluid, and synovial membrane. The cultivation of *B. burgdorferi* is very time consuming (6 weeks or more) and is offered by only a few laboratories. Polymerase chain reaction (PCR) can quickly and sensitively detect borrelial DNA, but should be interpreted with caution. It is crucial that a positive result is verified regarding specificity (e.g. by sequencing or probes), which typically allows precise identification of the detected species. The diagnostic sensitivity of PCR and culture averages 50–70% in case of skin biopsies (EM or ACA) and 10–30% in case of cerebrospinal fluid from patients with early neuroborreliosis. PCR can detect borrelia DNA in the joint fluid of 50–70% of patients with Lyme arthritis, while detection by culture extremely rarely succeeds here.[2,3,6,8,10]

Serology

Serological testing should be requested exclusively in case of sufficient clinical probability (≥20%), otherwise the positive predictive value of a positive test result is too small. If an examination is performed for a suspected late manifestation, however, the negative

Table 101.2 Diagnostic criteria for Lyme arthritis

Clinical criteria		Laboratory criteria	
Essential	**Supporting**	**Essential**	**Supporting**
Mono- or oligoarthritis of large joints (predominantly knee, also ankle, elbow, shoulder) Exclusion of differential diagnoses, no axial involvement	Other Lyme borreliosis manifestations or tick bite in patient´s history	Detection of *B. burgdorferi*-specific IgG antibodies (typically high titre) Synovial fluid (if obtainable) with neutrophilic pleocytosis	Detection of *B. burgdorferi* from synovial fluid or tissue by PCR or cultur

predictive value is very good, especially if there are only unspecific symptoms.

For the detection of antibodies, a sensitive immunoassay (EIA) is used as a screening test. Positive results are confirmed by immuno-blot to exclude unspecific reactions or cross-reactions. Especially in the early phase of LB, the serology can often still be negative. As a rule, specific IgM antibodies increase within 3 weeks after patho-gen transmission, while IgG antibodies may be detected approxi-mately 3 weeks later. In late manifestations, significantly elevated IgG antibody levels are usually found. An IgG-negative result there-fore excludes a late manifestation of LB with high probability. IgM antibodies are in suspected late manifestations without diagnostic value.

With suspected neuroborreliosis, the diagnosis can be confirmed by demonstrating a lymphocytic pleocytosis, protein elevation, and intrathecal *B. burgdorferi*-specific antibody production in the cer-ebrospinal fluid.

As a rule, serological follow-up examinations after antibiotic therapy of an LB do not result in relevant findings. The success of the therapy can only be seen clinically. Neither the persistence of specific IgM antibodies nor IgG antibodies alone justify further therapeutic measures.[2,3,8,10]

Methods not to be recommended for diagnostics

Among the non-evaluated and therefore not recommended tests are antigen tests from bodily fluids, PCR from urine or ticks, the detection of a decreased CD57+/CD3− lymphocyte subpopulation, the lymphocyte transformation test (LTT), HLA-DR subtyping, the

detection of so-called 'cystic forms', dark field microscopy, and the visual contrast sensitivity test (VCS).[2,38]

Therapy

Antibiotic treatment should be initiated as soon as possible after diagnosis, to shorten the course of the disease and to prevent the development of further manifestations or a chronic disease process. The treatment is stage-oriented and symptom-oriented. Doxycycline, amoxicillin, and ceftriaxone are the drugs of choice. Development of resistance to these antibiotics has not yet been proven, but *B. burgdorferi* shows primary resistance to numer-ous substances including gyrase inhibitors and sulfonamides. The therapy recommendations summarized in Table 101.5 are essen-tially the same as the recommendations or guidelines supported by numerous medical societies.[2,8,11,12]

Course and prognosis

In the early phase, one treatment cycle virtually always leads to healing of the disease. After antibiotic treatment of late manifesta-tions, it is often only in the course of several weeks or months that a gradual remission is seen, so that it frequently takes several months until the therapeutic success can be assessed. It is important to note that new manifestations of the disease do not occur after antibiotic therapy.

Severe courses of LB and only partial recoveries have been described, especially involving the central nervous system and the

Table 101.3 Differential diagnosis in Lyme borreliosis (important examples)

Erythema migrans	Insect-bite reaction, erysipelas, tinea, erythema anulare centrifugum, initial morphea, granuloma anulare, parvovirus B19 infection in children
Lyme carditis	Other (mainly viral) infections, coronary disease, non-infectious systemic diseases
Neuroborreliosis	Viral infections (e.g. tick-borne encephalitis), herpes zoster (pre eruption), spinal disc herniation, periarthropathia humeroscapularis, cervicobrachialgia, neoplastic infiltration, Guillain–Barré syndrome, multiple sclerosis
Borrelial lymphocytoma	Insect-bite reaction, foreign body granuloma, gynaecomastia, lymphomas and pseudolymphomas
Acrodermatitis chronica atrophicans	Chronic venous insufficiency, morphea, scleroderma, cortisone side effect, frostbite, erythromelalgia, acrocyanosis, skin atrophy
Lyme arthritis	Gout, pseudogout, septic arthritis, Löfgren´s syndrome, viral arthritis, psoriatic arthritis, reactive arthritis, enteropathic arthritis, rheumatoid arthritis (atypically beginning)

Table 101.4 Recommendations for a diagnostic approach

Tentative diagnosis	Antibody detection (serology)	Sensitivity	Puncture or biopsy for PCR/culture	Sensitivity
Early manifestations				
Erythema migrans	Only in atypical cases: immediately and follow up[a]	20–50%	Only in atypical cases: skin biopsy	50–70%
Borrelial lymphocytoma	Essential. If unclear, follow up[a]	70–90%	Skin biopsy; also for histology	?
Early neuroborreliosis (Bannwarth, meningitis, etc.)	Essential. CSF/serum pair. Demonstration of intrathecal specific antibody synthesis and signs of CSF inflammation. If unclear, follow up[a]	70–90%	CSF	10–20%
Late manifestations				
Lyme arthritis	Essential. Detection of specific IgG antibodies and usually broad spectrum of bands in the IgG-immunoblot in serum	90–100%	PCR from synovia or synovialis, positive culture extremely rare; joint aspiration diagnostics incl. cell count and differentiation	50–70% (only PCR)
Acrodermatitis chronica atrophicans	Essential detection of specific IgG antibodies and broad spectrum of bands in the IgG-immunoblot in serum	90–100%	Skin biopsy; also for histology	50–70%
Late neuroborreliosis	Essential. CSF/serum pair. Demonstration of intrathecal specific IgG antibody synthesis and signs of chronic CSF inflammation	90–100%	PCR and culture from CSF typically negative	

CSF, cerebrospinal fluid; PCR, polymerase chain reaction.
[a]Question: Seroconversion, significant rise in titre.

Table 101.5 Recommended antimicrobial regimens for treatment of patients with Lyme borreliosis for adults

Manifestation	Drug	Dosage per day	Duration, days (range)	Strength of recommendation
Erythema migrans	Doxycycline	1 × 200 mg or 2 × 100 mg PO	10–21	A
	Amoxicillin	3–4 × 500–1000 mg PO	14–21	
	Cefuroxime	2 × 500 mg PO	14–21	
	Azithromycin[a]	500 mg PO	7–10	
		or 2 × 500 mg day 1, 500 mg days 2–5	5	
Neuroborreliosis[c]	Ceftriaxone	1 × 2 g IV	14–21	A
	Cefotaxime	3 × 2 g IV	14–21	
	Penicillin G	4 × 5 MU IV	14–21	
	Doxycycline[b]	200–300 mg PO	14–21	
Carditis[d]	Ceftriaxone	1 × 2 g IV	14	D
	Cefotaxime	3 × 2 g IV	14	
	Penicillin G	4 × 5 MU IV	14	
Arthritis, acrodermatitis chronica atrophicans	Doxycycline	1 × 200 mg or 2 × 100 mg PO	30	B
	Amoxicillin	3 × 500–1000 mg	30	NA
	Ceftriaxone	1 × 2 g IV	14–21	NA
	Cefotaxime	3 × 2 g IV	14–21	

IV, intravenous; PO, oral; MU, mega units; NA, not available..
[a]Only for patients intolerant to doxycycline, amoxicillin, and cefuroxime.
[b]Only in uncomplicated cases; possibly 300 mg/day needed.
[c]For late neuroborreliosis IV therapy for 14–28 days.
[d]In first-degree atrioventricular block and PR <30 ms oral therapy for 14–21 days.

locomotor system, but fortunately are rare. Thus, LB is a serious disease with potentially grave organ manifestations, but generally with a benign course especially if it is detected and treated early.

While a *B. burgdorferi* infection, on the one hand, frequently takes a self-limiting course, the pathogen, on the other hand, may in rare cases persist for many years and cause a prolonged disease course. This is particularly true for the chronic neuroborreliosis with involvement of the central nervous system, as well as the ACA. These diseases usually heal only after thorough antibiotic therapy and in part with irreversible organ defects. This may also be true for Lyme arthritis, which can take a course over many years if left untreated. Rarely, it may persist for years—chronically—despite repeated courses of antibiotic treatment. This so-called treatment-resistant Lyme arthritis is presumably caused by infection-triggered immunopathological mechanisms. However, also these chronic arthritides most often slowly regress, but sometimes only after several years.

Clearly to be distinguished from these well-defined clinical courses of LB are patients who fear they are suffering from chronic LB because of unspecific symptoms and positive (sometimes even despite of negative) serology. These are particularly the patients who report persisting symptoms after antibiotic therapy of a confirmed LB in the sense of a so-called 'post-Lyme syndrome'. Despite a clear improvement of objective clinical signs these patients frequently complain about fatigue, impaired concentration, headaches or arthralgias and myalgias.[2,6,13,14] These symptoms can usually be assigned to a prolonged convalescence after successful therapy. Therapy studies, including those from Europe, show that the regression of symptoms especially of late manifestations can take weeks to months and that the success of therapy can be fully evaluated only after several months. Residuals of the disease persisting over longer time periods or only partial recoveries after antibiotic treatment are possible but rare.

Many patients also tend to assign new symptoms to the past LB. As the serology in these patients remains positive and does not permit a statement on the success of therapy, and furthermore direct pathogen detection or exclusion of infection is not possible with certainty, many fear that the past therapy was not sufficient. Follow-up studies, however, show that most symptoms reported after treated LB do not occur more frequently than in control groups without a history of borreliosis, aside from mild neurological residuals such as facial nerve weakness after acute neuroborreliosis or arthralgias after Lyme arthritis. Moreover, it could be demonstrated that an intensive antibiotic therapy over 90 days remains without effect in this situation as well. There are many indications that these are unspecific symptoms unrelated to LB that are not an expression of pathogen persistence and thus do not respond to antibiotic therapy.[12,15]

Aside from this, there is a large group of patients seeking help who never had certain symptoms of LB but ultimately only a 'seroprevalence titre' as evidence of a previous infection. For various reasons, these often desperate patients are convinced that they suffer from chronic LB. The need to explain the symptoms (for patients and their doctors), lack of knowledge about the actual course of the disease, uncontrolled misinformation such as can be found on the internet,

and the behaviour of some self-appointed borreliosis specialists with in part dubious, self-developed, and unevaluated diagnostic and therapeutic regimens, are only a few reasons contributing to this development.[13] The response of some symptoms to antibiotics, though usually only short-term and incomplete, seems to further support the tentative diagnosis. However, this 'treatment response' is usually due to non-specific effects of the drugs and to placebo effects. Numerous scientific studies argue unequivocally against the hypothesis that these patients suffer from LB, especially since there is no evidence for pathogen persistence and since even the most intensive antibiotic therapies are unsuccessful in the long term.

CHAPTER 102

Viral arthritis

Stanley J. Naides

Introduction

Viruses may affect the joints by a number of mechanisms. The mechanisms employed vary with the infecting virus based on mode of tissue entry, tissue tropism, mechanisms of replication, direct viral effects on cellular functions, the ability to establish persistent infection, local immune response, expression of host-like antigens, ability to alter host antigens, host age and genetic makeup, and the infection history of the host. Several viruses directly infect the cells of the synovium. The mechanism of injury may be through lysis of target cells. The target cells may die by one of three mechanisms. First, viral infection may result in classic cell necrosis with karyorrhexis. Second, the virus may initiate the cellular machinery for programmed cell death, or apoptosis. Third, the virus may express virally encoded cell surface antigens that elicit an immune response, that in turn targets killing of virally-infected cells.

Direct infection may also result in non-lytic mechanisms of viral arthritis pathogenesis. Viruses may coopt normal cell functions in such a way as to alter normal cell function. Viral gene products may transactivate host cell genes. Immune activation may result from cell surface expression of normally sequestered autoantigens or viral antigens or virally encoded cytokines. The infected cell would become a target for immune attack or the focus of recruitment of cytokine responsive cells. Viral infection leading to expression of viral antigens on the cell surface may serve as a novel foreign antigen and elicit an immune response. Alternatively, molecular mimicry of host autoantigens may break immune tolerance, resulting in generation of autoimmune responses. Immune complex disease may result when the humoral response generates sufficient antibody to cause deposition of immune complexes either locally, at the site of viral infection, or systemically with deposition of circulating immune complex in synovium.

Parvovirus B19

Human parvovirus B19 is a member of the family *Parvoviridae*, genus *erythrovirus*, consisting of parvoviruses autonomously replicating in erythroid precursors. B19 is a non-enveloped, single-stranded DNA virus measuring approximately 23 nm in diameter. Although infection of other tissue types may occur, viral replication is usually not as efficient in cells other than erythroid progenitors.

Epidemiology

B19 infection is common and geographically widespread. Seroepidemiological studies of community outbreaks of B19 infection demonstrate that a large proportion of B19 infections remain asymptomatic or present as undiagnosed non-specific viral illnesses. Approximately 50% of the general adult population has serological evidence of past B19 infection. Outbreaks of B19 infection occur in late winter and spring, although epidemics have also been reported in summer and autumn. Within a community, B19 outbreaks tend to cycle every 3–5 years, representing the period of time for a fresh cohort of susceptible children to enter the school system. Since the seroprevalence of anti-B19 IgG antibodies is only approximately 50% in adults, these periodic outbreaks often involve susceptible adults as well. The risk of infection in susceptible adults with multiple exposures may be as high as 50%. Workers in occupations with increased exposure to children, such as schoolteachers, daycare workers, and hospital personnel, have increased risk of infection.[1] Sporadic cases occur between outbreaks. Transmission is via nasopharyngeal secretions.

The incubation period between infection and onset of symptoms is 7–18 days. In human volunteer studies, introduction of B19 nasally was followed in 7 days by a flu-like illness associated with viraemia, viral shedding in nasal secretions, and areticulocytosis. At approximately 11 days after infection, an incipient anti-B19 IgM antibody response was associated with clearing of viraemia, cessation of nasal shedding of virus, and a second phase of clinical illness characterized by rash, arthralgia, and arthritis. Onset of the anti-B19 IgG antibody response occurred almost concurrently with the IgM response.[2] In natural infections, the temporal separation between the two phases of clinical illness is often blurred.

Additional B19-like viruses have been isolated and represent genotypic variants of the original B19 isolates, now designated genotype 1 and found worldwide. Genotype 2 consists of A6, LaLi/K71, and Vx strains. Genotype 3 consists of the V9 virus and related isolates. Protein homology between genotypes is 96–97% and no antigenic differences have been identified. Genotypes have similar biological behaviour and clinical presentations.

Clinical features

B19 is the cause of transient aplastic crisis in the setting of chronic haemolytic anaemia.[3] B19 causes erythema infectiosum, or fifth disease, a common rash illness of children characterized by bright red

Fig. 102.1 Classic 'slapped cheeks' of a child with erythema infectiosum, or fifth disease, caused by parvovirus B19.

'slapped cheeks' and a macular, maculopapular, and occasionally vesicular or haemorrhagic eruption on the torso and extremities (Figure 102.1). While infection in children may be asymptomatic, when symptoms do occur they tend to be mild and include sore throat, headache, fever, cough, anorexia, vomiting, diarrhoea, and arthralgia. Erythema infectiosum may also be seen in adults not previously infected. In adults, the rash tends to be subtler and the bright red 'slapped cheeks' absent. A number of uncommon dermatologic manifestations of B19 infection have been reported including a vesiculopustular eruption, purpura with or without thrombocytopenia, Henoch–Schönlein purpura, and a 'gloves and socks' erythema.

B19 infection may be associated with paraesthesias in the fingers. Rarely, progressive arm weakness has occurred, as has numbness of the toes. In such instances, nerve conduction studies show mild slowing of nerve conduction velocities and decreased amplitudes of motor and sensory potentials.[3]

B19 may infect the fetus, causing hydrops fetalis on the basis of either B19-induced anaemia or viral cardiomyopathy. B19 has been reported to less commonly cause pancytopenia, isolated anaemia, thrombocytopenia, leucopenia, myocarditis, neuropathy, hepatitis, or vasculitis.[3,4] Patients with congenital or acquired immune deficiencies, including prior chemotherapy for lymphoproliferative disorders, immunosuppressive therapy, or AIDS may fail to clear B19 infection, causing chronic or recurrent anaemia, thrombocytopenia, or leucopenia. B19 infection is the leading cause of pure red cell aplasia in AIDS patients.

Among B19-infected immunocompetent children under 10 years of age, arthralgia may occur in about 5% and joint swelling in only approximately 3%. In adolescents, joint pain and swelling occurs in about 12% and 5%, respectively. However, joint pain occurs in about 77% and joint swelling in 60% of adults 20 years of age or older.[5] In adults, B19 infection may be associated with a severe flu-like illness in which polyarthralgia and joint swelling are prominent. The distribution of involved joints is rheumatoid-like with prominent symmetric involvement of the metacarpophalangeal, proximal interphalangeal, wrist, knee, and ankle joints. Patients usually experience sudden-onset polyarthralgia or polyarthritis.

Onset of joint symptoms may or may not be preceded by a viral prodrome consisting of fever, malaise, chills, and myalgias. Most adults present with acute, moderately severe, symmetric polyarthritis that usually starts in the hands or knees and within 24–48 hours spreads to include the wrists, ankles, feet, elbows, and shoulders. Spinal involvement is uncommon. Joint symptoms in adults are usually self-limited, but a minority of adults have prolonged symptoms. Of those with chronic symptoms, approximately two-thirds have continuous symptoms of morning stiffness and arthralgia with intermittent flares. The remaining one-third are symptom free between flares. Morning stiffness is prominent. Rheumatoid factor may be present in low to moderate titre during the acute phase of infection but usually resolves.[6] Anti-DNA, anti-lymphocyte, anti-nuclear antibodies, and anti-phospholipid antibodies may also be found acutely. Joint erosions and rheumatoid nodules have not been reported. Chronic B19 arthropathy may last for years. Several weeks after the initial infection, symptoms of acute synovitis tend to resolve. Joint pain and stiffness remain prominent features in patients who continue to have symptoms. Approximately 12% of patients presenting with 'early synovitis' have B19-induced rheumatoid-like arthropathy, the majority of whom are women.[3] Adults usually lack the classic slapped-cheek rash seen in children.

The distribution of joint involvement in B19 arthropathy and its symmetry may suggest a diagnosis of rheumatoid arthritis (RA). An initial report of a HLA DR4 association was not supported by further study. The absence of rheumatoid nodules or joint destruction aids in the differential diagnosis of B19 arthropathy from classic, erosive RA.[3]

Diagnosis

Diagnosis is based on laboratory confirmation in the appropriate clinical setting. While detection of B19 virions or DNA in serum during viraemia is confirmatory, these have usually resolved when the patient presents with joint symptoms. The diagnosis of a *recent* B19 infection is usually confirmed by detection of anti-B19 IgM antibody. Commercially available tests use recombinant empty capsids for antibody detection.[3]

The anti-B19 IgM antibody response is usually positive for at least 2 months following onset of joint symptoms, but may wane shortly thereafter. However, the IgM antibody may be detectable in occasional patients for 6 months or longer. Because of the high seroprevalence of anti-B19 IgG in the adult population, detection of anti-B19 IgG antibody shortly after presentation of acute-onset joint symptoms in a patient, in the absence of anti-B19 IgM, suggests past B19 infection and other diagnoses should be entertained. Failure to obtain B19 serological testing at presentation may leave the diagnostic IgM antibody response undetected, leading to failure to diagnosis B19 arthropathy in those patients in whom joint symptoms persist. Testing for B19 DNA at the time of arthropathy presentation is unlikely to be useful. Finding B19 DNA in synovium in chronic arthropathy is of questionable diagnostic value given that B19 DNA is found in synovium in half of healthy military recruits undergoing arthroscopy for injury using sensitive polymerase chain reaction (PCR) techniques.[3,6,7]

Pathogenesis

Anti-B19 IgM antibody and acute-phase IgG antibody (less than 1 week after inoculation) recognize determinants on the major capsid protein, VP2. In convalescent serum, anti-B19 IgG antibody

recognizes determinants on the minor capsid protein VP1 structural protein.[8] Since B19 VP1 and VP2 are products of alternate transcription of the same open reading frame, VP1 contains an additional 227 N-terminal amino acids not present in VP2. VP1 therefore contains unique determinants not present in the truncated form represented by VP2; these determinants may be in the unique non-overlapping N-terminal region or, alternatively, represent conformational differences in the sequences shared between the two proteins. Western blot analysis of serum from individuals with congenital immune deficiency, prior chemotherapy, or AIDS, demonstrated the absence of convalescent anti-B19 IgG antibodies directed against VP1. These sera were unable to neutralize B19 virus in experimental bone marrow culture systems.[8] In the absence of neutralizing antibodies to B19, B19 persists in the bone marrow and may cause chronic or intermittent suppression of one or more haematopoietic lineages.

B19 NS1 is a member of the superfamily 3 of helicases found in DNA viruses. In non-erythroid cells, B19 fails to transcribe capsid mRNA, but does produce intact NS1[4] that induces apoptosis in the host cell[9–11] and damages host cell DNA by single strand nicking and bulky adduct formation (protein–DNA covalent bonding).[12] Presentation of self-DNA modified by covalent linkage to viral proteins may allow the immune system to break tolerance by activating anergic B lymphocytes though viral peptide recognition.[12] This mechanism may explain the detection of DNA antibodies in acute B19 infection and the prevalence of B19 antibodies in patients with systemic lupus erythematosus (SLE). It also suggests a role for B19 and other viruses with superfamily 3 helicases, e.g. EBNA in Epstein–Barr virus, in breaking tolerance to self-DNA in SLE.[12]

Management

There is no specific vaccine or treatment for B19 infection at this time. Neutralizing activity to B19 is found in commercially available pooled immunoglobulin because of the high seroprevalence of anti-B19 IgG antibodies in the adult population. Intravenous immunoglobulin has been successful in the treatment of bone marrow suppression and B19 persistence in immunocompromised patients. However, this may not be applicable to chronic arthropathy patients as viraemia is usually absent by onset of joint symptoms; treatment is symptomatic with non-steroidal anti-inflammatory agents (NSAIDs).

Rubella virus

Rubella virus is the sole member of the genus *rubivirus* in the *Togaviridae* family of enveloped RNA viruses. The spherical rubella virion measures 50–70 nm in diameter with a 30 nm dense core. An envelope is acquired by budding at vesicles or the cell surface. Spike-like projections on the envelope measuring 5–6 nm contain haemagglutinin activity detected by agglutination of erythrocytes from a variety of animal species.[13]

Epidemiology

Rubella host range is restricted to humans. Transmission is by nasopharyngeal secretions with peak incidence in late winter and spring. Widespread rubella vaccination altered the epidemiology of rubella infection which had previously occurred in 6–9 year cycles mostly in children. Now, the age profile has shifted toward young adults and infection rates are 10–20% of those in the pre-vaccine era. More recent rubella outbreaks in college students and in adults underscore the public health need for maintaining vaccination programmes.

Incubation time from infection to onset of rash is 14–21 days. Viraemia occurs 6–7 days before skin eruption, peaks immediately prior to eruption, and clears within 48 hours of rash. Virus shedding in nasopharyngeal secretions may be detected from 7 days before and until 14 days after skin eruption, but is maximal just before onset of rash until 5–6 days after eruption.[14]

Clinical features

The spectrum of clinical disease in children and adults ranges from asymptomatic infection to a classic syndrome of low-grade fever, rash, coryza, malaise, and prominent posterior cervical, postauricular, and occipital lymphadenopathy. Constitutional symptoms may precede the skin eruption by 5 days. The eruption may vary during a brief 2–3 day period, starting as a morbilliform facial eruption before spreading to the torso, and upper then lower extremities. The eruption may coalesce on the face and clear as the extremities become involved. Alternatively, the eruption may be limited to a transient blush.

Joint complaints are common in adult infection, especially in women. Joint symptoms may occur 1 week before or after onset of the rash. Joint involvement is usually symmetric and may be migratory, resolving over a few days to 2 weeks. Arthralgias are more common than frank arthritis. Stiffness is prominent. The metacarpophalangeal and proximal interphalangeal joints of the hands, the knees, wrists, ankles and elbows are most frequently involved. Periarthritis, tenosynovitis, and carpal tunnel syndrome may be seen. In some patients, symptoms may persist for several months or years.[15]

Current vaccination with live attenuated vaccine, RA27/3, has a complication rate of 15–25% characterized by arthralgia, myalgia, arthritis, and paraesthesias. The pattern of joint involvement is similar to natural infection. Arthritis usually occurs 2 weeks after inoculation and typically lasts less than a week. However, in some patients postvaccination rubella arthritis may persist for more than a year.[16]

In children, two syndromes of rheumatological interest may occur. In the 'arm syndrome,' a brachial radiculoneuropathy causes arm and hand pain, and dysaesthesias that are worse at night. The 'catcher's crouch' syndrome is a lumbar radiculoneuropathy characterized by popliteal fossa pain on arising in the morning. Those affected assume a 'catcher's crouch' position. The pain gradually decreases through the day. Both syndromes occur 1–2 months after vaccination. The initial episode may last up to 2 months, but recurrences are usually shorter in duration. Episodes may recur for up to 1 year, but there is no permanent damage.[17]

Diagnosis

Rubella is readily cultured from tissues and body fluids including throat swabs. Rubella RNA may be detected in tissue of body fluids by reverse transcription polymerase chain reaction (RT-PCR) amplification. Presence of anti-rubella IgM antibody or anti-IgG antibody seroconversion is diagnostic of rubella infection. Anti-rubella IgM and IgG are usually present at onset of joint symptoms. IgM antibody peaks 8–21 days after symptoms then decreases over the next 4–5 weeks to undetectable levels in most patients. Therefore, detection of anti-rubella IgM indicates recent infection,

usually in the last 1–2 months. Since anti-rubella IgG rises rapidly over a period of 7–21 days after onset symptoms, a diagnosis of rubella infection based on IgG serology can only be made with paired acute and convalescent sera.[14]

Pathogenesis

Failure to mount an adequate immune response to specific epitopes may allow rubella virus to persist in patients with rubella arthritis. Virus may be detected in synovial fluid during arthritis flares and in lymphocytes years after symptom resolution. Onset of rash and arthritis is coincident with the appearance of antibodies, including neutralizing antibodies to whole virus, suggesting a role for antibody or immune complexes in the synovitis.[14]

Management

NSAIDs may be used for symptom control. Low to moderate doses of steroids have been used to control symptoms and viraemia.

Hepatitis B virus

Hepatitis B virus (HBV) is a member of the family *Hepadnaviridae*, genus *orthohepadnavirus*. HBV is an enveloped double-stranded DNA icosahedral virus measuring 42 nm in diameter, the 'Dane' particle.[18]

Epidemiology

HBV is transmitted by parenteral and sexual routes. HBV infection occurs worldwide, but prevalence of hepatitis B surface antigen (Australian antigen) is higher in Asia, the Middle East, and sub-Saharan Africa. The prevalence in China may be as high as 10% compared to 0.01% in the United States. There is no known seasonality to primary HBV infections. Most acute infections in endemic regions occur at an early age, with many acquired perinatally from infected mothers, and are usually asymptomatic; incidence of infection in children may be as high as 5% annually, with gradual decline of carriage rates and specific antibody with advanced age. In developed countries, most infections are acquired in adulthood during sexual or needle exposures. Adult infection is more often associated with acute hepatitis; of those with hepatitis, 5–10% develop persistent infection. In endemic regions, HBV is a common cause of chronic liver disease and a leading cause of hepatocellular carcinoma.[18]

Clinical features

The incubation period from infection to hepatitis is usually 45–120 days. A preicteric prodromal period lasting several days to a month may be associated with fever, myalgia, malaise, anorexia, nausea, and vomiting. Significant viraemia occurs early in infection; soluble immune complexes with circulating hepatitis B surface antigen (HBsAg) are formed as anti-hepatitis B surface antigen antibodies (HBsAb) are produced. Immune-complex-mediated severe arthritis often occurs abruptly, concurrent with urticaria. Joint involvement is usually symmetric with simultaneous involvement of several joints at onset, but arthritis may be migratory or additive. The joints of the hand and knee are most often affected, but wrists, ankles, elbows, shoulders, and other large joints may be involved as well. Fusiform swelling may be seen in the small joints of the hand. Morning stiffness is common. Arthritis and urticaria may precede jaundice by days to weeks and may persist several

weeks after jaundice, but usually subside soon after onset of jaundice. Patients who develop chronic active hepatitis or chronic HBV viraemia may have recurrent arthralgias or arthritis. Polyarteritis nodosa (PAN) is frequently associated with chronic hepatitis B viraemia.

Diagnosis

Urticaria in the presence of polyarthritis should raise the possibility of HBV infection. Acute hepatitis may be asymptomatic, but elevated bilirubin and transaminases are usually present when the arthritis appears. Joint fluid examination is not diagnostic. At the time of arthritis onset, peak levels of serum HBsAg are detectable. Virions, viral DNA, viral polymerase, and hepatitis B e antigen may be detectable in serum. Anti-hepatitis B core antigen IgM antibodies are present and indicate acute HBV infection, as opposed to past or chronic infection.[19]

Pathogenesis

HBV arthritis is thought to be mediated by immune complex deposition in synovium. Immune complexes containing HBsAg, antibody, and complement components may be detected.

Management

Management is limited to supportive measures including NSAIDs.

Hepatitis C virus

Hepatitis C virus (HCV) is a member of the family *Flaviviridae*, genus *hepacivirus*. It is an enveloped single-stranded RNA spherical virus measuring 38–50 nm in diameter.

Epidemiology

HCV is distributed worldwide. Seroprevalence is less than 1% in developed Western countries but is higher in Africa and Asia where it may cause one-quarter or more of acute and chronic hepatitides. HCV is transmitted by the parenteral route; sexual transmission is rare. HCV genotypic variants have been described and these differ in their pathogenicity including severity of disease and response to interferon-α. HCV has 6 major genotypes groups or clades and over 50 genotypic subtypes.[20] As with other positive-strand RNA viruses, the viral polymerase is error prone, generating variants at a high rate.

Clinical features

Acute HCV infection is usually benign. Up to 80% of post-transfusion infections are anicteric and asymptomatic, even though liver transaminases may be markedly elevated acutely. Subsequently and prior to cirrhosis, liver enzymes are usually minimally elevated to normal. HCV is strongly associated with HBV-negative hepatocellular carcinoma, especially in Africa and Japan.

Acute-onset polyarthritis in a rheumatoid distribution, including the small joints of the hand, wrists, shoulders, knees, and hips, may occur in acute HCV infection.[21] HCV is often associated with type II cryoglobulinaemia in established infection. It may present as essential mixed cryoglobulinaemia, a triad of arthritis, palpable purpura, and cryoglobulinaemia. Indeed, a majority of patients originally described as having essential mixed cryoglobulinaemia had HCV infection. HCV infection is also seen in non-essential secondary cryoglobulinaemia although less commonly. The presence

of detectable anti-HCV antibodies in essential mixed cryoglobulinaemia is associated with more severe cutaneous involvement, e.g. Raynaud's phenomena, purpura, livedo, distal ulcers, and gangrene. HCV RNA may be found in 75% of cryoprecipitates from patients with essential mixed cryoglobulinaemia and anti-HCV antibodies.[22]

Diagnosis

Serological tests utilize an array of antigens in an enzyme immunoassay; a recombinant strip immunoblot assay (RIBA) is confirmatory. RT-PCR is used for diagnosis, identification of genotype, and detection of sequence variants associated with drug resistance.[23] A minority of patients may have HCV RNA detectable by PCR amplification methods in the absence of a positive serology. Transaminase levels may not reflect severity of viral load, hepatitis, or cryoglobulinaemia because hepatocytes die by apoptosis allowing hepatocyte content to be cleared by apoptotic mechanisms.[24]

Pathogenesis

Chronic HCV infection can lead to cirrhosis, endstage liver failure, and hepatocellular carcinoma but the mechanisms by which they occur are not known. HCV infection persists despite vigorous antibody response to an array of viral epitopes. The high rate of mutation in the envelope protein is responsible for emergence of neutralization escape mutants and quasispecies.[25] HCV is suspected to elicit cryoglobulins because HCV envelope glycoprotein has antibody Fc receptor properties that allow epitope spreading from HCV to bound immunoglobulin Fc.[26]

Management

Intravenous interferon-α has been shown to be efficacious in the treatment of chronic HCV hepatitis and HCV-associated cryoglobulinaemia. Ribavirin in combination with interferon-α2b, or higher doses of interferon-α2b alone when tolerated, improve response rates. Pegylation of interferon lengthens drug half-life. However, interferon therapy is often associated with undesirable side effects that discourage completion of the therapeutic course; relapse after completion of the initial course of therapy is common. Those with cryoglobulinaemic vasculitis failing interferon therapy may require immunosuppressive therapy. There is controversy whether interferon therapy precipitates autoimmune disease such as autoimmune thyroiditis. Inhibitors of the viral non-structural protein NS3/4A protease and NS5B polymerase, and other drugs, hold further therapeutic promise.[27] These agents will become available in 2014 and promise high rates of viral eradication after shorter courses of oral therapy. This promise has prompted recommendations for routine screening of at-risk populations.

Retroviruses

Human immunodeficiency virus (HIV)

Several musculoskeletal syndromes have been described in HIV-infected patients. Initial HIV infection may be associated with a transient flu-like illness with arthralgias. Later, three pain syndromes not associated with synovitis may be seen.[28] The concurrence of RA and HIV is thought to be very rare. An acute symmetric polyarthritis involving the small joints of the hands and the wrists has been described but it was associated with periosteal new bone formation about the involved joints, a feature not seen in RA.

Subacute oligoarticular arthritis primarily of the knees and ankles may cause severe arthralgia and disability but is transient, peaks in intensity within 1–6 weeks, and responds to NSAIDs. Synovial fluid is non-inflammatory. Mononuclear cell infiltrates may be seen in the synovium of the involved joints. In Brazil, a similar presentation has been described amongst heterosexual men with HIV and arthritis, with 83.5% polyarthritis, 16.5% oligoarthritis, and 97.5% symmetrical, almost always involving lower extremities and about a one-quarter with involvement of the great toe. Erythrocyte sedimentation rate (ESR) exceeded 100 mm/hour in more than one-half of cases. Rheumatoid factor was negative, synovial fluid sterile and non-inflammatory, and radiographs normal. Successive bouts resolved in 2–5 weeks with NSAIDs.[29]

As many as 10% of HIV-infected patients may experience 'painful articular syndrome' characterized by intermittent severe joint pain predominantly of the shoulders, elbows, and knees that lasts about a day. The pain may be incapacitating and require short-term narcotic analgesics. Fibromyalgia has been reported in HIV-infected patients with prevalence as high as 29% in one series. The role of HIV and other potential agents in these pain syndromes remains to be clarified. In addition to arthritis, disseminated interstitial lymphocytosis syndrome (DILS) may be seen in AIDS patients. In affected patients, a CD8-positive lymphocyte infiltrate of salivary glands causes parotid swelling. This entity needs to be differentiated from classic Sjögren's syndrome.[30]

Patients with reactive arthritis do not have sacroiliitis or anterior uveitis, nor do they present with the classic triad of arthritis, urethritis, and uveitis. The prevalence of HLA B27 positivity appears to be lower in the HIV-infected patients compared to non-HIV-associated reactive arthritis. In Africa where the route of HIV transmission is predominantly heterosexual, approximately 40% of HIV patients with joint symptoms in Zimbabwe have reactive arthritis, and another 40% have a pauciarticular presentation without extra-articular features characteristic of reactive arthritis.[31] In the United States, psoriatic arthritis limited to a pattern of asymmetric oligoarthritis may be seen in as many as one-third of HIV-infected patients with psoriasis, but the overall incidence of psoriasis does not appear to be significantly increased. Whether the different patterns of rheumatic disease expression are attributable to HIV infection itself or coinfection with other agents remains controversial.[32]

Human T lymphocyte leukaemia virus 1

Human T lymphocyte leukaemia virus (HTLV) is found in Japan, the Caribbean, South America, and sub-Saharan Africa where 1% of the population may be infected. HTLV-1 causes asymptomatic infection, leukaemia or lymphoma, myelopathy, or tropical spastic paraparesis, uveitis, or opportunistic infections. An association with inclusion body myositis has been reported. HTLV-1 is endemic in defined localities in Japan, historically associated with early European trade, where oligoarthritis and a nodular rash have been typical presentations. The patients have positive serology for anti-HTLV antibodies. Type C viral particles are seen in skin lesions. The presence of atypical synovial cells with lobulated nuclei and T cell synovial infiltrates suggests direct involvement of the synovial tissue by the leukemic process.[33] Patients with HTLV-1 infection may also have sicca symptoms. A number of reports associate HTLV-1 infection with Sjögren's syndrome, as well as autoimmune thyroid disease.[34]

Alphaviruses

Chikungunya virus

Chikungunya virus was originally isolated during an epidemic of febrile arthritis in Tanzania in 1952–1953. The local tribal word, chikungunya, 'that which twists or bends up', was applied to the virus and the disease. Retrospectively, it is likely that similar epidemics occurred in Indonesia, Africa, India, Asia, and possibly the southern United States from 1779 to 1828.[35]

Epidemiology

Chikungunya virus is transmitted from its reservoir hosts (baboons, monkeys, and, in Senegal, *Scotophilus* bat species) to humans by *Aedes* mosquitoes in south and west central Africa, Thailand, Vietnam, and India. *Mansonia africana* and mosquitoes from other genera may also act as vectors. In a 1964 epidemic in Bangkok, Thailand, an estimated 40 000 patients out of an urban area of 2 million were infected and 31% of the prospectively studied cohort seroconverted to chikungunya virus antibody positivity. Globalization may contribute to increasing risk of spread. An outbreak in Malaysia in 1998–1999 was attributed to migrant workers from endemic areas. A major outbreak occurred in the Emilia-Romagna region of north-eastern Italy in the summer of 2007.[36] The reinfestation of *Aedes aegypti* and the introduction of *Ae. albopictus* into the western hemisphere raises the spectre of an expanded geographic distribution.

Clinical features

Chikungunya fever has explosive onset associated with fever and severe arthralgia. The incubation period is usually 2–3 days but ranges over 1–12 days. Constitutional symptoms, rash and fever to 40 °C are accompanied by rigors. The acute illness may last 2–3 days with a range of 1–7 days. Suffusion of the conjunctiva is prominent. Sore throat, pharyngitis, headache, photophobia, retro-orbital pain, anorexia, nausea, vomiting, and abdominal pain may accompany the acute illness. Lymphadenopathy may be tender but is usually not massive. Following the acute illness, fever may resolve for 1–2 days before recrudescence. Polyarthralgia is migratory and predominantly affects the small joints of the hands, wrists, feet, and ankles with less prominent involvement of the large joints. Previously injured joints may be more severely affected. Stiffness and swelling may occur but large effusions are uncommon. In severe cases, symptoms may persist for months. Approximately 10% of patients have joint symptoms 1 year after infection. Generalized myalgia and back and shoulder pain are common. A destructive arthropathy may occur in a few adult patients with chronic symptoms. Low-titre rheumatoid factor may be found in those with longstanding symptoms.

Skin eruption is characterized by facial and neck flushing, followed by macular or maculopapular eruption beginning 1–10 days after illness onset. Typically, a rash occurs on day 2–5 and is associated with defervescence. The rash may last 1–5 days and may recur with fever. It is located on the torso, extremities, and occasionally the face, palms, and soles. It may be pruritic. In some patients, involved skin desquamates.[37] Isolated petechiae and mucosal bleeding may occur, usually without significant haemorrhage.

Symptoms in children tend to be milder. Nausea, vomiting, pharyngitis, and facial flushing are prominent features. Arthralgia, arthritis, and rash are uncommon, and milder and briefer in duration when present. Children may present with mild dengue-like haemorrhagic fever, headache, pharyngeal injection, vomiting, abdominal pain, constipation, diarrhoea, cough, or lymphadenopathy. Maternal–fetal transmission may result in severe neonatal infection.

Diagnosis

Chikungunya fever should be considered in any febrile patient resident in or returning from endemic areas. A history of epidemic occurrence should be sought. O'nyong-nyong virus, Mayaro virus, Ross River virus, rubella virus, parvovirus B19, dengue, and HBV infections may present similarly. Synovial fluid shows decreased viscosity with poor mucin clot, 2000–5000 white cells/mm^3. Therefore, the definitive diagnosis depends on laboratory confirmation.

Virus may be isolated during days 2–4 after infection. Haemagglutination and complement fixation assays and neutralizing antibody assays have been replaced by RT-PCR methods.[38]

Pathogenesis

Following mosquito bite, intense viraemia occurs within 48 hours. Viraemia begins to wane around day 3. The appearance of hemagglutination inhibition activity in neutralizing antibodies clears the viraemia. Involved skin shows erythrocyte extravasation from superficial capillaries and perivascular cuffing. The virus absorbs to human platelets causing aggregation, suggesting a mechanism for bleeding. Synovitis in chikungunya fever probably results from direct viral infection of synovium.[35]

Management

Management for the patient is supportive. During the acute attack, range of motion exercises ameliorate stiffness. NSAIDs are useful. However, chloroquine phosphate (250 mg/day) has been used when NSAIDs failed.

O'nyong-nyong virus

O'nyong-nyong virus is closely related to chikungunya virus. It was first described in the Acholi province of north-western Uganda in February, 1959, where its name means 'joint breaker.' Within 2 years, it had spread through Uganda and the surrounding region, affecting 2 million people. Serologically determined attack rates ranged from 50% to 60% with up to 78% of infected individuals becoming symptomatic. Disease spread at a rate of 2–3 km daily. After the epidemic, the virus was not detected again until it was isolated from *Anopheles funestus* mosquitoes in Kenya in 1978. *A. gambiae* also serves as a vector. Serological surveys indicate that o'nyong-nyong virus is endogenous. The non-human vertebrate reservoir for the virus is not known. In 1996–1997, o'nyong-nyong virus again appeared during an outbreak in south central Uganda.[39]

Clinical features

O'nyong-nyong fever is clinically similar to chikungunya infections. The incubation period lasts at least 8 days and is followed by sudden-onset polyarthralgia/polyarthritis. Four days later, appearance of skin eruptions is typically associated with improvement in joint symptoms. The eruption is uniform in nature and lasts 4–7 days before fading. The fever is not prominent but postcervical lymphadenopathy may be marked. Knees and ankles are most commonly affected. Arthralgias last 2–21 days with 1–14 days of immobilization.[40] Although residual joint pain often persists, there appear to be no long-term sequelae.

Diagnosis

Differential diagnosis includes chikungunya fever, igbo ora virus infection, and measles. Viral isolation by intracerebral injection into suckling mice produces runting, rash, and alopecia. Haemagglutination inhibition or complement fixation tests identify the virus. The differential diagnosis is similar to that of chikungunya fever. Mouse anti-sera raised against chikungunya virus or o'nyong-nyong virus react equally well with o'nyong-nyong virus, but o'nyong-nyong anti-sera do not react well with chikungunya virus. The mechanisms of o'nyong-nyong virus pathogenesis are unknown.[35]

Management

Management is symptomatic. Patients typically recover without long-term sequelae.

Igbo ora virus

Igbo Ora virus is serologically similar to chikungunya and o'nyong-nyong viruses. Initially, a single patient with fever, sore throat, and arthritis was identified. In 1984, an epidemic of fever, myalgias, arthralgias, and skin eruption occurred in the Ivory Coast. The term 'igbo ora' was coined: it means 'the disease that breaks your wings'. The virus was isolated from *A. funestus* and *A. gambiae* mosquitoes, and from affected individuals. Domestic animals show a higher seroprevalance than humans, suggesting that humans are a secondary host. Growth in culture in VERO and MRC5 causes lysis while growth in MDCK and MA104 cells is less cytotoxic.[41]

Ross River virus (epidemic polyarthritis)

Epidemics of fever and rash have been observed in Australia since 1928. Isolation of Ross River virus from mosquitoes, its serological association with epidemic polyarthritis, and the isolation of the virus from epidemic polyarthritis patients in Australia confirmed Ross River virus as the etiologic agent of epidemic polyarthritis.[35] Antibodies to Ross River virus have been observed in the sera of endogenous populations in Papua New Guinea, West New Guinea, the Bismarck Archipelago, Rossel Island, and the Solomon Islands. From 1979 to 1980, a major epidemic of febrile polyarthritis occurred in Fiji, affecting over 40 000 individuals. Serological surveys suggested that a low level of Ross River virus infection was present throughout the Fijian islands before 1979 but that following the epidemic, up to 90% of the residents of some communities had antibody. A similar epidemic occurred in the Cook Islands early in 1980. Antibodies to Ross River virus are not found in the Asiatic zone west of Weber's line (a hypothetical line separating the Australian biogeographic zone from the Asiatic zone).

In Australia, both endemic cases and epidemics occur in temperate and tropical zones. Significant numbers of cases are reported in Queensland and New South Wales, although cases and outbreaks are described in other regions as well. Seroprevalence may reach only 6–15% in temperate coastal zones but is 27–39% in the plains of the Murray Valley river system.[42] High rainfall, which increases mosquito populations, usually precedes epidemic periods. Cases occur from the spring through the fall.

The major vectors are *Ae. vigilax* on the eastern coast of Australia and *Ae.camptorhynchus* in southern Australia, where the mosquito breeds in salt marshes. *Culex annulirostris* is a fresh-water breeding vector. Other Australian *Aedes* species and *Mansonia uniformus* may also serve as vectors. Several mammalian species may serve as intermediate hosts, including domestic animals, rodents, and marsupials. In the Pacific island outbreaks, *Ae. polynesiensis*, *Ae. aegypti*, *Ae. vigilax*, and *C. annulirostris* may have contributed as well.

In Queensland, annual rates of disease range from 31.5 to 288.3 per 100 000 person years.[43] During epidemics in Fiji and New South Wales, the majority of those infected were symptomatic. While male and female infection rates were similar, there was a predominance of women in presenting cases. Children have a case/infection ratio lower than adults.

Clinical features

Arthralgias occur abruptly after a 7–11 day incubation period.[35] A macular, popular, or maculapapular skin eruption, that may be pruritic, typically follows onset of arthralgia by 1–2 days; in some patients, rash may precede or follow joint symptoms by 11 days or 15 days, respectively. Occasionally, vesicles, papules, or petechiae are seen. The trunk and extremities are typically involved although involvement of the palms, soles, and face may occur. The rash resolves by fading to a brownish discoloration or by desquamation. Despite the name of the disease, one-half of patients have no fever, and in those who do, modest fevers may last only 1–3 days. Headache, nausea, and myalgia are common. Mild photophobia, respiratory symptoms, and lymphadenopathy may occur.

A majority of patients have severe, incapacitating arthralgia. Joint distribution is often asymmetric and migratory, commonly involving the metacarpophalangeal and finger interphalangeal joints, wrists, knees, and ankles. Shoulders, elbows, and toes may also be involved. Axial, hip, and temporomandibular involvement occasionally occurs. Arthralgias are worse in the morning and after periods of inactivity. Mild exercise tends to improve joint symptoms. One-third will have frank synovitis. Polyarticular swelling and tenosynovitis are common. As many as one-third have paraesthesias, or palm or sole pain. Some patients have classic carpal tunnel syndrome. Half of all patients are able to resume their activities of daily living within 4 weeks although residual polyarthralgia may be present. Joint symptoms recur but episodes of relapse gradually resolve. A few patients will continue to have joint symptoms for up to 3 years.[44]

Diagnosis

The diagnosis of Ross River virus infection should be considered in anyone with a febrile arthritis in the appropriate geographic setting. Acute rubella arthritis may present in a similar fashion, although the signs and symptoms of an upper respiratory infection are more prominent in rubella. Patients may present without a rash. The differential diagnosis then would include early seronegative RA, SLE, parvovirus B19 infection, HBV infection, HCV infection, other alphavirus infections, Henoch–Schönlein purpura, and drug hypersensitivities. In those individuals who develop vesicles, differential from varicella or the occasional parvovirus B19 infection would need to be considered.

Synovial fluid cell counts range from 1500 to 13 800 cells/mm³. Monocytes and vacuolated macrophages dominate with few neutrophils. Virus has been isolated only from antibody-negative sera. In the Australian epidemics prior to 1979, patients were antibody positive at the time of presentation. However, in the Pacific island epidemics of 1979–80, patients remained viraemic and serologically negative for up to a week following onset of symptoms. Ross River virus antigen is detectable by fluorescent antibody staining of C6/36 cells inoculated with acute patient serum. Virus in serum is stable for up to a month at 0 to −10 °C.

Pathogenesis

Ross River viral antigen may be detected by specific immunofluorescence in monocytes and macrophages early, but intact virus is not identifiable by electron microscopy or cell culture.[35] The dermis shows mild perivascular mononuclear cell, mostly T lymphocytic, infiltrate in both erythematous and purpuric eruptions. The purpuric form of eruption also shows extravasation of erythrocytes. Synovium demonstrates synovial lining layer hypertrophy, vascular proliferation, and mononuclear cell infiltration. Viral RNA can be found by RT-PCR. Ross River virus antigen may be found in epithelial cells in the erythematous or purpuric skin lesions, and in the perivascular zone in the erythematous lesion.[45]

Management

Management of the acute infection is symptomatic. Aspirin or NSAIDs provide relief for joint pain. Corticosteroids may shorten time of recovery and do not appear to exacerbate symptoms.[46] Occasional patients may develop more persistent joint symptoms, but full recovery is usual.

Barmah forest virus

This circulates in the same geographic areas as does Ross River virus and presents in a similar fashion. A major outbreak occurred in summer and autumn of 2002 and 2003.[47]

Sindbis virus

Sindbis virus is the prototype alphavirus used for molecular virology studies. It was isolated from *Culex* mosquitoes in the Egyptian village of the same name in 1952.

Epidemiology

Sindbis virus infection occurs in Sweden, Finland, and the neighbouring Karelian isthmus of Russia where it is known locally as Okelbo disease, Pogosta disease, or Karelian fever, respectively.[35] *Aedes*, *Culex*, and *Culiseta* species transmit the virus to humans. Birds are an intermediate host. Cases are confined to predominantly forested areas where seroprevalence is approximately 5%. Individuals involved in outdoor activities or occupations are at risk. Sindbis virus infection has also been reported as sporadic cases and small outbreaks in Uganda, South Africa, Zimbabwe, Central Africa, and Australia.[35]

Clinical features

Skin eruption and arthralgia are the initial symptoms although one may precede the other by a few days. Fever may be present although it is not high. Constitutional symptoms including headache, fatigue, malaise, nausea, vomiting, pharyngitis, and paraesthesias may be present but are usually not severe. Macular skin eruptions typically begin on the torso, spreading to the arms and legs, palms, soles, and occasionally head. The macules may evolve to papules that have a tendency to vesiculate. Vesiculation is particularly prominent on pressure points, including the palms and soles. As the eruption fades, a brownish discoloration is left. Vesicles on the palms and soles may become haemorrhagic. The rash may recur during convalescence.

Arthralgia and arthritis involve the small joints of the hands and feet, wrists, elbows, ankles, and knees. Occasionally, the axial skeleton becomes involved. Tendonitis is common, often involving the extensor tendons of the hand and the Achilles tendon. Non-erosive chronic arthropathy is common in both Swedish and Finnish reports, with up to one-half of patients having symptoms 2.5 years after onset. A smaller number have symptoms as long as 5–6 years after infection.[48]

Diagnosis

Haemagglutination inhibition and complement fixation tests may establish the diagnosis. Antibodies appear during the first week of illness. A real time RT-PCR assay for detection of Sindbis viral RNA has been developed.

Pathogenesis

Little is known about the pathogenesis of Sindbis virus disease. Virus has been isolated from a skin vesicle in the absence of viraemia. Skin lesions show perivascular oedema, haemorrhage, lymphocytic infiltrates, and areas of necrosis. Sindbis virus is capable of replication in human macrophages which are activated to release proinflammatory cytokines including macrophage inhibitory factor, tumour necrosis factor α, interleukin (IL)-1β, and IL-6. Antiviral IgM may persist for years, raising the possibility that Sindbis virus arthritis is associated with viral persistence and direct viral effect on the synovium.

Management

Management is supportive.

Mayaro virus

This virus was first recognized in Trinidad in 1954 and has caused epidemics in Bolivia and Brazil. Mayaro virus is transmitted from monkey to man by *Haemogogus* mosquitoes in the South American tropical rain forest. Mayaro virus was responsible for an outbreak in Belterra, Brazil in 1988 with 800 out of 4000 exposed latex gatherers becoming infected. The clinical attack rate was 80%. Illness was characterized by sudden onset of fever, headache, dizziness, chills, and arthralgias in the wrists, fingers, ankles, and toes. About 20% had joint swelling. Unilateral inguinal lymphadenopathy was seen in some patients. Leucopenia was common. Viraemia was present during the first 1–2 days of illness. After 2–5 days, fever resolved but a maculopapular rash on the trunk and extremities appeared. The rash lasted about 3 days. Recovery was usually complete, although some patients had persistent arthralgias at 2 month follow-up.[49]

Cases were detected in 2007–2008 in Manaus, the urban capital of Amazonas state in western Brazil, suggesting that the infection is endemic in the area.[50] Imported cases have been identified in non-endemic areas of Brazil and in the United States and France after travel from the endemic area in the Brazil–Bolivia–Peru interborder region, and in the Netherlands after travel from Surinam, an area not reported to have Mayaro virus. Of interest, Mayaro virus has been isolated from a bird in Louisiana, raising the spectre of emergence of Mayaro virus in North America.

Other viruses

Apart from specific viral infections noted above in which arthralgia and/or arthritis is typically a prominent feature, there are a host of commonly encountered viral infections in which joint involvement is occasionally seen. Children with varicella have been reported rarely to develop brief monoarticular or pauciatricular arthritis that is thought to be viral in origin; in both children and adults, knee arthritis has been reported. Adults who develop mumps occasionally develop small- or large-joint synovitis lasting up to several weeks. Arthritis may precede or follow parotitis by up to 4 weeks.

Infection with adenovirus and coxsackieviruses A9, B2, B3, B4, and B6 have been associated with recurrent episodes of polyarthritis, pleuritis, myalgia, rash, pharyngitis, myocarditis, and leucocytosis. Epstein–Barr virus associated mononucleosis is frequently accompanied by polyarthralgia, but occasional monoarticular knee arthritis occurs. Polyarthritis, fever, and myalgias due to echovirus 9 infection have been reported in a few cases. Arthritis associated with herpes simplex virus or cytomegalovirus infections are likewise rare. *Herpes hominis* occasionally causes arthritis of the knee known as herpes gladiatorum because it is seen in wrestlers. Vaccinia virus has been associated with non-bacterial postvaccination knee arthritis as a rare complication.

CHAPTER 103

Mycobacterial diseases

Rita Abdulkader and Richard A. Watts

Introduction

Tuberculosis (TB) and leprosy are the main diseases caused by mycobacteria. Their manifestations result from chronic granulomatous infections caused by *M. tuberculosis* and *M. leprae*. These are obligate intracellular aerobic acid fast bacilli. Atypical mycobacteria such as *M. avium-intracellulare* and *M. marinum* are uncommon causes of musculoskeletal infection.

Tuberculosis

Epidemiology

The World Health Organization (WHO) reported 8.8 million new cases of tuberculosis in 2010.[1] Despite a fall in the number of reported cases, TB still poses a significant health challenge globally. Efforts to control the disease are hampered by the prevalence of HIV infection, and the emergence of multidrug resistant (MDR) and extremely drug resistant (XDR) TB.[2] Extrapulmonary TB including musculoskeletal infection is commoner in immunocompromised patients. These patients are also at a higher risk of developing MDR TB.[2] Musculoskeletal infection accounts for 1–3% of all TB infections; it can occur at any age, but it is rare in infancy.[3]

Transmission of the pathogen in the majority of cases is from a human host with active pulmonary disease via droplets. Host factors largely determine the course of the infection. The risk is increased in immunocompromised individuals, through HIV coinfection or medication. Malnutrition, substance abuse, and the presence of chronic disease are also associated with increased risk.[2] After reaching the pulmonary alveoli, the bacilli are phagocytosed by macrophages where they multiply. The resulting inflammatory response leads to the formation of granulomata typical of tuberculosis, consisting of a necrotic caseating centre, multinucleated giant cells, epitheloid cells, and peripheral lymphocytes. The primary infection is symptomatic in only one-third of patients.[2] Cell-mediated immune response is important in containing the infection, and this occurs in most cases. Afterwards, the bacilli remain dormant within the macrophages for many years. During this time the patient is completely asymptomatic and non-infectious. The tuberculin skin test is usually positive. This is recognised as latent TB. Reactivation of latent TB is responsible for 90% of active TB cases in adults. Active TB will develop in 10% of immunocompetent individuals with latent TB during their lifetime, most commonly within the first 2 years of the infection.[2]

Clinical manifestations

Early diagnosis and treatment of musculoskeletal TB is an important factor in reducing long-term damage and possible disability. However, this is usually challenging and a high index of suspicion is required to establish the diagnosis early. The infection usually develops after haematogenous dissemination of the bacilli; however, transmission via lymphatic vessels, local reactivation of latent microorganisms, or less commonly direct invasion from an adjacent site may also occur.[4,5] The course of the disease is usually indolent over weeks to months. Delay in diagnosis for several months is common. Systemic symptoms of fever, weight loss, malaise, and night sweats may point to the diagnosis, although they are frequently absent.[6] Active pulmonary disease is present in less than 50% of cases.[3]

The most common site of infection is the spine in about 50% of cases. Extraspinal TB usually manifests as monarthritis in a large weight bearing joint. Osteomyelitis and soft tissue infection including myositis, bursitis, and tenosynovitis are rarer. Poncet's disease, a reactive arthritis to *M. tuberculosis* infection, is occasionally reported, but its occurrence as an entity is debatable.

Spinal tuberculosis (Pott's disease)

The lower thoracic and upper lumbar spine is most commonly affected. The infection usually begins at the anterior aspect of the vertebra, adjacent to the superior or inferior endplates. It can directly spread across the subchondral plate to the adjacent disc or track beneath the longitudinal anterior and posterior ligaments sparing the disc.[7] With progression of the infection, the vertebral body collapses and anterior wedging occurs. Gibbus formation and vertebral instability may ensue. The slow progression of intervertebral disc involvement helps differentiate spinal tuberculosis from pyogenic infections in adults.[8] The posterior elements are affected in TB, and this distinguishes TB from other bacterial infections[5]; however, it raises the possibility of metastatic malignancy (Figure 103.1).[3] The typical appearance is of two adjacent vertebrae affected with disc destruction and paravertebral abscess. Single vertebral or skip lesions are less frequent (Figure 103.2).[4] After healing, vertebral ankylosis occurs.

The most common symptom is pain, which is usually worse at night, waking the patient up from sleep. Patients may present after vertebral collapse with kyphosis, or with neurological complications. A paravertebral collection can track along fascial planes and

discharge in distant locations. In the lumbar spine, cold abscesses can involve the iliopsoas muscle, tracking along its sheath to the groin or thigh.[3] In the thoracic spine they can track along the ribs to the anterior chest wall. In the neck, a retropharyngeal abscess may develop and cause compressive symptoms with hoarseness,

Fig. 103.1 Thoracic spine radiograph showing destruction of the left pedicle of T8 (black arrow) with associated paravertebral soft tissue mass (white arrow). Disc spaces are preserved. The differential diagnosis also includes malignancy.

dysphagia, and stridor. Neurological symptoms may result from local oedema and vascular congestion, from direct compression due to vertebral collapse, or from posterior extension of a cold abscess. Less commonly intramedullary tuberculoma have been implicated and very rarely spinal vascular thrombosis and infarction can occur.[9,10] Symptoms vary from difficulty in walking, or radicular pain, to a more severe picture of cauda equina syndrome, paraplegia, or quadriplegia. Tuberculosis can involve the atlanto-axial articulation, resulting in instability. Neurological involvement at this level can cause irreversible quadriplegia. Even after healing, neurological complications can occur as a result of spinal stenosis, gibbus formation, or peridural fibrosis.[9] A shorter duration of symptoms and slow progression indicate a better diagnosis when neurological symptoms occur. The presence of paraplegia, flaccid paralysis, myelomalacia, or a syrinx on MRI carries a worse prognosis.[9]

Tuberculous arthritis

Tuberculous arthritis occurs in 30% of cases of musculoskeletal TB.[8] It is most commonly monoarticular, affecting weightbearing joints. Sacroiliac, shoulder, elbow, and ankle joints may also be affected.[11] Multifocal disease is encountered in 10% of cases.[8]

Symptoms include pain, stiffness, effusion, and synovial thickening with minimal inflammation. Compared to pyogenic infections, cartilage loss occurs late in the disease.[11] Rice bodies may form with longstanding disease. Sinuses may be complicated by secondary infection. Eventually, joint deformity and fibrous ankylosis develop (Figure 103.3).

Tubercular osteomyelitis

This is a rare form of skeletal TB. The commonest sites affected include the tibia, femur and short bones in the hands and feet.[3] Multifocal disease may be encountered in immunocompromised
Fig. 103.2 MRI of an adolescent girl showing a tuberculous focus of infection at the mid-dorsal level together with a pulmonary lesion.
Fairbank, J. Oxford Textbook of Trauma and Orthopaedics

Fig. 103.3 Tuberculosis of the left hip with narrowing of the joint space, lateral erosive changes, and secondary marginal osteophytes. The femoral head is expanded and flattened.

patients.[11] The infection usually affects the metaphysis of the long bones, and may spread to the adjacent joint. In children, extension across the growth plate is characteristic of TB.[3,9] Clinical features include mild pain, tenderness, soft tissue swelling, and sinus formation. Pathological fractures may occur.

A less common type is cystic TB, which may be multifocal, and is most commonly encountered in the lower limbs in children. In adults it tends to affect the axial skeleton.[3]

Dactylitis is usually painless, affecting children under 6 years of age in 85% of cases. It can be difficult to differentiate from chronic osteomyelitis.[8]

Investigations and diagnosis

The diagnosis of musculoskeletal TB relies on a combination of clinical, radiological, histological, and microbiological features. No one test rules out the diagnosis. In areas where TB is endemic, treatment should be initiated if the clinical picture and radiological features are suggestive of the diagnosis.[9]

Laboratory tests

Inflammatory markers are usually raised, with evidence of anaemia and lymphocytosis. In 10% of patients both the white blood cell count (WBC) and erythrocyte sedimentation rate (ESR) are normal.[5] Testing for HIV should be considered.

The tuberculin skin test is positive in most cases. However, its usefulness is limited in endemic areas and it is not specific to *M. tuberculosis*; false-positive results are encountered with previous BCG vaccination. A negative test does not rule out *M. tuberculosis* especially in immunocompromised individuals.

Interferon-gamma release assays (IGRA) may support the diagnosis. They are performed on whole blood or mononuclear cells to detect the presence of T cells previously sensitized to *M. tuberculosis* through release of interferon-gamma. As they use proteins specific to *M. tuberculosis*, previous BCG vaccine does not affect the result of IGRAs. However, they are unable to differentiate active from latent TB. A negative test does not rule out active TB. Serological tests for antibodies to *M. tuberculosis* are

not recommended in routine practice due to discrepancies in their sensitivity and specificity.

Tissue or fluid samples for microbiological and histological confirmation can be obtained through open biopsy or using imaging guidance. Samples should be stained for acid-fast bacilli (AFB) using Ziehl–Neelsen or auramine fluorescent stain, which provide a quick diagnostic method, but with low sensitivity. Additionally, a smear does not differentiate atypical mycobacteria from *M. tuberculosis*. The identification of typical necrotizing granulomata on histopathological examination strongly suggests the diagnosis.

Culture from an aspirate or biopsy is the gold standard for diagnosis. It is important to avoid culturing fistula fluid because of the presence of secondary infections, which may confuse the diagnosis. Culture is time consuming but it allows assessment of drug sensitivity. Liquid-based media culture give quicker results than conventional solid-based media. With the use of automated liquid culture systems, positive results may be obtained within 2 weeks.[6,7]

Nucleic acid amplification using polymerase chain reaction (PCR) techniques is more sensitive than AFB staining, and quicker than cultures. Experience in using this method in skeletal TB is still accumulating. Reports suggest a sensitivity of 78% and specificity of 100%.[10] This technique detects the presence of the mycobacteria regardless of their activity, and this should be taken into account when interpreting the results.

Imaging studies

Imaging may aid the diagnosis. The sensitivity and specificity varies between imaging techniques and correlation with clinical pictures is required. Radiographs have low sensitivity early in the disease. Ultrasound and MRI scan are the main imaging modalities in diagnosis and assessment of bursitis, myositis, and tenosynovitis. Isotope bone scintigraphy can help in localizing the infection, but false-negative results were reported in 35% of cases of spinal disease.[3]

Spine

Plain radiographic changes require 3–5 months to develop with destruction of about 50% of trabecular bone occurring before changes are detected.[8] Disc space narrowing and demineralization of endplates occur. Erosions without reactive sclerosis are characteristic of TB infection. Scalloping of the vertebra results from the presence of a paraspinal abscess.[3] Asymmetry of the psoas shadow may be seen.[9] Later, wedge fracture develops.

CT identifies the extent of bone and soft tissue disease, vertebral fragmentation (exploded vertebra appearance),[8] and the presence of paraspinal abscesses. The presence of calcification within a paraspinal abscess is characteristic of TB infection.[5]

MRI is the modality of choice, with a sensitivity of 100% and specificity of 88%.[7] MRI detects early bone marrow oedema, disc involvement, and endplate changes. Relative preservation of the intervertebral disc (floating disc), disruption of the endplate, and the presence of paravertebral soft tissue are features with high sensitivity and specificity.[7] It is also useful in the assessment of soft tissue disease (cold abscesses, horseshoe appearance), and the cause and extent of neurological involvement.

Tuberculous arthritis

The features on plain radiography are usually non-specific. The Phemister triad is a combination of juxtaarticular osteopenia, peripheral osseous erosions, and gradual loss of joint space, and is suggestive of TB arthritis.[11] Osteolytic lesions and cartilage loose bodies occur as the disease progresses. Occasionally wedge-shaped

areas of necrosis are present on both sides of the joint (kissing sequestra).[11] MRI is the modality of choice for early diagnosis. The synovial membrane typically is hypointense on T2-weighted images and enhanced with gadolinium.[8]

Osteomyelitis

Osteopenia and osteolytic lesions with little or no periosteal reaction are demonstrated on plain radiography.[3] Multiple oval lesions are observed in the cystic form.[11] In dactylitis, cystic expansion of the bone with coarse trabecular pattern and periosteal reaction occur, this appearance is termed spina ventosa.[8] MRI scan allows a detailed assessment including sinus tracts and abscesses.

Treatment

The mainstay of treatment is chemotherapy. Surgery plays a supportive role in selected cases. Anti-tuberculosis drugs have excellent tissue penetration in bone and joint, and chemotherapy is effective in 90% of cases. Compliance is important to avoid developing drug resistance.[9]

The first-line drugs used in treatment of TB are isoniazid, rifampicin, ethambutol, and pyrazinamide. Treatment regimens usually consist of two phases, an initial phase and a continuation phase. Treatment should include isoniazid and rifampicin throughout, in addition to ethambutol and pyrazinamide for the initial 2 months. Daily regimens are recommended.

Monitoring for side effects is important. Baseline full blood count, kidney function, and liver function should be obtained. Liver function should be monitored in the presence of pre-existing liver disease or significant risk factors. Visual acuity and green–red discrimination should be monitored with ethambutol.[12,13] The physician should be alert to possible interactions, especially between rifampicin and HIV treatment.[13] Treatment should be continued for 6–9 months in extraspinal TB.[2,12,13] The length of treatment in spinal disease is controversial. The Medical Research Council trials suggested that uncomplicated spinal TB can be treated successfully with multidrug regimens for 6 months. However, many argue that treatment should be at least for 9 months to reduce relapse rates. In complicated cases 12–18 months treatment may be required.[7,9] MDR TB (resistance to isoniazid and rifampicin) is suspected when improvement is delayed, with continuous bony destruction or the appearance of new lesions after 3–5 months of treatment.[7] Every effort should be then made to ascertain sensitivity. Treatment is with 4–6 drugs for at least 24 months in spinal disease.[7] Surgery may play a role in these patients.

Surgical treatment is usually reserved for resistant disease and complications. In spinal disease, intervention should be considered with the development or worsening of neurologic deficit. Other indications for surgery include panvertebral disease, spinal instability, or significant kyphosis.[7] In joint disease osteotomy, arthrodesis, and joint replacement may be indicated.[9]

Tumour necrosis factor inhibitors and tuberculosis

The introduction of tumour necrosis factor (TNF) inhibitors for the treatment of rheumatoid arthritis (RA) is associated with an increased rate of latent TB reactivation. The risk is three- to fourfold higher with infliximab and adalimumab compared to etanercept. There is an increased incidence of extrapulmonary and disseminated TB.[14,15]

Patients starting treatment with TNF inhibitors should be monitored closely for signs of TB reactivation, especially within the first year. Reactivation may occur after cessation of treatment, and monitoring should continue for at least 6 months afterwards.

All patients should be screened for the presence of latent TB before initiating TNF inhibitors. Identification of risk factors, history of previous exposure or infection, and a chest radiograph are mandatory. Tuberculin skin test is even less reliable in patients on immunosuppressive treatment, and false-negative rates are more frequent. IGRAs are more sensitive in these patients, and are recommended. If TNF inhibitors are indicated in cases of previous exposure, infection, or evidence of latent or active TB, they should be managed in close liaison with a TB specialist.

Atypical mycobacterial skeletal infection

Skeletal infections with atypical mycobacteria occur mainly through direct inoculation after trauma, surgical intervention, or intraarticular corticosteroid injections. Haematogenous dissemination with multifocal disease is encountered in immunocompromised patients.[4] Unlike *M. tuberculosis*, atypical mycobacteria are present in the soil and water and are not obligate parasites.[4] Synovitis and tenosynovitis are most commonly caused by *M. avium-intracellulare*, *M. haemophilum*, and *M. marinum*. Joint disease was also reported less commonly with *M. fortuitum*, *M. abscessus*, *M. chelonae*, and *M. kansasii*. Osteomyelitis has been reported particularly following surgical procedures. These microorganisms are usually resistant to conventional anti-tuberculosis drugs. Multidrug regimens containing azithromycin, clarithromycin, fluroquinolones, or aminoglycosides may be used depending on the sensitivity of the mycobacteria. Rifampicin is also used in *M. avium-intracellulare* and *M. haemophilum* infections. *M. kansasii* responds to treatment with isoniazid, ethambutol, and rifampicin. Prolonged durations of treatment in addition to surgical excision and debridement are usually required.[16]

Leprosy (Hansen's disease)

Epidemiology

In 2010, 228 474 new cases of leprosy were reported to WHO from 130 countries around the world.[17] The prevalence of leprosy has been falling over the last decade, but it is still the leading infectious cause of disability worldwide. At the time of diagnosis, nerve damage is already present in one-third of cases.[18] Leprosy can affect people of any age, but it is extremely rare in those younger than 1 year old. In adults lepromatous leprosy is commoner in males, with a male to female ratio of 2:1. In children tuberculoid leprosy is usual.[19] HIV infection does not increase the risk of infection and is not associated with more severe manifestations or treatment resistance.[20]

Pathogenesis

Leprosy is mainly caused by *M. leprae*. A newly identified mycobacterium, *M. lepromatosis*, may also cause lepromatous leprosy. Humans are the main reservoir of the pathogen. The mode of transmission is not well established, but is most likely through respiratory droplets from person to person. The possibility of transmission from animals was suggested with the identification of a strain of *M. leprae* in the southern United States, which infects both wild armadillos and humans.

Most individuals exposed to leprosy do not develop the infection. The risk increases in close household contacts, especially with

increased bacterial load.[18] Genetic factors play a role in the susceptibility to the infection and the clinical expression of the disease.[19]

The interaction between *M. leprae* and the immune system of the host accounts for the variation in clinical manifestations of leprosy. In tuberculoid leprosy, evidence of specific cell-mediated response is present, with formation of organized granulomata with predominance of CD4+ T cells and a positive lepromin skin test. In lepromatous leprosy, there is evidence of a humoral but not cell-mediated response to *M. leprae*. Granulomata are absent in the lesions with preponderance of CD8+ T cells and the skin test is negative.[19,20]

Clinical features

M. leprae has a predilection for Schwann cells and macrophages. The incubation period varies from only few months to decades. The disease progresses slowly, mainly affecting the skin and peripheral nerves.

In tuberculoid leprosy, there are few asymmetrical macules with low numbers of bacilli. These macules are usually well defined, dry, and hypopigmented with reduced sensation. Neuropathy is asymmetrical with thickening of the involved nerve and early loss of sensory and motor function. The ulnar and common peroneal nerves are most commonly affected. In lepromatous leprosy, macules, nodules, papules or plaques may occur. They are numerous and symmetrical. High bacterial load exists in nasal secretions and skin lesions. Saddlenose deformity from septal perforation, keratitis, iridocyclitis, and testicular scarring and atrophy occur. Symmetrical peripheral neuropathy develops gradually, later in the disease. Intermediate forms of the disease exist in between these two polar types.

Leprosy reactions are episodes of acute inflammation, which interrupt the course of the chronic disease, possibly resulting in major nerve damage. Concurrent infection, pregnancy, and physical and emotional stress are some of the predisposing events. Reactions may occur after initiation or completion of treatment.[18] There are two types of leprosy reactions:

- **Type 1 reactions** are cell-mediated immune reactions. They occur in borderline forms of leprosy resulting in neuritis, formation of new skin lesions, and inflammation of existing ones. They may occur after treatment initiation (reversal reaction) or in the context of worsening immunity (downgrading).

- **Type 2 reactions** (erythema nodosum leprosum) are immune complex mediated. They occur in multibacillary disease, usually within 2 years after starting treatment, and present with systemic symptoms, fever, tender nodules, arthritis, eye symptoms, and neuritis.[18,19,21]

Skeletal involvement in leprosy occurs as a consequence of peripheral neuropathy. Neuropathic arthropathy results in joint destruction in weightbearing joints, hands, and feet. Ulcers and secondary infections complicate the picture. A 'licked candy stick' appearance on plain radiographs occurs from tapering osteolysis. Resorption of digits and toes may occur. Polyarticular inflammatory arthritis occurs during leprosy reactions. It is usually short lived, mainly affecting hands and feet. A chronic inflammatory arthritis mimicking rheumatoid arthritis, sacroilitis, and tenosynovitis have also been reported.[21]

M. leprae osteomyelitis is rare; it usually results from direct extension of the infection from the overlying skin. Haematogenous spread is less common.

Classification of leprosy

The Ridley and Jopling classification identifies five forms according to the clinical and histopathological features: two polar forms, tuberculoid (TT) and lepromatous leprosy (LL), and three intermediate forms, borderline tuberculoid (BT), mid-borderline (BB), and borderline lepromatous (BL). Classification systems proposed by WHO rely either on skin smear results or the number of skin lesions. In paucibacillary disease, skin smears are negative at all sites. The presence of positive smears at any site indicates multibacillary leprosy. Classification according to the number of skin lesions is used to determine the treatment regimen:

- **paucibacillary leprosy**: five or fewer skin lesions

- **multibacillary leprosy**: six or more skin lesions.

Investigations

A clinical diagnosis of leprosy can be made in the presence of one of the following features:

- the presence of a skin lesion consistent with leprosy, with definite loss of sensation, with or without nerve thickening

- positive skin smears or tissue biopsy.

Identification of the pathogen on microscopy in slit-skin smears, usually taken from a peripheral site (earlobes), nasal smears, tissue biopsies, or synovial fluid is the gold standard for diagnosis but sensitivity is low in paucibacillary disease. Culture of *M. leprae* is not used in routine practice, as the organism can only be cultured in murine footpads and armadillos and not *in vitro*. Several months are required for positive results. The detection of antiphenolic glycolipid-1 antibodies (PG-1) may assist the diagnosis. They are positive in 90% of LL, and 40 to 50% of paucibacillary disease.[21] *M. leprae* identification using PCR is a sensitive tool but is not routinely used in clinical practice. The lepromin test is positive in tuberculoid leprosy, indicating the presence of cell-mediated immunity.

Treatment

Multidrug treatment should be used to avoid the emergence of drug resistance. Reconstructive surgery may improve the functional outcome and reduce residual disability.

The regimen recommended by WHO includes dapsone 100 mg/day and rifampicin 600 mg once a month for 6 months in paucibacillary disease. In multibacillary disease, clofazimine 300 mg once a month and 50 mg/day is added to this regimen; treatment should continue for a year. A single skin lesion is treated with one dose of rifampicin 600 mg with ofloxacin 400 mg, and minocycline 100 mg.

The treatment of leprosy reactions aims to control symptoms and reduce nerve damage. Symptomatic treatment may suffice in mild cases. Relapse occurs frequently and monitoring is required.[18] Type1 reaction is treated with high-dose oral steroids, reduced every 2–4 weeks for 4–6 months.[19] In severe or recurrent type 2 reactions, high-dose corticosteroid is usually needed for 3 months. Clofazimine is used if the response is unsatisfactory or there are significant side effects with corticosteroids. Pentoxifylline can also be used in these cases. Thalidomide is effective especially in reducing recurrence, however, it is not recommended by WHO because of the risk of malformations associated with its use in pregnancy.

Patient on anti-leprosy drugs should not stop their treatment during reactions.

Brucellar arthritis

Esperanza Merino and Eliseo Pascual

Introduction

Infection of the joints is the most frequent local complication of brucellosis, and a common cause of infectious arthritis in countries where the disease is endemic.

Epidemiology

Brucellosis is a worldwide zoonosis that has affected humans for at least 2000 years[1] and has managed to elude eradication even in most developed countries. Renewed scientific interest has been fuelled by its recent re-emergence and enhanced surveillance in many areas of the world.[2] More than 500 000 new cases occur annually, but it is estimated that the number of brucella-infected individuals may be up to 26 times higher, because brucellosis remains underdiagnosed and under-reported.[2]

The disease is prevalent in countries of the Mediterranean basin, the Near East, South America, and possibly sub-Saharan Africa. The epidemiology has now changed significantly because several areas traditionally considered to be endemic have achieved control of the disease.

In northern Europe the disease is considered to have been eradicated. In southern countries its incidence has reduced greatly, although small areas remains endemic in the south of Spain, Italy, and around Portugal. However, in many Asian republics of the former Soviet Union, the Balkan peninsula, and Turkey it remains a major public health problem. In the United States cases of brucellosis occur mostly in California and Texas due to ingestion of unpasteurized products or related to travel to endemic areas in Mexico. Most areas of Latin America have achieved control of the disease but in Mexico, Argentina, and Peru the disease remains endemic. Nowadays infection is acquired during foreign travel or from consumption of infected marketed dairy products, mainly in immigrant populations.

In endemic countries brucellosis is more prevalent in the 15–35 year age group,[3] but in Western countries the age-specific incidence was highest in persons 60–69 years of age, mainly first-generation immigrants who keep closer contact with their homelands.[4] Male predominance is observed only in the working age group and in countries where brucellosis is related to occupational exposure.

Brucellosis occurs naturally in domesticated animals, and its transmission to humans most often occurs through consumption of infected, unpasteurized dairy products (especially raw milk, soft cheese, butter, and ice cream), direct contact and care of infected animals (sheep, cattle, goats, pigs), or inhalation of their secretions.[5] Patients often recall possibly infected animals or their unpasteurized products, but this evidence may be missing. The disease can be accidentally acquired by laboratory personnel.[6] Rare human-to-human transmission has been reported.

General characteristics of the organism

Brucella species are small, non-motile facultative intracellular aerobic rods that can multiply within phagocytic cells with humans as end hosts. Gram staining demonstrates single, tiny, Gram-negative coccobacilli. Brucella species can survive 2 days in milk at 8 °C, up to 3 weeks in frozen meat, and up to 3 months in goat cheese. They remain viable in animal excretions for more than 40 days, but are sensitive to heat, disinfectants, and pasteurization. Brucella are slow growing and require specific culture conditions, including prolonged incubation (as long as 30 days in some media).

There are six brucella species, four of which are recognized human zoonoses: *Brucella melitensis, B. abortus, B. suis*, and *B. canis*. The majority of human cases worldwide are attributed to *B. melitensis* and in general, *B. melitensis* and *B. suis* are more virulent for humans than *B. abortus* or B. *canis*.[5] The complete sequencing of the *B. melitensis*, *B. abortus*, and *B. suis* genomes was achieved in 2001–2.[7]

After infection, brucella are readily ingested by polymorphonuclear leucocytes and macrophages, reaching local lymph nodes; the organisms replicate intracellularly and bacteria from lysed cells can infect other cells or disseminate systemically. A majority of brucella are rapidly eliminated by phagolysosomal fusion, but 15–30% survive.[6,8,9] During the intracellular stage, brucella display a range of survival strategies to suppress host immune response: they can inactivate the innate immune system, withstand the direct action of complement and other bactericidal substances, and evade the action of polymorphonuclear cells and macrophages. Brucella can establish long-lasting infection within host cells, and they promote the chronicity of infection. Cell-mediated immunity appears to be the principal mechanism of recovery and partial resistance to subsequent reinfection. Interferon-gamma activates the bactericidal function in macrophages to hamper the intracellular survival of brucella, then cytotoxicity of CD8 and gamma-delta T cells destroys the infected macrophages and finally Th1-type antibodies

opsonize the pathogen to facilitate phagocytosis.[10] Antibody response, although important for diagnostic purposes, appears to play a minor role in the immune response to the infection.

In humans, brucella infection results in the formation of non-caseating sarcoidosis-like granulomas, consisting of epithelioid cells, polymorphonuclear leucocytes, lymphocytes, and some giant cells. The granulomatous response is typical of *B. abortus*, the granulomas produced by *B. melitensis* are very small, and *B. suis* infection is accompanied by chronic abscess formation.[11]

General characteristics of the disease

Human brucellosis is a systemic infection that may present with a broad spectrum of clinical manifestations and its complications can affect almost all organs and systems. The manifestations of the disease are non-specific, and no combination of signs or symptoms can be considered as characteristic.[12] The bulk of human disease is caused by *B. melitensis* and *B. abortus* and their clinical presentation is similar, although comparative studies are few. The incubation period after contact is usually 1–4 weeks although it may be as long as several months; localized disease may present after an asymptomatic/paucisymptomatic undiagnosed acute phase.[6,13] Epidemiological data suggest that brucellosis occurs in 40–50% of contacts.[3] The term 'chronic brucellosis' was coined in the preantibiotic era, referring to patients with persistent symptoms of disease after treatment of brucellosis, but in the majority a bacteriologically proven relapse or localized disease can be diagnosed.

Insidious onset of fever is almost universal with night sweats (with a peculiar, mouldy odour) followed in 40–50% by arthralgias, myalgias, and low back pain or arthritis.[14] Constitutional symptoms—weight loss, weakness fatigue, malaise, and headache—occur in 20–40%. Hepatosplenomegaly is found about one-third of patients, and lymphadenopathy in about 10%. Other manifestations including neurobrucellosis, endocarditis, hepatitis, and epididimo-orchitis may occur. Childhood brucellosis generally exhibits a more benign course in terms of the rate and severity of complications.[15] Subclinical disease occurs, and may heal spontaneously, but patients may present with relapses following previous subclinical disease, or with late, localized complications, simulating a very long incubation period.

Relapse following treatment occurs in about 5–15%, generally within the first 6 months after treatment, and it has been related to inadequate choice of antibiotics, shortened treatment duration, poor compliance, or localized infection.[16]

Brucellar arthritis

General considerations

Arthralgia is more common in brucellosis than in other febrile illnesses. It has been recorded in 70% of patients with brucellosis, with similar frequency in children or adults[3]; its presence may be a clue to the disease.

Bone scinitigraphy in patients with brucellosis and musculoskeletal symptoms has been reported as being frequently abnormal, often in multiple sites; some of the minor musculoskeletal symptoms of these patients may result from localized infection. Since the treatment of brucellar arthritis and that of uncomplicated brucellosis is the same, once brucellosis is diagnosed, it is not worthwhile searching for arthritis to explain minor or unclear musculoskeletal symptoms.

The reported prevalence of ostearticular involvement ranges from 20% to 60%: 20% in Spain,[17] 28.5% in Iran,[18] 42% in Greece,[12] 47.7% in Saudi Arabia,[19] 59.2% in Macedonia,[20] 25.3% in Turkey,[3] and 25% in the United States.[21]

The bulk of musculoskeletal involvement is most often large joint, sacroiliitis, and spondylitis. The frequency varies according to the characteristics of the reported patients; in general sacroiliitis predominates in younger adults and as a result of *B. mellitensis* infection, while spondylitis is observed in older patients, and peripheral arthritis occurs in all ages, predominating in children and young adults. The discrepancies in the frequency and distribution of ostearticular brucellosis relate to the characteristics of the examined population, stages of the diseases, diversity of definition of the cases, nature of the causative agent, and diagnostic procedures undergone, as well as the prospective/retrospective nature of studies.

Arthritis of peripheral joints

Large peripheral joints are a common site of localized infection. In all age groups, the hip is the most common location, followed by the knee. Ankles, shoulders, elbows, wrists, and sternoclavicular joints contribute a small percentage of cases. Although brucellosis arthritis is generally monoarticular; oligoarticular and polyarticular arthritis have been reported in one-fifth to one-half of the patients with arthritis.[22–25] Involvement of the small joints of hands and feet is rare, although a 'rheumatoid like' distribution may occur.

Peripheral joint arthritis often, but not necessarily always, predominates over other disease manifestations. It usually occurs during the acute phase of the disease or during a relapse, and fever or other general symptoms of the disease frequently accompany the arthritis, which tends to be symptomatic from the start; so the patients tend to seek prompt medical attention. The joints are swollen and painful, and an effusion is generally seen. Joint inflammation is not as intense as it is in some septic arthritides due to pyogenic organisms, and there is seldom obvious redness or unusual warmth in the skin. Six cases of arthritis of in prosthetic joints have been reported.[26] Local complications, such as popliteal cyst rupture also occur.[24]

If diagnosis or treatment is delayed the joint is damaged, resulting in radiological abnormalities with joint space narrowing and damage to the joint surfaces, similar to other infectious arthritides. The interval between initiation of infection and the appearance of structural damage in the joint tends to be longer than in pyogenic arthritides, but probably shorter than in tuberculosis. The sequelae of infection depends on timing of treatment; when treatment is started early enough, no sequelae develop.

Bursitis and tenosynovitis due to *B. melitensis*, *B. abortus*, and *B. suis* may also occur.

Sacroiliitis

The sacroiliac joint is frequently involved. The incidence ranges from 30% to 75% in recent series[3,18,22]; in our own experience in Spain it is 36%. Sacroiliitis is uncommon in children and seems an unusual complication of *B. abortus* and *B. suis*.

Sacroiliitis tends to occur in the acute, febrile phase of the disease, is usually unilateral but can be bilateral, and is usually symptomatic from the start[27]; other joints can be simultaneously affected. In some patients the pain becomes so intense that for two or three days they can hardly move from the bed,[28] and many have severe

pain when walking. Radiation of pain to the buttock, posterior thigh, and even below is not unusual. In these patients, any movement of the leg is very painful, and hip manoeuvres or straight leg elevation may seem positive: in this setting, clinical differentiation of sacroiliitis from hip disease or sciatica may be difficult. Gently tapping on the lower surface of the heel while the patient keeps the leg extended usually localizes the pain to the sacroiliac area. Other sacroiliac manoeuvres may result too painful and be difficult to interpret. Evaluation of patients with less intense symptoms is easier with standard manoeuvres.

Radiological exploration in the early stage of disease is normal, but within 2–3 weeks radiological abnormalities such as blurring of the subchondral osseous line, narrowing and widening of the interosseous line, and narrowing and widening of the interosseous space (changes which are similar to septic sacroiliac arthritis) are observed (Figure 104.1). Bone scintigraphy provides early evidence of sacroiliitis in most cases (Figure 104.2).[22] MRI may detect early bone marrow oedema and intra-articular synovial fluid.[29]

Symptoms ease rapidly after introduction of antimicrobial treatment, indicating its infectious nature, and no sequelae or later joint disease occurs. Though possibly very painful, brucellar sacroileitis is a mild disease associated with a good outcome similar to that observed for patients with uncomplicated brucellosis.

Spondylitis

Brucellar spondylitis is most often seen in adult and elderly patients, frequently men (probably due to a higher frequency of occupational disease in many countries and not a real sex difference). Reported percentages vary according to the characteristics of the series and are higher in series where bone scintigraphy has been used for diagnosis reaching 50% of the musculoskeletal focal disease.[22] The lumbar spine is most frequently affected, followed by dorsal and less frequently cervical spine.[30,31] In contrast to peripheral arthritis or sacroiliitis, spondylitis is often a later feature. In a prospectively collected series of 96 patients 91% were febrile and 88% had chills or rigor,[30] but patients may also present with only vague symptoms of a general infectious disorder, and be afebrile.

Systemic features tend to occur when spinal infection presents shortly after disease onset. Presentation of spinal disease is often insidious, and its hallmark is local pain of variable intensity, often moderate, which may allow the patient to maintain a fairly normal life. Pressure or percussion of the spinous processes of the affected

Fig. 104.2 Bone scan of the posterior pelvis of a patient with left brucellar sacroiliitis of short duration and normal radiograph.

vertebrae often reproduces the pain and paravertebral muscles may be tender. Cord or nerve root compression due to epidural abscesses (more frequent in cervical spondylitis) can occur. Small paravertebral abscesses or paravertebral masses are frequent and psoas abscesses occur.[30] These abscesses clear with medical treatment. The newer imaging techniques allows easy detection of lesions that were formerly overlooked. Material obtained from the abscesses is usually sterile. Some patients can develop epidural abscesses from the infected disc space. Compression of the medulla or nerve roots is found more frequently in cervical spondylitis, which should be considered a severe manifestation of the disease.

In the very early phase, radiography of the affected segments is normal. After 2 months, nearly all patients show radiographic alterations. The first sign is narrowing of the disc, without bone abnormalities. Later, two different changes are seen in the limiting vertebral endplates: a limited form with an erosion, generally in the anterosuperior vertebral angle, with sclerotic base, which is considered to be characteristic of brucellar spondylitis (Figure 104.3); and a diffuse form, in which the corresponding vertebral endplates show erosions, accompanied by narrowing of the disc space (Figure 104.3). Early signs of repair occur, with the appearance of osteophytes. Both pathological and radiological data suggest that the infection begins in the vertebra, and then spreads to the disc. In a series of 35 patients with brucellar spondylitis in whom MRI was carried out,[32] 32 of them had involvement in only a single spine region: 31 had diffuse disease of a disc space, two of them had focal disease at an anterior vertebral angle, and one had diffuse disease at a disc space and focal disease at another level. The two remaining patients had contiguous involvement of multiple levels (>2). Paraspinal masses were noted in 22/35, epidural masses in 27/35, and masses with root compression in 19/35. In this series one patient underwent laminectomy, but none developed neurological sequelae. Bone scintigraphy frequently shows increased uptake at the level of the affected disc space, even when radiologically normal.

Spondylitis heals with antimicrobial treatment (requiring a longer duration than in the other locations of arthritis) and residual pain may remain. Early diagnosis and treatment, and consequently less structural damage, are followed by a better recovery.

Fig. 104.1 Radiograph of the sacroiliac joints, showing widening and erosions of the right joint in a patient with long-standing brucellar sacroiliitis.
Fig. 104.3 Brucellar infection at the lumbar spine. (a) Lateral radiograph of lumbar vertebrae, showing an upper corner lesion, with sclerotic base in L4, considered characteristic of brucellar spondylitis. Reduction in the height of the disc space is also seen. (b) CT section across the upper vertebral plateau of L4 showing an anterior lytic lesion and adjacent soft tissue mass. (c) T1-weighted MRI showing a sagittal section: there is marked oedema in the bodies of the L3 and L4 vertebrae, narrowing of the disc space, and a mass bulging anteriorly; intravertebral lesions connected to the disc space are also seen. (d) Same sagittal cut, gadolinium enhanced. Areas of inflammation are now seen light, including the intravertebral lesions indicating that they are vascularized, and an anterior dark abscess is seen.
Figure kindly provided by Dr Jaime Fernández Campillo.

Diagnostic investigations

Clinical approach

The clinical features of brucellosis are non-specific. The manifestations of brucellar joint disease are similar to those of other infectious peripheral or axial arthritides, and may also resemble some inflammatory arthritides; presentation can be acute, but usually less than pyogenic infections. Nevertheless, in the following circumstances, appropriate testing for brucellosis should always be done:

- in all undiagnosed arthritides, with features fitting those of brucellosis, occurring in areas where the disease is endemic, or in patients with a history of possible exposure to the disease through travel to endemic areas, ingestion of possibly contaminated imported products, or in exposed laboratory workers

- in all cases of undiagnosed acute unilateral sacroiliitis

- in all cases of undiagnosed disc-space infection, especially those with radiological evidence of localized vertebral angle infection, or infection of multiple levels.

About 25% of patients do not recall exposure to possibly infected animals or unpasteurized dairy products.

Due to the lack of a single standardized laboratory test, diagnosis of human brucellosis remains difficult. Brucella cultures require special prolonged processing and have a low yield. Serology is more rapid and effective, although there is not an internationally standardized test since adequate cut-off points have to be defined for each test and for different populations (related to endemicity). In the near future, molecular techniques may revolutionize the laboratory diagnosis of human brucellosis.

General laboratory features

The laboratory features of brucellosis are non-specific. Although white blood cell counts are usually normal, leucocytosis is observed in about 9% of patients and if found, focal disease should be considered. Leucopenia and thrombocytopenia are seen with similar frequencies (10%) and anaemia in 25%.[33] Minor abnormalities in hepatic enzymes are common.

The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are usually elevated[18,20] and normal values are not unusual in late and localized forms such as spondylitis.

There were no significant laboratory differences between brucellosis with or without osteoarticular forms, except for a higher rate of anaemia in patients without osteoarticular involvement.[18]

Synovial fluid analysis

Published data of synovial fluid analysis in brucellar arthritis are scarce. Unlike bacterial arthritis caused by other microorganisms, in brucellar arthritis, the synovial fluid leucocyte count is frequently less than 50 000/mm^3, with a predominance of lymphomononuclear cells.[26,28,34,35] and 6000–18000/mm^3.

Glucose levels were within normal limits in the above series. Lactic acid levels have also been found to be normal. *B. melitensis* has been isolated from some of the above synovial fluids. Our own unpublished data from 18 prospectively studied patients showed different results. The cell counts were 3200–90000/mm^3; glucose was low in some of the fluids (0–100 mg/dL, (mean 47) and lactic acid was also high on a few occasions (13–138 mg/dL, (mean 74). *B. melitensis* was recovered from 73% of those fluids, many cultured in blood culture flasks and many with cell counts suggestive of non-infectious inflammatory synovial fluid.

Bacteriological diagnosis

Isolation of brucella

Definitive diagnosis of brucellosis requires isolation of brucella from blood, synovial fluid, or other sources, and should always be attempted when the disease is suspected. It provides a definitive diagnosis, and the possibility of differentiating *B. melitensis*, *B. abortus*, and *B. suis*, which is not possible with the usual serological tests, although subtyping of brucella species is not necessary for treatment.[36] Due to the specific requirements of brucella isolation, the laboratory should be warned when brucellosis is a possibility. Isolation rates are variable depending on the stage of disease, previous use of antibiotic, the clinical specimen, and the culture methods.[36] Bacteraemia is an early event in brucellosis, so isolation rates are much higher during first 2 weeks of symptoms (80–90% in acute forms, and 30–70% in more chronic cases), also depending on the technical approach.[37] The recovery rate of brucella is improved when blood samples are taken in the pyrexial phase and by collecting multiple blood samples or material from infection sites; bacterial isolation is also highly dependent on the total volume of the sample.[36] Bone marrow culture is considered the gold standard for the diagnosis of brucellosis, since it is more sensitive than blood cultures, the time to detection is shorter, and the sensitivity is not reduced by prior use of antibiotics.[36]

Brucella are slow-growing organisms, often requiring longer incubation. Although they will grow in the usual media the rate of recovery is low and different enriched media, prolonged culture times, and subcultures have been used. The classic biphasic (solid and liquid) Ruiz-Castañeda blood culture medium is still in use but growth is slow and may require up to 30 days; it is a simple medium that does not require special laboratory conditions. Semiautomated methods are more effective, considerably shortening the time to detection (<4 days).[38] Recovery of brucella from body fluids is higher using this blood culture system, and it has been recommended to inoculate synovial fluid in blood culture flasks and processed in automated blood culture systems.[26]

Despite the better performance of these culture systems, a prolonged incubation period and periodic subcultures for at least 4 weeks are still recommended to reliably exclude a brucella infection. The lysis-centrifugation technique provides rapid diagnoses (2–3 days) and has higher sensitivity independent of the stage of illness.[26,39,40] The newer continuous monitoring methods are advantageous because of their shorter time to detection.[36] Colonies suspicious for brucella can be confirmed with a commercially available biochemical test such as API 20 NE or semiautomated metabolic biotyping systems that facilitate the rapid detection from culture, minimizing the risk of laboratory infection.[36] Matrix-assisted laser desorption/ionization mass spectrometry has proved to be very useful in the direct identification of members of the genus brucella from culture plates and blood culture bottles in few minutes.[41]

Serological diagnosis

Attempts to isolate brucella from blood or other sources are not always successful; besides, culture may require a long incubation period and still show no growth. In these circumstances, the possibility of a simpler and more rapid serological diagnosis remains very attractive. But due to the lack of a single reliable laboratory test, the unavailability of international standardization, the high background prevalence of anti-brucella antibodies in endemic countries, and long-term persistence of significant antibody titres after successful treatment, human brucellosis remains difficult to diagnose.[36] The serum agglutination test (SAT) remains generally accepted as the reference method in the serological diagnosis of brucellosis. The antigen used is generally obtained from *B. abortus*, and it reacts against *B. abortus*, and *B. melitensis*, and *B. suis*, but does not allowing differentiation among them. The non-cross-reacting *B. canis* serological diagnosis requires specific antigen preparations.[42]

The SAT detects agglutination antibodies against brucella in serum; SAT titres greater than 1:160 in non-endemic areas or greater than 1:320 in endemic areas are considered as consistent with active brucellosis if accompanied by clinical symptoms. A four-fold or greater rise in brucella agglutination titre between acute and convalescent phase serum (>2 weeks apart) studied at the same laboratory may prove infection. Definitive cure correlates well with lower SAT titres, although 3–5% of clinically cured patients maintain significant SAT titres. False negative rates are high (1) in the early course of the disease (even bacteraemic patients may present with titre <1:160); (2) in the setting of immunosuppression; and (3) in the presence of blocking antibodies or the so-called 'prozone' phenomenon (inhibition of agglutination at low dilutions due to an excess of antibodies, detected by the brucellar Coombs test) that occurs in late or focal brucellosis or during relapses. These blocking antibodies increase over agglutinating antibodies along the course of infection and the Coombs test is routinely recommended as an extension of the SAT.

Enzyme-linked immunosorbent assay (ELISA) allows a better interpretation of the clinical situation; besides, the measurement of specific antibodies may detect occasional patients undiscovered by other serological tests.[36] ELISA is more sensitive than SAT in chronic and past brucellosis, but in acute cases SAT show the same results and is simpler and less expensive.[36]

The Rose Bengal test (RBT) is a rapid slide-type agglutination assay and because of its simplicity is used as screening test for human brucellosis. Although overall sensitivity and specificity reported by RBT varies widely in a recent review comparing 208 sera from patients with brucellosis, 20 contacts with no brucellosis and 1559 controls, a diagnostic titre greater than 4 in the RBT resulted in 87.4% sensitivity (infected patients) and 100% specificity.

The simplicity and affordability of the RBT make it close to the ideal test for screening, especially for small hospitals and laboratories.[43]

The classical serologic tests, such as the SAT and Coombs test, are labour-intensive and time-consuming. Brucellacapt (Vircell, Granada, Spain) is a simpler test showing better reproducibility that detects total anti-brucella antibodies. It has been shown to be superior to the SAT in all stages of disease including relapses and has a similar yield to the Coombs test; it is recommended for use in endemic countries.[44,23,45,46]

Treatment

There have been three important recommendations in recent times: WHO/FAO (WHO 2006),[47] the Ionnina recommendations for the treatment of human brucellosis,[48] and a *BMJ* review on the subject.[49] As first-line treatment for uncomplicated brucellosis all recommended combined regimens include doxycycline for 6 weeks (Table 104.1). WHO recommended adding rifampicin for 6 weeks, however, it has become apparent that aminoglycosides are a better choice than rifampicin and at Ionnina the recommended first choice added streptomycin (2–3 weeks) to doxycycline. Besides this, the doxicicline–rifampicin combination has been widely used because of the difficulties of administering streptomycin in less well-resourced areas. Because of the greater availability of gentamycin and its lesser ototoxicity the *BMJ* review recommends 2 weeks of gentamycin added to the 6 weeks of doxycycline based on extensive studies which support the combination.[50,51]

Interestingly, it has been shown that brucella isolated from relapsing patients shows similar sensitivities to those of the original isolate,[52] and the limited capacity to produce resistance has been confirmed in more recent reports,[53] although drug resistance has been reported. Relapses or late, localized disease may result from insufficient duration of treatment, poor compliance, or unrecognized focal disease in apparently uncomplicated brucellosis and too short treatment. In any case uncertainties about brucellosis treatment remain, and better treatment regimens are required for patients with difficult or severe disease. In this setting triple therapy with either co-trimoxazole or a quinolone is added to a regimen of doxycycline/rifampicin or doxycycline/gentamycin has been used with promising results.

Brucella spondylitis

Most brucellar complications respond well to standard regimens; however, brucellar spondylitis, neurobrucellosis, endocarditis, and localized suppurative lesions warrant special consideration. An 'impossible meta-analysis'—described as such by the authors because of the heterogeneity of the studies on which it is based—on the results of the treatment of brucellar spondylitis concluded that what matters for the outcome is the duration of treatment, rather than the drug regimen used.[54] Although this meta-analysis did not conclude that streptomycin-containing regimens might be superior, the slight superiority of doxycycline/streptomycin (or gentamycin) in uncomplicated brucellosis underlines the frequent statement that the outcome of spondylitis may potentially be improved when such regimens are used. Although the optimal duration of therapy remains undefined, the available data supports a duration of not less than 3 months[48,30] and probably 6 months,[49,55] with streptomycin or gentamicin during the first 3 weeks. Large paravertebral or abscesses have been drained percutaneously with CT guidance, but they may also respond well to antibiotic treatment. Surgery has been reserved for exceptional cases or epidural abscess and progressive signs of neurological deficit. Lack of controlled trials in these less usual situations requires careful evaluation of the individual cases. Brucellar spondylitis has a good prognosis, and under medical treatment patients recover in 1–3 months. Brucella antibody titres have been recommended to assess therapeutic efficacy and resolution of the disease.[36] In peripheral arthritis regular drainage of the affected joints appears unnecessary, as it is done in pyogenic arthritis to avoid joint damage.

In children up to 8 years of age, co-trimoxazole plus rifampin for 4–6 weeks and doxycycline plus rifampicin in older children are the recommended treatments for uncomplicated brucellosis. In those with osteoarticular disease a regimen containing an aminoglycoside is considered more effective: co-trimoxazole for 6 weeks plus a parenteral aminoglycoside (gentamicin or streptomycin) for the first 14 days of therapy is recommended for children under 8 years of age, and for children over 8 year of age co-trimoxazole should be changeable for an oral tetracycline.[56] The systematic review and meta-analysis of randomized controlled trials made by Skalky supports the use of co-trimoxazole monotherapy for a prolonged period of time (up to 6 months), and this may be useful in some circumstances.

Prevention

Brucellosis may be prevented by vaccination of domestic animals. When the occurrence of brucellosis is controlled in animal reservoirs the incidence in humans show a significant decline, but this requires a sustained vaccination programme over several years. Vaccination for the prevention of human brucellosis is not available.

Postexposure prophylaxis after laboratory exposure to brucella isolates should be offered as soon as brucella exposure has been identified.

Table 104.1 Recommendations for the treatment of uncomplicated brucellosis in non-pregnant adults

	WHO 2006	Ioannina 2007[48]	BMJ 2008[49]
First-line regimen	Doxycycline+rifampicin 6 weeks	Doxycycline 6 weeks+ Streptomycin 2–3 weeks	Doxycycline 6 weeks+gentamicin 2 weeks or Doxycycline +rifampicin 6 weeks+ +gentamicin 2 weeks
Alternative	Tetracycline 6 weeks+ Streptomycin 2–3 weeks	Doxycycline+rifampicin 6 weeks	Doxycycline 6 weeks+ Streptomycin 2 weeks

CHAPTER 105

Parasitic infection

Olabambo Ogunbambi and Yusuf I. Patel

Introduction

Parasitism defines the relationship between two organisms, where the host provides both habitat and nourishment to the parasite. In order to establish itself within the environment of the host, the parasite must develop the ability to evade or tolerate the immune response of the host.[1] Pathogenicity depends on a variety of factors including host fitness and parasitic virulence.[2]

Immunity to parasites
