The high prevalence of comorbid conditions associated with gout (Table 141.1) necessitates consideration of these conditions when formulating a management plan for patients with gout. Gout may be considered a 'red flag' for future metabolic and CVD, and risk factors should be carefully addressed. This includes assessment of smoking status, BMI, blood pressure, serum creatinine, fasting glucose, and lipids. A focused, patient-centred approach to these risk factors is of benefit in patients with gout,[89] and includes weight loss strategies, promotion of physical activity, smoking cessation support (including nicotine replacement therapy), and pharmacological management of hypertension, dyslipidaemia, and diabetes. Despite its mild urate-elevating effects, low-dose aspirin should not be withheld in patients at high cardiovascular risk. Thiazide diuretics should be avoided for management of hypertension in patients with gout. Certain agents such as losartan, fenofibrate, amlodipine, and atorvastatin have modest urate-lowering effects and may be preferentially selected to manage relevant comorbidities in patients with gout.[9]

Case history 2

A 50 year old man has had recurrent gout flares for the last 15 years. He is currently experiencing gout flares every 2 months, usually in his feet or knees. He has had 2 weeks off work in the last year due to gout flares. He has a family history of gout affecting his father and paternal uncle. He is currently taking bendrofluazide, accupril, and felodipine for management of hypertension, and allopurinol 300 mg daily. He drinks 25 units of beer per week. Examination shows BMI 35 kg/m², blood pressure 150/90 mmHg, no tophi or synovitis. Serum urate is 0.45 mmol/litre (0.65 mmol/litre prior to starting allopurinol), creatinine 92 μmol/litre, eGFR 80 ml/min/1.73 m², total cholesterol/HDL ratio 8.2, fasting glucose 6.8 mmol/litre. Knee aspiration at the time of a previous gout flare has confirmed the presence of MSU crystals. What are the treatment options?

Comments: This man has recurrent gout flares with associated work disability. It is likely that his gout has occurred due to his genetic risk, obesity, diuretic use, and high purine intake. Serum urate-lowering below 0.36 mmol/litre is required to achieve dissolution of MSU crystals and suppression of acute gout attacks. Non-pharmacological therapy should include weight loss, avoidance of sugar-sweetened drinks, and reduction of beer intake. Prevention of gout flares can be achieved through low-dose colchicine prophylaxis (0.5 mg daily–twice daily), and intensification of his ULT. Adherence to allopurinol should be assessed. Provided adherence is assured, allopurinol dose should be gradually increased (by 100 mg monthly, to maximum dose 900 mg daily) to achieve a target serum urate. He also has poorly controlled hypertension, dyslipidaemia, and impaired fasting glucose. Management of these comorbid conditions includes screening for type 2 diabetes, stopping bendrofluazide, and commencing alternative anti-hypertensive agents such as losartan and amlodipine. Lipid-lowering therapy with atorvastatin should also be commenced.

Education and adherence

Despite the availability of effective therapies for gout management, this condition is often poorly managed, with low ULT prescription rates, infrequent monitoring of serum urate, poor adherence to ULT, and failure to achieve serum urate targets.[90] Suboptimal gout management leads to unnecessary pain, disability, and loss of productivity. Both practitioners and patients may contribute to poor gout management, and education of both groups is essential. A treat-to serum urate target is frequently effective in improving long-term gout management.[91] This approach allows both the health professional and the patient to determine the efficacy of treatment, which is particularly important in the early stages of ULT when the clinical benefits may not be immediately apparent. Practitioners need to provide appropriate education to patients, ensure continuity of ULT prescription, modify ULT according to serum urate results, and arrange careful monitoring of serum urate concentrations, to ensure that serum urate targets are achieved and maintained. Patients should also have an action plan to ensure prompt, safe, and effective management of flares. Patient education focusing on the central role of hyperuricaemia in MSU crystal formation, and the importance of serum urate reduction to a level below saturation levels is essential to ensure engagement and adherence to long-term ULT. Careful commencement of ULT at gradually increasing doses and with appropriate prophylaxis also plays an important role in ensuring that the patient continues with ULT long-term.

Conclusion

Gout is a common inflammatory arthritis caused by deposition of MSU crystals. This condition causes important musculoskeletal disability, and is frequently associated with major comorbid conditions. A number of treatments are available for effective management of gout, to manage and prevent acute flares, and to prevent the consequences of MSU crystal deposition. Long-term successful therapy of gout requires reduction of serum urate below saturation concentrations, at least below 0.36 mmol/litre.

Conflict of interest statement

Nicola Dalbeth has acted as a consultant to the following companies: Takeda, Ardea Biosciences, Novartis, Fonterra, Metabolex, Abbott Laboratories, Roche.

Calcium pyrophosphate crystal deposition (CPPD)

Edward Roddy and Michael Doherty

Introduction

Calcium pyrophosphate (CPP) crystal deposition (CPPD) in articular cartilage is a common age-related phenomenon. CPP crystals deposit almost exclusively within articular tissues, preferentially fibrocartilage, and are the most common cause of cartilage calcification (chondrocalcinosis, CC). In 1961, Daniel McCarthy first identified CPP crystals in synovial fluid obtained from acutely inflamed knees of patients with CC, leading to introduction of the term 'pseudogout', because of its clinical similarity to acute gout.[1]

Definitions and classification criteria

After the identification of CPP crystals as the cause of acute pseudogout by McCarty and colleagues,[1] other clinical phenotypes were soon recognized. Their descriptions were also prefixed by 'pseudo' and included 'pseudo-rheumatoid arthritis', 'pseudo-osteoarthritis' (with or without inflammation) and 'pseudo-neuropathic' arthritis in addition to 'lanthanic' (asymptomatic) radiographic CC.[2] Furthermore, the term 'pyrophosphate arthropathy' became increasingly used to describe CPPD occurring with coexistent structural osteoarthritis (OA). This expanding complex nomenclature caused considerable confusion over subsequent years, leading to inconsistent application of these terms. Furthermore, it is unclear whether all these syndromes are distinct, mutually exclusive subsets and whether CPP crystals are the causative agents in all subsets or are merely innocent bystanders. Also the prefix 'pseudo-' arguably implies that CPPD is of less interest and importance than other crystal arthropathies, principally gout.[3]

The European League Against Rheumatism (EULAR) CPPD Task Force has recently suggested a simplified terminology (Table 142.1),[4] proposing that:

- 'Calcium pyrophosphate dihydrate' crystals be simplified to **calcium pyrophosphate (CPP)** crystals, analogous to gout where 'monosodium urate monohydrate' is abbreviated to monosodium urate.
- **Calcium pyrophosphate deposition (CPPD)** should be used as an umbrella term for all instances of CPP crystal occurrence.

- **Chondrocalcinosis (CC)** is used to describe cartilage calcification of any cause including CPPD or basic calcium phosphates (BCP) identified by imaging or histological examination.
- **Acute CPP crystal arthritis** is used to describe acute onset, self-limiting attacks of synovitis due to CPP crystals (formerly 'pseudogout').
- **OA with CPPD** refers to concurrence of CPPD in a joint with structural changes of OA (previously 'pyrophosphate arthropathy') whether symptomatic or asymptomatic.
- **Chronic CPP crystal inflammatory arthritis** describes the occurrence of a chronic inflammatory arthritis (often with changes of OA) with associated CPPD.

Epidemiology

CPPD is a common age-related phenomenon in the general population. Epidemiological studies report the prevalence of radiographic CC and/or OA with CPPD (formerly 'pyrophosphate arthropathy') (Table 142.2). The true prevalence of symptomatic CPPD is unknown. A community survey of 1727 adults (mean age 63.7 years) from Nottingham (United Kingdom) identified a crude prevalence of radiographic knee CC of 7.0% which equated to an age, gender, and knee pain standardized prevalence estimate of 4.5% in those aged 40 years and over.[5] In the Framingham survey, a similar prevalence estimate for radiographic knee CC of 8.1% was found in a population of 1425 adults aged over 63 years.[6] The prevalence of radiographic CC at the knee and/or wrist was 10% in a Spanish population of 261 general practice attenders aged over 60 years.[7] Similarly, a community survey of 1629 subjects aged 65 years and over from north-eastern Italy found the crude prevalence of radiographic CC at the knee and/or pelvis to be 10.4%, equating to a prevalence of 10.0% after adjustment for age and gender.[8] The prevalence of radiographic CC at the knee and wrist have been compared between white subjects from the Framingham population and a population of 2506 Chinese subjects aged 60 years and over from Beijing (China).[9] Radiographic CC at both sites was less prevalent in Chinese subjects than white subjects, with wrist CC being particularly uncommon in the Chinese population. A Swedish cross-sectional survey of three cohorts of adults aged 70,

Table 142.1 EULAR proposal for terminology

Term	Definition
Calcium pyrophosphate (CPP) crystals	Simplified name for calcium pyrophosphate dihydrate crystals
Calcium pyrophosphate deposition (CPPD)	Umbrella term for all instances of CPP crystal occurrence
Chondrocalcinosis (CC)	Cartilage calcification, identified by imaging or histological identification. Commonly but not always due to CPPD
Clinical presentations associated with CPPD	
Asymptomatic CPPD	CPPD with no apparent clinical consequence, either isolated CC or OA with CPPD
OA with CPPD	CPPD in a joint which also shows changes of OA, on imaging or histological examination
Acute CPP crystal arthritis	Acute onset, self-limiting synovitis with CPPD (replacing the term 'pseudogout')
Chronic CPP crystal inflammatory arthritis	Chronic inflammatory arthritis associated with CPPD

CPP, calcium pyrophosphate; CPPD; calcium pyrophosphate crystal deposition; EULAR, European League Against Rheumatism; OA, osteoarthritis.

From Zhang et al.[4]

Table 142.2 Prevalence of chondrocalcinosis (CC) by age and gender

Author	Study location	Study population	Joints examined	Prevalence of CC	Prevalence by gender		Prevalence by age group	
Bergström[10]	Göteborg, Sweden	352 adults aged 70, 75, and 79 years	Knees, wrists, fingers	11.5%	Women	14.7%	70 years	7.5%
					Men	5.5%	75 years	10.1%
							79 years	16.0%
Felson[6]	Framingham, USA	1425 adults aged 63–93 years	Knees	8.1%	Women	9.0%	<65 years	3.6%
					Men	6.9%	65–69 years	3.2%
					Age-adjusted RR 1.33 (95% CI 0.92, 1.92)		70–74 years	7.3%
							75–79 years	9.8%
							80–84 years	16.5%
							≥85 years	27.1%
Sanmarti[7]	Catalonia, Spain	261 GP attenders aged ≥60 years	Knees, hands	10%	Women	14%	60–69 years	7%
					Men	6%	70–79 years	13%
							≥80 years	43%
Neame[5]	Nottingham, UK	1727 adults aged ≥40 years	Knees	Crude 7.0% Standardized[a] 4.5%	Women	6.1%	Ranges from:	
					Men	8.2%	55–59 years	3.7%
					Age-adjusted OR 0.79 (95% CI 0.51, 1.12)		to	
							80–84 years	17.5%
Ramonda[8]	North-eastern Italy	1629 adults aged ≥65 years	Knees, pelvis	10.4%	Women	12.8%	65–74 years	7.8%
					Men	7.0%	75–84 years	9.4%
							≥85 years	21.1%

CI, confidence interval; GP, general practitioner; RR, relative risk.

[a]Standardized for age, gender, and knee pain.

75, and 79 years (352 participants) found that radiographic CC was most common at the knee (8.5%) followed by the wrist (5.1%) and then the fingers (1.7%).[10]

There is clear evidence that the prevalence of radiographic CC increase with age (Table 142.2).[5–10] The risk of CPPD doubles with every 10-year increase in age between 45 and 85 years (odds ratio (OR) 2.25, 95% confidence interval (CI) 1.79, 2.82).[11] However, the association of CPPD with gender is less clear. Radiographic CC was more prevalent in females than males in the Spanish (females 14%, males 6%), Italian (female 12.8%, males 7%), and Swedish (females 14.7%, males 5.6%) populations described above.[7,8,10] However, in the Nottingham and Framingham populations no difference in the prevalence of radiographic CC at the knee was seen between the genders after adjustment for age.[5,6]

In the Nottingham study,[11] OA with CPPD ('pyrophosphate arthropathy') at the knee was defined as the occurrence of radiographic CC with radiographic evidence of OA (Kellgren and Lawrence grade ≥2[12]). The crude prevalence of OA with CPPD at the knee was 3.4%, reducing slightly to 2.4% when standardized for age, gender, and knee pain.[11] There was an increased risk of OA with CPPD with increasing age (OR 2.88 per 10-year increase) but no association with gender.

Aetiopathogenesis

Pathophysiology

CPP crystals form in the extracellular compartment of cartilage from calcium ions and extracellular inorganic pyrophosphate (ePPi). The concentration of ePPi appears to be the most important factor determining formation of CPP crystals,[13] high calcium concentration alone being insufficient to increase CPP crystal formation.[14]

Inorganic pyrophosphate is not absorbed from the gut, so all PPi in humans is produced endogenously. PPi is an important regulator of normal mineralization in bones and teeth and inhibits calcium crystal formation elsewhere in the body. Modest concentrations of PPi stimulate BCP formation, but higher concentrations inhibit BCP crystal formation and growth. In cartilage, nucleotide triphosphates are released from resting chondrocytes and hydrolysed by nucleotide pyrophosphohydrolase (NTPPH) enzymes to produce PPi.[15,16] The ectoenzyme NTPPH plasma cell-membrane glycoprotein-1 (PC-1) on chondrocytes and matrix vesicles is the dominant source of cartilage matrix and synovial fluid PPi.[17,18] However, ePPi may also originate from the transport of intracellular PPi across the plasma membrane by the multipass transmembrane protein ANKH (Ankylosis human).[19,20] Once formed, ePPi is hydrolysed to orthophosphate by tissue non-specific alkaline phosphatase (TNAP),[21] requiring magnesium as a cofactor. High ePPi levels therefore can arise from reduced TNAP activity or increased activity of PC-1 or ANKH (Figure 142.1). Growth factors including transforming growth factor (TGF)-β, interleukin (IL)-1β), and insulin-like growth factor-1 (IGF-1) influence ePPi levels via their action on PC-1, TNAP, or ANKH.[3] Histologically, CPP crystals mainly occur in the mid-zone of cartilage and strongly coassociate with the hypertrophic chondrocyte phenotype. Such metabolically active cells associate with higher ePPi levels in cartilage and synovial fluid.[3]

A sufficiently high ionic product for (Ca × ePPi) is essential for CPP crystal formation, but additional characteristics of the cartilage
Fig. 142.1 Outline of metabolism of inorganic pyrophosphate. ANKH, ankylosis human multipass transmembrane protein; AP, alkaline phosphatase; Ca++, calcium ions; CPPD, Calcium pyrophosphate crystal deposition; IGF1, insulin-like growth factor-1; IL-1, interleukin-1; Mg2+, magnesium ions; NTP, nucleotide triphosphates; OA, osteoarthritis; PC1, plasma cell-membrane glycoprotein-1; Pi, orthophosphate; PPi, inorganic pyrophosphate; TGFβ, transforming growth factor-β; TNF, tumour necrosis factor.

extracellular matrix may either increase or inhibit the initial nucleation and subsequent growth of CPP crystals. We know very little about these tissue factors but there are data to support proteoglycan as an inhibitor and lipid, osteopontin and transglutaminases as promotors of CPPD.[3] In OA cartilage, the balance of these opposing factors is in favour of CPP crystal formation.

Acute CPP crystal arthritis is presumed to occur from 'shedding' of preformed CPP crystals from cartilage into the joint space, analogous to that in gout. Within cartilage the crystals are protected from interaction with inflammatory mediators, but inside the joint space CPP crystals trigger acute inflammation via activation of the NALP3 'inflammasome' with subsequent IL-1β driven neutrophilic inflammation.[3,22] Presumably low-grade chronic inflammation may be caused by more sustained release of smaller amounts of crystals. CPPD may also have detrimental biomechanical effects on load transmission through cartilage and shed CPP crystals may act as abrasives at the cartilage–cartilage interface.[3]

Risk factors for CPPD

Age

As discussed above, there is very strong evidence that age is an important risk factor for sporadic CC.

Prior joint damage and osteoarthritis

There is a clear, well-established association between OA and CPPD. Based on pooled data from nine epidemiological studies analysed by the EULAR Task Force, people with OA have between two and three times the risk of CPPD of people without OA (pooled OR 2.66; 95%CI 2.00, 3.54).[4] However, the role of CPP crystals in the pathogenesis of OA and vice versa is not completely understood.[23] Whereas BCP crystals are universally found in endstage OA, endstage articular cartilage specimens from knees and hips display CPP crystals in only 18% and 10% respectively.[24,25] Deposition of crystals, both monosodium urate and CPP, occurred predominantly

at sites of cartilage damage in one cadaveric observational study, although 8% of crystal deposits occurred without gross evidence of cartilage damage, suggesting that damage is not essential for crystal deposition.[26] The presence of CPP crystals associates with greater radiographic OA severity.[27] CPP crystals exacerbate OA when directly introduced into mechanically stressed rabbit knee joints,[28] and promote expression of inflammatory cytokines and matrix metalloproteinases.[29] CPP crystals have therefore been assumed to promote cartilage damage in humans. The presence of synovial fluid CPP crystals or radiographic CC led to progression of radiographic knee OA in one prospective study of 350 participants.[30] A number of local mechanical factors including joint hypermobility, ligamentous laxity and instability,[31,32] trauma,[33] and joint damage from surgery including meniscectomy[34] have been suggested to predispose to localized secondary deposition of CPPD crystals in the context of joint damage. In contrast, other radiographic and MRI studies have not found an association between CPPD and OA progression. In one prospective study of 104 participants with CPPD at various joints, change in structural arthropathy was minimal over 4.6 years and unrelated to the presence, extent, or progression of radiographic CC.[35] In prospective studies of cartilage loss measured with serial MRI scans, radiographic CC was not predictive of cartilage loss in one cohort and even suggested to protect against cartilage loss in another.[36] To explain this latter finding, CC has been proposed to be a marker of hypertrophic chondrocyte differentiation and a reparative response of the chondrocyte matrix to cartilage damage.

One community-based case-control study found that the association between radiographic CC and patellofemoral and tibiofemoral OA occurs through a shared association with osteophyte,[5] although this finding is not supported by all studies including pooled data analysed by the EULAR Task Force.[4]

Familial CPPD

Familial CC due to CPPD, usually showing autosomal dominant inheritance, is rare but has been reported from many different countries. The commonest phenotype is early onset in the third to fourth decades of recurrent acute CPP crystal arthritis, florid polyarticular CC, and a variable severity of associated structural arthritis (radiographically identical to OA) ranging from absent to marked.[37–39] A less frequently reported phenotype is late onset presentation in the sixth to seventh decades of oligoarticular CC mainly confined to the knees, and arthritis resembling sporadic OA with CPPD.[40] However, this second, less dramatic form may be relatively under-recognized. In one United Kingdom family recurrent infantile seizures between the ages of 6 months and 6 years occurs in all affected individuals,[39] but extra-articular associations are not reported in other kindreds.

Two genetic associations have been identified in familial CC due to CPPD: the CC gene 1 (*CCAL1*) locus on chromosome 8q in one American family with premature OA and CPPD,[41] and CC gene 2 (*CCAL2*) on chromosome 5p15 in British, French, and Argentinian families with CC.[42,43] No responsible gene has been identified at the *CCAL1* locus but *CCAL2* has been identified as the *ANKH* gene. A mutation of the homologous *ANK* gene in mice was first studied as a cause of extensive intra-and extra-articular BCP deposition which results in progressive joint immobility (hence 'ankylosis'). The mouse mutation leads to reduced activity of ANK and thus low levels of ePPi; in the absence of normal

inhibition of BCP by ePPi there is uncontrolled widespread BCP crystal deposition.[44] However the *ANKH* mutation identified in human familial CC leads to a gain rather than a loss in function of ANKH with resulting very high levels of ePPi and predisposition to CPPD.

The heritability of common CC and CPPD remains unclear. One United Kingdom community-based sibling study found no significant genetic contribution to apparently sporadic CC or OA with CPPD,[11] but one case-control study found increased risk of apparently sporadic CC through inheritance of a −4 bp G-to-A *ANKH* 5⬚-untranslated region transition that upregulates expression of ANKH with subsequent elevation of ePPi.[45]

Metabolic diseases

Numerous metabolic conditions have been reported to associate with CC. However, the best evidence exists for primary hyperparathyroidism, haemochromatosis, hypomagnesaemia, and hypophosphatasia.[46,47]

Uncontrolled case series provide evidence of an association between CC and primary hyperparathyroidism. Whereas primary hyperparathyroidism is very uncommon in patients with CC (none out of 91 patients in one series[48]), as many as one in five patients with primary hyperparathyroidism exhibit radiographic CC.[49] Analysis of pooled data by the EULAR Task Force found patients with hyperparathyroidism to be three times more likely to have CPPD than controls (OR 3.03; 95%CI 1.15, 8.02).[4] Hyperparathyroidism potentially predisposes to CPP crystal formation by increasing ePPi levels (via inhibition of TNAP by calcium ions and parathyroid hormone (PTH) and stimulation of adenylate cyclase by PTH) and by increasing calcium and thus the (Ca × PPi) ionic product (Figure 142.1).

Like hyperparathyroidism, hereditary haemochromatosis has a very low prevalence in people with CC. In one study, the *C282Y* homozygous and *C282Y/H63D* heterozygous states were seen in 1.6% and 3.1% of people with CC and/or acute CPP crystal arthritis respectively.[50] In contrast, the prevalence of CC in untreated hereditary haemochromatosis was 30% in one study and CC appeared to correlate with age and ferritin levels.[51] Furthermore, the concentration of serum PTH 44–68 also correlates with the number of joints affected by CC in hereditary haemochromatosis and is increased in CPPD.[51,52] Hospital-based studies suggest that CPPD occurs at a younger age in patients with haemochromatosis than those without and that the presence of CC in haemochromatosis associates with structural arthropathy.[52,53] Iron has an inhibitory effect on TNAP activity and is also a nucleating factor for CPP crystals (Figure 142.1).

Hypomagnesaemia predisposes to CPPD in congenital magnesium-losing nephropathies (Gitelman's and Bartter's syndromes) and intestinal failure.[54,55] Diuretic-induced hypomagnesaemia is thought to explain the association of radiographic CC with diuretic use (OR 2.07; 95%CI 1.02, 4.19).[5] The breakdown of ePPi to inorganic phosphate by TNAP requires magnesium as a cofactor, hence hypomagnesaemia impairs this reaction allowing PPi to accumulate (Figure 142.1).

Case reports and case series also report an association between young-onset CC and severe hypophosphatasia which is characterized by skeletal deformities and marked underactivity of TNAP (Figure 142.1).[46,47] The very high ePPi levels inhibit BCP formation leading to poor bone mineralization and tendency to fracture.

Clinical features

Asymptomatic CPPD

CC due to CPPD, with or without changes of structural changes of OA, is a frequent incidental radiographic finding in elderly people. Although radiographic CC can be associated with clinical symptoms (mainly acute CPP crystal arthritis), a thorough clinical assessment is required as regional pain can easily be erroneously attributed to CPPD.

Osteoarthritis with CPPD

CPPD is commonly accompanied by OA, particularly in elderly women. Clinical presentation mimics OA and is characterized by chronic pain, stiffness, and functional impairment. The knee is the most frequent and severely affected joint.[56] Other commonly affected joints include the shoulder, wrist/hand, and ankle. Examination reveals physical signs of OA: bony swelling, crepitus, restricted movement, and deformity. However, there may also be superimposed attacks of acute CPP crystal arthritis (see below) or varying degrees of synovitis (often most marked at the knee, radio-carpal, or glenohumeral joint).

OA with CPPD can be difficult to distinguish from uncomplicated OA, particularly at the knee. However, several clinical clues can aid differentiation:

◆ the distribution of affected joints; although both conditions commonly affect the knee, target joints for CPPD (shoulder, ankle, wrist) are uncommon sites for primary OA

◆ superimposed acute attacks (NB: osteoarthritic joints also encourage urate crystal deposition)

◆ the presence of more symptoms and signs of inflammation than in uncomplicated OA.

The prognosis of OA with CPPD is generally good. The course is usually benign, particularly with respect to small and medium-sized joints. In one prospective hospital-based study, only 27% of participants reported a decline in symptoms over a mean follow-up period of 4.6 years.[35] Progression, when it occurs, is usually slow and related to knees, hips, or shoulders although patients with OA and CPPD undergo total knee replacement surgery at an older age than patients with uncomplicated OA.[57] Occasionally severe, rapidly progressive, destructive arthropathy may occur at these sites, usually in very elderly women and is associated with severe pain, recurrent haemarthrosis (shoulder, knee), and occasional joint leakage. Mixed crystal deposition (CPP plus BCP) is often found on synovial fluid analysis.

Acute CPP crystal arthritis

Acute CPP crystal arthritis should be considered in the differential diagnosis of any acute hot swollen joint in the elderly. It usually presents with an acute attack of synovitis affecting a single peripheral joint. The most commonly affected joint is the knee followed by the wrist/hand, ankle, and shoulder.[56] Pain is usually severe and typically reaches peak intensity rapidly, within 6–24 hours of symptom onset. Signs of synovitis, namely swelling, warmth, exquisite tenderness to touch, and sometimes overlying erythema, are present on physical examination. EULAR recommendations for the diagnosis of CPPD state that rapid development of synovitis with pain, stiffness, swelling, and tenderness with or without erythema

are highly characteristic of acute crystal synovitis but are not specific to CPP crystals; however, involvement of the knee, wrist, or shoulder in a person aged over 65 years makes acute crystal CPP arthritis likely.[4]

Oligoarticular attacks are uncommon and polyarticular attacks rare. Systemic features such as fever or confusion are common in elderly people. Attacks are usually spontaneous, but may be provoked by intercurrent illness, local trauma, or surgery. Even without treatment, attacks are self-limiting and typically resolve within 1–2 weeks.

Chronic CPP crystal inflammatory arthritis

Chronic CPP crystal inflammatory arthritis presents with chronic inflammatory symptoms and signs such as morning stiffness and synovitis with occasional systemic upset. The pattern of joint involvement is most commonly mono- or oligoarticular (89%) but may be polyarticular (11%).[48] The differential diagnosis includes rheumatoid arthritis and polymyalgia rheumatica.

Rarer presentations

Although CPP crystals usually deposit within articular cartilage within synovial joints, soft tissue CPPD can cause acute tendinitis (triceps, Achilles),[58] tenosynovitis (hand flexors, extensors),[59] and bursitis (olecranon, infrapatellar, retrocalcaneal),[60] usually in patients with widespread CPP crystals. Flexor tenosynovitis at the wrist can cause median and ulnar nerve compression.[59] In contrast to gout, where tophi occur relatively commonly, tophaceous CPPD is rare and usually presents as solitary lesions in areas of chondroid metaplasia (usually benign cartilage tumours).

Spinal CPPD is uncommon with cervical spinal involvement particularly rare. Acute CPP crystal arthritis can present with acute severe posterior neck pain and systemic upset ('crowned dens' syndrome). Fever is present in up to 80% of patients.[61] CT imaging of the cervical spine demonstrates linear calcific deposits within the transverse ligament of the atlas and other periodontoid structures. Compressive cervical myelopathy due to CPPD involvement of the cervical spine is also described.[62]

Investigation and diagnosis

Synovial fluid analysis

Identification of CPP crystals by compensated polarized light microscopy of aspirated synovial fluid is the reference standard for the diagnosis of CPPD.[4] CPP crystals often exhibit no birefringence, or only weak (positive) birefringence, and are small (2–10 μm in length) and of varying morphology, most commonly rhomboid or rod-shaped (Figure 142.2). Identification of CPP crystals confirms the diagnosis of acute CPP crystal arthritis, OA with CPPD, and chronic CPP crystal inflammatory arthritis, and allows the important differential diagnoses of septic arthritis and gout to be excluded. CPP crystals can be seen in synovial fluid aspirated from asymptomatic knees that have never been affected by acute CPP crystal arthritis or in between attacks.[63] In acute CPP crystal arthritis, aspirated fluid is often turbid or bloodstained with an elevated cell count (more than 90% neutrophils). Acute CPP crystal arthritis and septic arthritis can coexist, so if joint sepsis is suspected on clinical grounds then microbiological examination of aspirated fluid must be performed even if CPP crystals are identified.[4]
Fig. 142.2 Photograph of CPP crystals under compensated polarized light microscopy.

Fig. 142.3 Plain radiograph of the knee showing chondrocalcinosis (CC) of articular hyaline and fibrocartilage within the medial and lateral tibiofemoral compartments.

Plain radiographs

The cardinal radiographic feature of CPPD is CC—calcification of articular fibrocartilage or hyaline cartilage (Figure 142.3). This is most commonly seen at the menisci of the knees, wrist triangular cartilage, and symphysis pubis. Although radiographic CC of articular cartilage is often taken to be diagnostic of CPPD, other crystals, principally BCP, can also appear as linear calcification of articular cartilage. Furthermore, radiographs are insensitive and may fail to detect small crystal deposits. Radiographic CC is seen in only 29–93% of cases of proven CPPD.[4,48,63] Hence, although radiographic CC supports the diagnosis of CPPD, definitive diagnosis needs to be crystal proven.[4]

OA with CPPD is characterized by CC and features of OA: cartilage loss, subchondral cysts and sclerosis, and osteophytes (Figure 142.4). There are certain radiographic features which may help to distinguish OA with CPPD from uncomplicated OA:

◆ distribution of affected joints includes joints that are uncommonly affected by primary OA (eg wrist, shoulder, ankle)

◆ prominent osteophyte formation giving a distinctive hypertrophic OA appearance

◆ prominent osteochondral bodies.

In destructive arthropathy, marked cartilage and bone attrition with fragmentation and loose osseous bodies may resemble a Charcot joint.

Plain radiographs can also be helpful in distinguishing chronic CPP crystal inflammatory arthritis from other inflammatory arthropathies such as rheumatoid arthritis (RA). Wrist involvement is common in both RA and CPPD and rheumatoid factor more commonly positive in elderly people, which may make it difficult to tell them apart. In addition to radiographic CC and identification of CPP crystals, absence of marginal erosions is suggestive of chronic CPP crystal inflammatory arthritis.[23]

Ultrasound

Three patterns of ultrasonographic calcification have been proposed to represent CPPD[64,65]:
Fig. 142.4 Plain radiograph of the knee showing OA with CPPD: note chondrocalcinosis (CC) of articular fibrocartilage within the lateral tibiofemoral compartment and osteophyte and joint space narrowing at the medial tibiofemoral compartment.

1. thin hyperechoic bands, parallel to the surface of the hyaline cartilage (frequently observed in the knee)

2. a 'punctuate' pattern consisting of several thin hyperechoic spots, more common in fibrous cartilage and tendons

3. homogeneous hyperechoic nodular or oval deposits localized in bursae and articular recesses.

In a small study of 11 subjects with ultrasonographic evidence of CPPD at the knee, wrist and shoulder and 13 control subjects, pattern 2 was the most common, followed by pattern 1: pattern 3 was seen in only one participant.[65] Further analysis of the findings of this study by the EULAR Task Force found the sensitivity of ultrasound to detect CPPD using a gold standard of synovial fluid CPP crystal identification to be 100% compared to 82% for radiographs.[4] One further small study reported

ultrasonography to be both sensitive (87%) and specific (96%) to detect CPPD at the knee, again compared to synovial fluid CPP crystal identification.[66] The EULAR Task Force conclude that positive ultrasound findings strongly support the diagnosis of CPPD (likelihood ratio 24.2).[4]

Ultrasound has the additional advantages of minimizing ionizing radiation exposure, providing 'real-time', dynamic, high-resolution images at low cost, identifying subclinical joint effusions which can be aspirated facilitating a crystal-proven diagnosis, and allowing differentiation between crystal arthropathies. The 'double contour sign'—thickening and hyperechogenecity of the superficial margin of the articular cartilage independent of the angle of insonation—is an ultrasonographic feature specific to gout.[64,67,68] Furthermore, CPPD calcification appears hyperechogenic on ultrasound and creates a posterior shadowing only with large lesions (>10 mm diameter) in contrast to BCP crystal deposits which are hypoechoic and present posterior shadowing even at an early stage.[65] However, although ultrasound has great potential as a diagnostic technique for CPPD further large studies are required to validate these preliminary findings.

Blood tests and screening for predisposing metabolic conditions

There are no specific diagnostic blood tests for CPPD. However, during attacks of acute CPP crystal arthritis a marked acute-phase response is usually seen, with high erythrocyte sedimentation rate (ESR), neutrophil leucocytosis, thrombocytosis, elevated C-reactive protein (CRP). Modest elevations of ESR and CRP may also accompany chronic CPP crystal inflammatory arthritis.

Metabolic predisposition is rare and routine screening of all patients is unwarranted. Nevertheless, CPPD can be the presenting feature of metabolic or familial disease, and screening for primary hyperparathyroidism, haemochromatosis, hypomagnesaemia and hypophosphatasia should be considered:

- in patients aged under 55 years with CC or acute CPP crystal arthritis
- if there is florid polyarticular CC[4]
- if there are additional clinical features to suggest metabolic disease.

Screening tests should include serum calcium, alkaline phosphatase, magnesium, ferritin, and liver function.

Management

Asymptomatic chondrocalcinosis

Asymptomatic CC does not require specific management other than screening for metabolic disorders as described above.

Osteoarthritis with CPPD

Treatment of OA with CPPD is very similar to the treatment of OA alone.[69] In contrast to gout, where urate-lowering therapy forms the mainstay of long-term management, there is no specific treatment to reduce and prevent deposition of CPP crystals. Optimal treatment combines non-pharmacological and pharmacological modalities and should include education and advice, local quadriceps strengthening and generalized aerobic fitness exercises,

weight loss if the patient is overweight or obese, and graded analgesia commencing with oral paracetamol and topical NSAID, as advocated in numerous clinical guidelines.[70–74] In some cases, joint replacement surgery may be required. Superimposed attacks of acute CPP crystal arthritis should be treated as outlined in the next section.

Acute CPP crystal arthritis

Treatment of acute CPP crystal arthritis aims to rapidly relieve associated pain and swelling. There are few high-quality research studies of interventions for acute CPP crystal arthritis and existing recommendations are based largely on clinical experience, expert consensus, and extrapolation of research evidence supporting treatments for acute gout.[69] Available treatments include local application of ice topically to an affected joint, oral non-steroidal anti-inflammatory drugs (NSAIDs) (with a proton pump inhibitor if indicated), colchicine, glucocorticosteroids (intra-articular, oral or parenteral), or adrenocorticotrophic hormone (ACTH).

There are no published research studies to date of topical ice therapy for acute CPP crystal arthritis. However, one small randomized controlled trial (RCT) demonstrates its efficacy for the treatment of acute gout,[75] and the use of topical ice therapy for acute CPP crystal arthritis, with temporary rest of the affected joint, was strongly supported by the EULAR Task Force.[69] Clinical experience suggests that both NSAID and oral colchicine are effective treatments for acute CPP crystal arthritis. However, robust studies are lacking and the recommendation for their use is extrapolated from studies of acute gout. Both treatments should be used with caution in elderly people because of the high incidence of side effects such as gastrointestinal bleeding, cardiovascular events, and renal failure with NSAIDs and diarrhoea, nausea, and vomiting with oral colchicine. Drug interactions between NSAIDs and other drugs such as aspirin and warfarin are also commonplace in elderly people. The EULAR Task Force advises that consideration should be given to coprescription of a gastroprotective agent with NSAIDs.[69] Traditional oral colchicine dosing regimes such as 1 mg loading followed by 0.5 mg every 2 hours very frequently result in gastrointestinal adverse events. The incidence of diarrhoea and vomiting was 100% in an RCT of a similar high-dose regime for acute gout.[76] A lower-dose regime (e.g. 0.5 mg two to four times daily) is therefore recommended by the EULAR Task Force,[69] based on expert consensus. Although the efficacy of intravenous colchicine is reported,[77] the intravenous route is no longer recommended because of the risk of serious, potentially life-threatening, toxicity.

In view of frequent comorbidity and contraindications to or poor tolerance of NSAIDs or oral colchicine in the older person with acute CPP crystal arthritis, management can be challenging. Glucocorticosteroids can be a particularly useful and effective treatment.[69] The EULAR Task Force strongly recommends joint aspiration and intra-articular injection of long-acting glucocorticosteroid as an effective and safe treatment for mono- or oligoarticular attacks of acute CPP crystal arthritis, although again research evidence for this is very weak.[69,78] In a hospital setting, especially in an elderly patient with an attack triggered by intercurrent illness or surgery, joint aspiration and injection should be considered best practice.

Case history

A 72-year woman is being treated in hospital following a fall. Her medical history includes knee osteoarthritis and hypertension. She develops acute onset of severe pain and swelling affecting her right knee which was extremely painful within just 6 hours. She feels unwell and has a low-grade fever. Examination reveals a hot, tender, tense effusion with restricted movement. There is wasting of the quadriceps and palpable coarse crepitus.

Because of the rapidity of development of her synovitis a diagnosis of acute crystal synovitis is made. She has no history of chronic diuretic use or renal impairment, and this together with her age and known knee OA suggest acute CPP crystal arthritis rather than acute gout. 80 mL of turbid synovial fluid is aspirated from the knee and she is injected with intra-articular triamcinolone acetonide and given local ice packs, resulting in rapid reduction in her pain. Compensated polarized light microscopy of the aspirated fluid reveals small predominantly intracellular rhomboid crystals exhibiting weak positive or no birefringence. ESR and CRP are both elevated at 66 mm/hour and 133 mg/dL respectively. Plain radiography of the knee reveals linear calcification of articular fibrocartilage, and features of osteoarthritis, namely medial joint space narrowing and osteophytosis. Gram stain and culture of the fluid at 48 hours does not reveal any organisms (sepsis is extremely unlikely given the rapidity of development of her tense effusion, but coexistent sepsis should be excluded in an unwell hospitalized patient). She is provided with verbal and written information about OA with CPPD and given advice on how to lose weight. She is also assessed and treated by a physiotherapist who prescribes a home exercise programme consisting of quadriceps strengthening exercises and aerobic exercise. Oral paracetamol and topical NSAIDs are recommended for long-term analgesia.

Intramuscular glucocorticosteroid is a useful treatment when monoarticular attacks occur at sites not amenable to injection, such as the midfoot, or attacks are oligo- or polyarticular. One small non-randomized trial demonstrates the superior efficacy of both intramuscular betamethasone 7 mg and intravenous methylprednisolone 125 mg compared to oral diclofenac in patients with acute crystal synovitis[79] (number needed to treat 3[69]). Intramuscular injection of triamcinolone acetonide 60 mg provided rapid relief from acute CPP crystal arthritis in one small prospective uncontrolled study.[80] Although there are no RCTs of oral glucocorticosteroids for acute CPP crystal arthritis, oral prednisolone 35 mg daily is as effective as NSAID for the treatment of acute gout,[81] and is an effective alternative to intra-articular glucocorticosteroid for polyarticular attacks.[69]

ACTH stimulates adrenal glucocorticosteroid release and has a direct anti-inflammatory effect via the melanocortin type 3 receptor.[82] Parenteral ACTH 40 or 80 units (three intravenous, intramuscular, or subcutaneous doses) provided rapid symptomatic relief in a retrospective study of 38 patients with acute crystal-induced synovitis.[83] Side effects included hypokalaemia, hyperglycaemia, fluid retention, and rebound arthritis although these were reported as mild and easily controlled. Although not widely used in routine clinical practice, ACTH may be a safe and effective treatment for acute CPP crystal arthritis, though further studies are required.

Recently, there has been interest in the use of IL-1 receptor antagonists to treat acute CPP crystal arthritis. Following phagocytosis by synovial cells, CPP crystals activate the NALP3 inflammasome, an intracellular receptor within monocytes.[22] Subsequently, secretion of IL-1β initiates a neutrophilic inflammatory reaction.[3,22] The efficacy of the IL-1 receptor antagonist anakinra (100 mg daily) to provide rapid symptomatic relief from resistant acute CPP crystal arthritis in which glucocorticosteroids, NSAIDs, and colchicine were either ineffective or contra-indicated is described.[84] Other IL-1 inhibitors such as rilonacept have been used to treat acute gout,[85] and may also be effective for the treatment of acute CPP crystal arthritis although further evaluation is required.

Prophylaxis against frequent recurrent attacks of acute CPP crystal arthritis can be attempted with low-dose oral colchicine (e.g. 0.5 mg once to twice daily) or low-dose oral NSAID (with gastroprotection if indicated).[69] There are no empirical research studies of NSAIDs in this setting. However, one small uncontrolled study followed 10 patients with acute CPP crystal arthritis for 1 year before and 1 year after receiving oral colchicine (0.6 mg twice daily), demonstrating a reduction in the number of acute attacks from 32 in the year preceding initiation of therapy to 10 while taking the drug.[86] These findings suggest that colchicine may be of benefit for prophylaxis against acute attacks. However, use of NSAID or colchicine needs to be considered carefully in elderly patients and further evidence is required.

Chronic CPP crystal inflammatory arthritis

There is no specific therapy for chronic CPP crystal inflammatory arthritis. The EULAR Task Force recommends, in order of preference, an oral NSAID (with gastroprotection if necessary), colchicine 0.5–1.0 mg daily, low-dose glucocorticosteroid, methotrexate, and hydroxychloroquine.[69] The recommendation of NSAID is based upon clinical experience and extrapolation from research studies in gout and OA. The Task Force commented that there is no evidence to support the use of low-dose glucocorticosteroids for chronic CPP crystal inflammatory arthritis.

Low-dose colchicine (0.5 mg twice daily for 8 weeks) has been shown to have additional benefit for pain and function to intra-articular methylprednisolone and oral piroxicam in a randomized double-blind placebo-controlled trial of 39 patients with OA of the knee and clinical signs of persistent inflammation, although only 74% and 38% of participants had a crystal-proven diagnosis of CPPD and radiographic CC respectively.[87] Colchicine was well tolerated and the incidence of gastrointestinal side effects in the colchicine group did not differ significantly from those given placebo.

A small case series of five patients with polyarticular chronic CPP crystal inflammatory arthritis reported improvements in pain, swollen and tender joint counts, and acute-phase reactants such as ESR and CRP with methotrexate at a doses of 5–20 mg weekly.[88] However, another series of just three patients with severe destructive monoarticular or oligoarticular CPPD treated with methotrexate at doses of 7.5–12.5 mg weekly did not report any benefit.[89] Hence further larger studies of methotrexate in CPPD are needed.

Hydroxychloroquine at doses of 200–400 mg daily brought about superior differences in joint swelling and tenderness to placebo in a small 6-month double-blind RCT of 36 participants with

chronic CPP crystal inflammatory arthritis.[90] Treatment was well tolerated.

Since magnesium has an important role as a cofactor for TNAP in the metabolism of PPi and hypomagnesaemia is a recognized risk factor for CPPD, magnesium supplementation would appear to be a logical treatment approach for CPPD, although it was not recommended by the EULAR Task Force.[69] In a randomized placebo-controlled trial of 38 participants with chronic CPP crystal inflammatory arthritis, greater improvements in pain, stiffness, knee effusion and tenderness were seen at 6 months in those treated with magnesium carbonate (30 mEq per day) compared to placebo.[91] Improvement was unrelated to baseline magnesium level and there was no change in radiographic CC over the course of the study.

Although not specifically recommended by the EULAR Task Force, intra-articular injection of yttrium-90 (radiosynovectomy) may be of benefit for chronic CPP crystal inflammatory arthritis. In one small study of 15 patients with bilateral symmetrical CPPD of the knee, each participant underwent intra-articular injection of yttrium-90 plus triamcinolone hexacetonide into one knee and saline plus triamcinolone hexacetonide into the other knee.[92] At 6 months, improvements were seen in pain, stiffness, joint-line tenderness, effusion, and range of movement in the yttrium-90-injected knees compared to saline-injected knees. The EULAR Task Force concludes that the role of radiosynovectomy is unclear as this is the only published study.[69]

Given the reported success of IL-1 blockade of acute crystal synovitis with anakinra and rilonacept,[84,85] it would appear logical that such agents would be beneficial for chronic CPP crystal inflammatory arthritis. However, specific RCTs examining the use of these agents in chronic CPP crystal inflammatory arthritis are required.

Conclusion

CPPD is a common age-related phenomenon in the general population. Recent developments include: the proposal of a new uniform terminology and the first evidence-based recommendations for diagnosis and management of CPPD by the EULAR CPPD Task Force; advances in understanding of the pathophysiology of PPi metabolism and the mechanisms by which crystals invoke an inflammatory response via the NALP3 inflammasome and secretion of IL-1β; and the emergence of new diagnostic modalities such as ultrasound. However, although there is a great wealth of clinical experience of the treatment of this prevalent, painful and disabling condition, there is a paucity of large, high-quality research studies concerning its diagnosis and management. Existing recommendations for treatment are largely based on clinical experience, expert consensus and extrapolation from other crystal arthropathies such as gout. Further high-quality studies are much needed.

CHAPTER 143

Osteoporosis

Kanako Yoshida, Rosemary J. Hollick,
and David M. Reid

Introduction

The management of osteoporosis aims to prevent a first or subsequent fracture. Lifestyle changes are helpful but for individuals with a high fracture risk pharmacological intervention is necessary. Recent advances in our understanding of bone biology has expanded the number of drugs available for the prevention and treatment of postmenopausal osteoporosis to include oral and intravenous bisphosphonates, strontium ranelate, raloxifene, parathyroid hormone analogues and most recently denosumab. A few studies have also examined their efficacy in the treatment of osteoporosis in men, glucocorticoid-induced osteoporosis, and cancer treatment induced bone loss. As an increasing number of drugs becoming available for the management of osteoporosis, along with some emerging concerns regarding their long term safety, there is an increasing need for a more stratified approach, with individual fracture risk assessment targeting therapy to those most at risk of fracture.

Introduction

Osteoporosis is the most common metabolic bone disease and has been defined as 'a systemic bone disease characterized by low bone mass and microarchitectural deterioration of bone tissue, leading to enhanced fragility and a consequent increase in fracture risk'.[1–2]

Epidemiology

Osteoporosis is a silent disease and the consequent condition of fracture is serious with significant morbidity and mortality. The global burden of osteoporotic fractures is significant particularly in the developed countries, with fractures estimated to account for 1.75% of the burden of non-communicable diseases in Europe and 0.83% worldwide.[3] Nine million osteoporotic fractures were estimated to have occurred worldwide in 2000, with 1.6 million hip and 1.4 million clinical vertebral fractures, the greatest number of these occurring in Europe (34.8%).[3] A total of 2.7 million osteoporotic fractures were estimated in men and women in Europe with an estimated direct cost of € 36 billion. In the United Kingdom, the lifetime risk of having any fractures was estimated to be 53.2% in

women and 20.7% in men who are 50 years old.[4] In Sweden, the remaining lifetime risk of hip fracture alone at age 50 years old is quoted as 22.9% for women and 10.7% for men, while for any common osteoporotic fracture, which additionally includes the spine, shoulder, and forearm, it is 46.4% in women and 22.4% in men. With the rapidly growing elderly population and the fracture incidence increasing exponentially in some countries with age, numbers are expected to rise to 6.3 million hip fractures (? worldwide) in 2050.[5]

Hip fractures are the most serious adverse outcome of osteoporotic fractures and the 1 year mortality rates have been reported as 18–31%.[6] Many studies have suggested that the mortality in elderly women sustaining a hip fracture is highest for the 6 months immediately after the fracture but the effect may remain for several years afterwards,[7] unexplained by pre-existing comorbidities. Although men are less at risk of fractures overall, morbidity and mortality, particularly for hip fractures, is graver in men than women,[8] with men being twice as likely to die as women.[9] Many survivors are left with significant morbidity,[10] with one-half of ambulatory patients requiring assistance with activities of daily living and up to one-third of older people become totally dependent or in a nursing home within a year of hip fracture.[7]

Diagnosis

Although microarchitectural structural composition can be seen using three-dimensional (3D) CT or scanning electron micrograph (SEM) to look for osteoporosis (Figure 143.1), it is not practical to use these techniques for diagnosis. Dual-energy X-ray absorptiometry (DXA) was developed as a non-invasive, reproducible, and acceptable method to measure the amount of bone, expressed as bone mineral density (BMD). Conventionally DXA measurements are undertaken at the proximal femur and lumbar spine. BMD has a normal distribution in the population, and the cut-off for 'osteoporosis' using DXA, as defined by a World Health Organization (WHO) report[2] for postmenopausal women, is more than 2.5 standard deviations (SD) below the young normal mean (defined as a T-score), with 'osteopenia' defined as T-score of 1–2.5 SD and 'normal' defined as T-score no more than 1 SD below the
Fig. 143.1 Scanning electron micrograph of the trabecular structure of cancellous bone from a (A) normal subject and a patient with osteoporosis (B).

young adult mean. However, the definition based on DXA only captures information on the amount of bone, with no information regarding its quality, architectural properties, or geometry. Furthermore, although BMD can be a useful measure of osteoporosis at the population level, it does not adequately predict fragility fractures in individuals when used alone. Accordingly, the focus has shifted recently to assess individual risk using a combination of risk factors, some of which are independent of BMD—the most commonly used technology at present is the FRAX tool.[12]

As a fracture occurs when the force of the impact is greater than the strength of the bone, risk factors for fracture can encompass both of these elements, as shown schematically in Figure 143.2. The relationship is complex, with many risk factors affecting both bone strength and force of impact to the bone.

Risk factors for osteoporosis and fracture

Age and sex

Epidemiological studies have shown the overall fracture incidence has a bimodal distribution with a peak in childhood and early adulthood and a secondary peak in later life, but it is the increased fractures seen after the age of 50 which relate primarily to osteoporosis. Although vertebral fracture is the most common fragility fracture in both males and females, hip fracture is the most clinically important outcome of osteoporosis, requiring hospital admission and leading to major disability and excess mortality. The majority of hip fractures occur after a fall, with that risk increasing with age especially in women.[13] Although men have a higher mortality rate after hip fracture than women,[14] 80% of hip fractures occur in women and 90% in those over the age of 50. There is an exponential rise in hip fracture incidence after age 75 in women.[15] In contrast, only about 25% of vertebral fractures are related to falls and the prevalence of vertebral fractures in both sexes is much closer, perhaps as a result of a predominance of occupation-related trauma fractures in men. Wrist fracture pattern is similar to that of the hip with female predominance with estimated female to male ratio of 4:1.

Bone mineral density

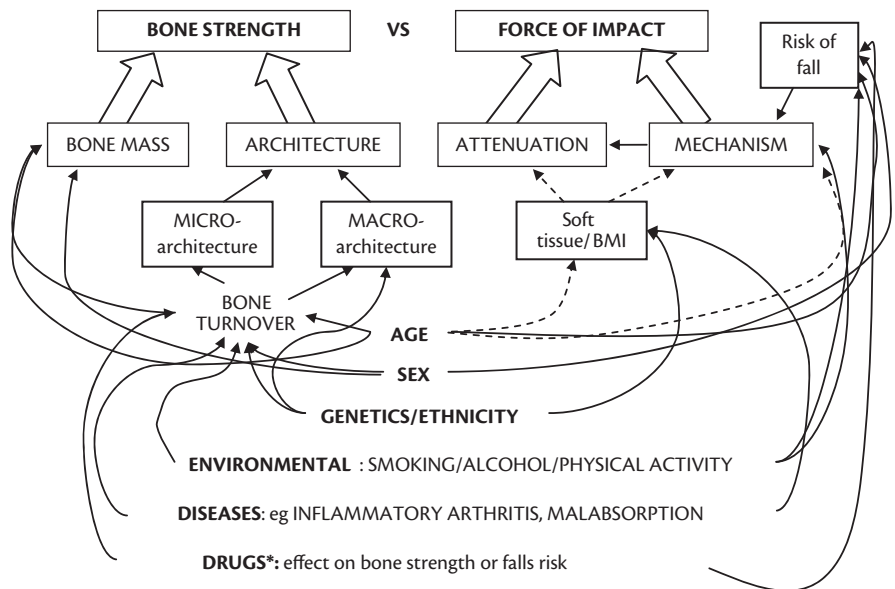
Age and sex also influence bone strength and studies have focused on BMD as a measurable factor determining bone strength. Bone mass peaks around age 30, and starts to decline thereafter. Unlike


Fig. 143.2 Schematic diagram illustrating risk factors of fracture. Fracture occurs as a consequence of force of impact to the bone being greater than bone strength. *Drug use will contribute to the risk of fracture either as having an effect on bone strength such as with steroid use, or through increasing the falls risk, as seen with the use of benzodiazepines, or potentially via both mechanisms, as with anti-psychotic drug use.

men who have a gradual and linear loss in bone mass after the age of 40, women have smaller bone size and lower peak bone mass and, in addition undergo accelerated bone loss immediately after the menopause. For each decrease in standard deviation of BMD, there is an estimated 1.5–3-fold increase in fracture risk.[16] When BMD is considered as the diagnostic marker of osteoporosis, its prevalence increases with age at the hip and other skeletal sites categorizing 30% of postmenopausal white women aged 50 or over as having osteoporosis.[2]

Genetics

Genetic factors have the strongest influence on BMD; it is estimated that 70–80% is heritable. Many genes have been implicated in association studies,[17] but increasingly genome-wide association studies (GWAS) are flagging up new genomic areas with influences on BMD and/or fracture. A recent meta-analysis showed 56 loci, of which 32 were new, associated with BMD at the hip and/or spine, and 14 of these also appeared to be associated with fracture risk.[18]

Previous fracture

Subsequent fracture risk is greatly increased by previous osteoporotic fracture especially at the same site, with a greater than 10-fold increased risk of subsequent vertebral fracture in those with an incident vertebral fracture.[19] In the multicentre United States Study of Osteoporotic Fractures (SOF) involving 9704 women aged 65 years or more, vertebral deformity was associated with a relative risk of 5.4 (95% CI 4.4–6.6) of future vertebral deformity, 2.8-fold risk (95% CI 2.3–3.4) of future hip fracture deformity, and 1.9-fold risk (95% CI 1.7–2.1) of non-vertebral deformity with significance remaining after adjustment for age and calcaneal BMD.[20] Similarly in a European study, European Prospective Osteoporosis Study (EPOS), the number and nature of vertebral deformity predicted not only future vertebral deformities[21] but also incident hip fracture with an age-adjusted rate ratio of 2.8 (95% CI 2.1–9.4).[22]

Geographical distribution and ethnicity

The incidence and prevalence of fractures also varies according to ethnicity and geographical location and this is most prominently seen in hip fracture. North American and Scandinavian countries have the highest age-adjusted rates, while Mediterranean countries, Latin America, and Asian populations have lower fracture rates. Many studies including the Women's Health Initiative have reported that black women have a lower risk of fracture than white women.[23] Vertebral fracture prevalence was 20–80% greater in Hiroshima[24] and 25% lower in Beijing[25] than for postmenopausal white women in Minnesota, despite the lower hip rates in both Asian cities. Geographical variation in fracture rates have also been observed within the same country, with people from rural regions having lower fracture rates than those from urban areas of the same country,[26,27] suggesting the importance of environmental factors.

Time trends

In many developed countries including the United States,[28] Canada,[29] Finland,[30] Norway,[31] England,[32] and Australia,[33] age-standardized fracture rates have started to plateau or decline, at least for hip fractures in women, although others have not reported this, including Germany[34] and Japan,[35] where age-adjusted rates continue to show an increase. Ethnicity and geographic variation may affect the findings; the incidence of hip fracture doubled in

Hispanic women in California from 1983 to 2000,[36] and significant increases have been recently observed in the rapidly urbanizing city of Beijing, China.[37] The trend of increasing fractures in Asia contributes significantly to the estimated increasing global burden of fractures with over one-half of female hip fractures occurring in Asia by 2050.[5] Although hip fracture rates are not decreasing in all settings, inpatient mortality rates appear to be declining,[28,32] perhaps reflecting an improvement in hip fracture care.

Additional risk factors, some of which are independent of BMD, are shown in Table 143.1. In addition a number of both hereditary and non-hereditary diseases and drugs (Table 143.2) are linked to osteoporosis primarily by an influence on bone mass.

Table 143.1 Summary of risk factors for fracture

Female gender	Premature menopause
Age[a]	Primary or secondary amenorrhoea
	Primary and secondary hypogonadism in man
Asian or white ethnicity	Previous fragility fracture[a]
Low BMD	Glucocorticoid therapy[a]
High bone turnover[a]	Family history of hip fracture[a]
Poor visual acuity[a]	Low body weight[a]
Neuromuscular disorders[a]	Cigarette smoking[a]
	Excessive alcohol consumption[a]
	Prolonged immobilization
	Low dietary calcium intake
	Vitamin D deficiency

[a]Independent or partly independent of bone mineral density (BMD).

Table 143.2 Diseases and their drugs associated with osteoporosis

Diseases associated with osteoporosis	Drugs and associated diseases associated with osteoporosis
Hereditary	Exogenous glucocorticoids
Rickets and osteogenesis imperfecta	Cancer therapies
Endocrine and metabolic	Aromatase inhibitors
Hyogonadism, hyperparathyroidism, hyperthyroidism, Cushing's syndrome,	Gonadotrophin releasing hormone agonists
Gut diseases	Androgen deprivation therapies
Coeliac disease	Others
Bone marrow diseases	Warfarin?
Multiple myeloma, mastocytosis	Proton pump inhibitors (e.g. omeprazole)
Rheumatological diseases	Thyroid hormones in excess
Systemic lupus erythematosus, ankylosing spondylitis, rheumatoid arthritis	Medroxyprogesterone acetate

Management of osteoporosis

Goals of intervention

The management of postmenopausal osteoporosis aims to prevent a first or subsequent fracture by slowing/preventing bone loss, maintaining bone strength, and minimizing skeletal trauma. Changes in lifestyle are helpful but women with a high fracture risk will often also need pharmacological intervention. In primary care, specific goals are to:

- maximize peak bone mass
- identify patients at highest risk of fracture
- use investigations cost-effectively
- exclude secondary osteoporosis
- provide lifestyle advice to all those at risk
- provide appropriate drug treatment to those at highest risk and encourage compliance
- identify and manage those at increased risk of falls.

All women should be encouraged to take steps to prevent bone loss and fractures, such as eating a balanced diet (including adequate intake of calcium and vitamin D), participating in appropriate weightbearing exercise, not smoking, avoiding excessive alcohol consumption, and instituting measures to prevent falls. Some of these steps, such as smoking cessation and exercise, offer health benefits beyond their effects on osteoporosis.

Ensuring adequate 'intake' of vitamin D may be achieved by eating a healthy diet—oily fish and some eggs—and getting 10 minutes' exposure to the sun once or twice per day to the extremities in summer (between May and September in the Northern hemisphere). Falls prevention strategies include ensuring a safe and well-lit home environment, appropriate footwear/walking devices, optimizing medical conditions (e.g. Parkinson's disease), ensuring adequate visual correction, and minimizing iatrogenic causes such as postural hypotension or excessive sedation. Recent guidelines extol the virtue of exercise and vitamin D in fall prevention.[39]

Investigation of patients with osteoporosis or fracture

Before embarking on pharmaceutical therapy it is important to exclude secondary cause of osteoporosis, especially in those with pre-existing vertebral fractures (Table 143.3). The assessment of serum 25-hydroxyvitamin D is controversial but should be considered in those in whom deficiency may influence the choice of therapy, for example when using intravenous bisphosphonates, which may induce hypocalcaemia if the patients is not vitamin D replete.

Assessment and treatment

Who to treat with drugs?

Population screening for osteoporosis or risk of fracture is not yet considered cost-effective. However, in those with incident fracture, especially vertebral fracture, or in whom multiple clinical risk factors are detected, further assessment and treatment is recommended.[40] Increasingly the use of assessment tools based on 10-year assessment of fracture risk such as the online FRAX tool[12] are being used. An alternative approach for use in general

Table 143.3 Investigations to exclude secondary osteoporosis

Serum/plasma test	Secondary cause considered
ESR	Malignancy, inflammatory musculoskeletal disorders
FBC	Multiple myeloma
Calcium, phosphate, alkaline phosphatase	Osteomalacia, Paget's disease, hyperparathyroidism and other metabolic bone diseases
Liver function tests (AAT, γGT, etc)	Chronic liver disease
Proteins and electrophoresis	Multiple myeloma
Creatinine	Chronic renal disease
Endomyseal antibodies	Coeliac disease
T_4, TSH	Exclude thyrotoxicosis
25-OH vitamin D	Severe deficiency

ESR, erythrocyte sedimentation rate; FBC, full blood count; T_4, thyroxine; TSH, thyroid stimulating hormone.

practice, Qfracture,[41] does not allow the incorporation of BMD. In the United Kingdom, intervention thresholds have been published by the National Osteoporosis Guideline Group (NOGG)[42] (available via the UK version of the FRAX tool[12,43]).

Drug therapy

The main pharmacological therapies available for the prevention and treatment of osteoporosis are bisphosphonates, strontium ranelate, raloxifene, parathyroid hormone analogues, and more recently denosumab. All reduce the risk of vertebral fracture and some also reduce the risk of non-vertebral fracture, including hip fracture. In the United Kingdom, evidence based guidelines from the National Institute for Health and Clinical Excellence (NICE) for primary[44] and secondary[45] prevention of osteoporosis, the Scottish Intercollegiate Guidelines Network (SIGN),[46] and National Osteoporosis Guideline Group (NOGG)[47] all recommend oral bisphosphonates as first-line choice in the management of postmenopausal osteoporosis because of their efficacy and cost-effectiveness. For those who are intolerant of oral bisphosphonates or in whom their use is contraindicated, alternative options include intravenous bisphosphonate preparations such as ibandronate and zoledronic acid, strontium ranelate, raloxifene, and denosumab. Because of their high cost, use of parathyroid hormone analogues such as teriparatide is generally restricted to those with severe osteoporosis at very high risk of fracture. Table 143.4 summarizes the grading of evidence relating to the fracture reduction efficacy of drug therapies currently licensed for the management of osteoporosis. There is still a role for hormone replacement therapy (HRT) in the management of osteoporosis however it is no longer considered first-line treatment in the majority of women due to an increased risk of breast cancer.

Bisphosphonates

Bisphosphonates are synthetic analogues of pyrophosphate with a high affinity for hydroxyapatite crystals in bone, suppressing bone turnover and increasing BMD at the lumbar spine and other sites via inhibition of osteoclast-mediated bone resorption. First-generation

Table 143.4 Grade of evidence relating to fracture reduction of pharmacological interventions in postmenopausal women with osteoporosis

Drug	Vertebral fracture	Non-vertebral fracture	Hip fracture
Alendronate	A	A	A
Ibandronate	A	A[a]	nae
Risedronate	A	A	A
Zolendronate	A	A	A
Denosumab	A	A	A
Raloxifene	A	nae	nae
Strontium ranelate	A	A	A[a]
Teriparatide	A	A	nae
PTH (1–84)	A	nae	nae

nae, not adequately evaluated; PTH, recombinant parathyroid hormone.
[a]In subsets of patients (post-hoc analysis).
Adapted from National Osteoporosis Guideline Group Guideline for the diagnosis and management of osteoporosis in postmenopausal women and men from the age of 50 years in the UK.[48]

bisphosphonates such as etidronate induce apoptosis in osteoclasts, whereas newer nitrogen-containing bisphosphonates such as alendronate, risedronate, ibandronate, and zoledronate interfere with the mevalonate pathway and inhibit recruitment and function of osteoclasts.[49]

Alendronate and risedronate are usually administered once weekly for greater convenience. Ibandronate is a monthly therapy at a dose of 150 mg and is also available as a 3 mg intravenous injection every 3 months. Meta-analyses have demonstrated that alendronate and risedronate reduce the incidence of vertebral, non-vertebral, and hip fractures. Both etidronate and ibandronate have been shown to reduce the incidence of vertebral fractures, but their impact on non-vertebral and hip fractures is less clear.[50] Therapeutic equivalence has been demonstrated between oral and intravenous ibandronate.[51] Zoledronic acid is licensed for the treatment of osteoporosis in both men and women as a 5 mg intravenous infusion once yearly. It has been shown to significantly reduce the risk of vertebral, non-vertebral, and hip fractures in osteoporotic post-menopausal women,[52] and to reduce vertebral and non-vertebral fractures and mortality in both men and women following surgical repair of hip fracture.[53]

Tolerability and safety of bisphosphonates
Gastrointestinal side effects
Gastrointestinal (GI) side effects are common and include nausea, dyspepsia, diarrhoea, oesophageal and gastric irritation, erosions, and ulceration.[54] They are a major cause of poor compliance and discontinuation of therapy and are more common in patients with a history of upper GI disorders and those taking concomitant non-steroidal anti-inflammatory drugs (NSAIDs), proton pump inhibitors, or histamine receptor blockers.[55] The anatomical distribution of oesophageal and gastric damage is consistent with a topical irritant effect.[54] Oral bisphosphonates interact with food and drink and therefore must be taken on an empty stomach at least 30 minutes before eating and with plenty of water, with the patient

remaining upright for at least 30 minutes after dosing to minimize side effects.[49] Intravenous preparations may circumvent the topical irritant effects of oral bisphosphonates.

Atrial fibrillation
Atrial fibrillation (AF) was first identified in a phase 3 zoledronic acid registration trial, but a subsequent meta-analysis of randomized controlled trials (RCTs) and observational studies found a non-significantly higher risk of AF in bisphosphonate users although registry-based studies suggest little or no increased risk of AF in bisphosphonate users.[56–59]

Subtrochanteric and femoral shaft fractures
The overall incidence of subtrochanteric and femoral shaft fractures is very low, accounting for less than 10% of all femoral fractures. The majority occur as a result of high-energy trauma, but almost 300 case series and reports of subtrochanteric/femoral shaft fractures occurring in patients treated with long-term bisphosphonate therapy have been identified (median duration 7 years; range 1.3–17 years). Recent studies have shown that the risk of atypical fracture appears to increase with increasing duration of bisphosphonate use, although the overall absolute risk of atypical fracture was extremely low. It is difficult to draw definitive conclusions regarding causality and further carefully adjudicated large scale clinical case-control studies are required.

Osteonecrosis of the jaw
Defined by the presence of exposed bone in the mouth which fails to heal after appropriate intervention over a period of 6–8 weeks, osteonecrosis of the jaw has been associated with bisphosphonate use, mainly in those receiving high-dose intravenous bisphosphonates for the management of malignant conditions. It is likely that bisphosphonate-induced osteonecrosis of the jaw (BONJ) results from direct toxicity to cells of the bone and soft tissue from high-potency bisphosphonates, probably acting through their effects on the mevalonate pathway. Incidence is rare, with estimates ranging from 1 in 10 000 to less than 1 in 100 000 persons per year of exposure. Patients should not be discouraged from taking bisphosphonates in the first instance, nor from undergoing dental treatment while taking them. There is no evidence that stopping ongoing bisphosphonate therapy prior to dental work is necessary as bisphosphonates persist in the skeletal system for years after discontinuation, although it is recommended that patients inform their dentist if they are taking a bisphosphonate and ensure regular dental check-ups.[57]

Oesophageal carcinoma
In 2009, the United States Food and Drug Administration (FDA) reported on 23 cases in the United States and 31 cases in Europe and Japan of oesophageal carcinoma in patients receiving oral bisphosphonates. Registry studies from Denmark and the United States found no increased incidence amongst oral bisphosphonate users compared to those receiving other osteoporosis medications, and two subsequent studies using data from the UK General Practice Research Database have produced conflicting results.[58,59]. Conclusive evidence for a casual association between oesophageal cancer and bisphosphonate use is lacking.

Other side effects of treatment
Intravenous bisphosphonates are associated with an acute-phase reaction occurring to a variable degree in 10–50% of patients, comprising of fever, myalgia, arthralgia, and flu-like symptoms 1–3 days

post-infusion. It is much less likely to occur with second and subsequent infusions.[56] Bisphosphonates have also rarely been associated with ocular disturbances such as conjunctivitis, blurred vision, eye pain. and uveitis.[60] Zoledronic acid has been associated with reports of renal failure and impairment following its use, especially in patients with pre-existing renal impairment or concomitant use of nephrotoxic drugs. Zoledronate should not be used in patients with a creatinine clearance less than 35 mL/min,[61] although caution should also be exercised when using oral bisphosphonates in patients with significant renal impairment.

Strontium ranelate

Strontium ranelate is an orally active agent that appears to act by dissociating bone resorption from bone formation, thus increasing bone mass and strength, although its exact mechanism of action remains unclear.[62] In phase 2 trials strontium ranelate 2 g/day reduced the relative risk of new vertebral fractures by 41%[63] with a relative risk reduction of 16% for all non-vertebral fractures and 19% for major fragility fractures.[64] Subgroup analysis of women aged 74 years or more(mean age 80 years) with femoral neck BMD within the osteoporotic range, demonstrated a 36% relative risk reduction in hip fracture. Follow-up studies suggest that the antifracture efficacy of strontium ranelate is sustained over a period of 8 years.[65] The increases in BMD observed in all studies involving strontium ranelate were larger than expected. This partly reflects the uptake of strontium in bone, which has a higher X-ray absorption than calcium, resulting in artificially higher BMD values [66] that account for approximately 50% of the measured change in BMD over 3 years of treatment with strontium ranelate.

The majority of the fracture reduction efficacy with strontium ranelate comes from studies involving elderly osteoporotic patients over the age of 75 years, and it is a useful alternative in such patients who are intolerant or have a contraindication to bisphosphonate therapy or who struggle with the strict dosing instructions. It is administered daily as a 2 g sachet dissolved in water. Food, milk, and calcium-containing products reduce the bioavailability of strontium ranelate by up to 70%, therefore it should be taken at least 2 hours after eating, preferably at night.

Commonly noted side effects include nausea, diarrhoea, and headache, which were usually mild and transient. However, pooled results from the two major phase 3 trials[63,64] revealed that the annual incidence of venous thromboembolism (VTE) observed over 5 years in the strontium ranelate group was approximately 0.9% vs 0.6% in the placebo group. The European Medicines Agency recently recommended that strontium ranelate is contraindicated in patients with a current or previous history of VTE and those who are temporarily or permanently immobilized. Other side effects reported include hypersensitivity reactions such as drug rash with eosinophilia and systemic symptoms (DRESS), Stevens–Johnson syndrome, and toxic epidermal necrolysis.

Selective oestrogen receptor modulators

Selective oestrogen receptor modulators (SERMs) provide the skeletal benefits of oestrogen without its adverse effects on the endometrium and breast. Raloxifene is the only SERM currently available in the United Kingdom for use in the prevention and treatment of osteoporosis. Other SERMs with proven anti-fracture efficacy include bazedoxifene and lasofoxifene. Raloxifene acts as an agonist at the oestrogen receptor in bone, mimicking the actions

of oestrogen by inhibiting bone resorption and increasing bone density, whereas in uterine and breast tissue it acts as an antagonist at the oestrogen receptor.[67] The main evidence for fracture reduction with raloxifene comes from the MORE (Multiple Outcomes of Raloxifene Evaluation) study,[68] where women with postmenopausal osteoporosis randomized to raloxifene 60 mg/day (the licensed dose) had a 30–50% relative risk reduction in vertebral fracture compared to placebo depending on the presence or absence of pre-existing vertebral fractures. No significant reduction in the risk of non-vertebral fractures was observed, a finding supported by the subsequent CORE (Continuing outcomes Relevant to Evista) study.[69]

SERMs are generally indicated for use in women who are within 10 years of the menopause as this period is associated with a marked increase in bone resorption and subsequent bone loss as a result of the reduction in oestrogen levels.

Common adverse effects of raloxifene include hot flushes, leg cramps, peripheral oedema, and influenza symptoms,[67,70] and a pooled 1.7-fold increase in the incidence of VTE (95% CI 0.93–3.14). SERMs should not therefore be prescribed to women with an active or past history of VTE, and treatment discontinued at least 72 hours before and during any periods of prolonged immobilization. Despite the beneficial effects of SERMs on lipid metabolism, studies have found no significant difference in the incidence of myocardial infarction or stroke and in the RUTH (Raloxifene Use for The Heart) study[71] there was an increased risk of fatal stroke (HR 1.49; 95% CI 1.00–2.24) The RUTH study also demonstrated a significant reduction in the risk of oestrogen receptor positive invasive breast cancer, consistent with observations from previous studies.

Denosumab

Denosumab is a fully human monoclonal immunoglobulin G2 (IgG2) antibody directed against receptor activator of NFκB ligand (RANKL).[72] Denosumab binds to RANKL, preventing interaction with its receptor RANK, located on osteoclasts and osteoclast precursors, thereby inhibiting osteoclast differentiation and reversibly inhibiting osteoclast-mediated bone resorption in cortical and trabecular bone.[73] Denosumab is recommended for use in postmenopausal women with osteoporosis who are unable to tolerate oral bisphosphonates, or comply with their strict dosing instructions, or have a contraindication to their use, at a dose of 60 mg by subcutaneous injection every 6 months.[74,75] In those patients with significant renal impairment, denosumab represents a useful alternative treatment option as renal impairment has no effect on the pharmacokinetics of denosumab.[72]

The main evidence for fracture reduction efficacy comes from the phase 3 Fracture Reduction Evaluation of Denosumab in Osteoporosis Every 6 Months (FREEDOM) trial,[76] which showed that 60 mg denosumab given subcutaneously every 6 months for 3 years significantly reduced the risk of new radiographic vertebral fracture by 68%, non-vertebral fracture by 20% (HR 0.80; 95% CI 0.67–0.95, p<0.01) and hip fracture by 40%. Denosumab was also associated with a relative increase in BMD at the lumbar spine and total hip, with significant reductions in bone turnover markers (BTMs) relative to placebo, an effect which appears rapidly reversible on stopping treatment. An extension study[77] has shown fracture incidence rates remaining low, with a progressive increase in BMD and sustained, but not progressive, reductions in BTMs in

the 5-year treatment group (long-term denosumab group) with an apparent maintenance of anti-fracture efficacy.

Denosumab has only recently been approved for clinical use, therefore safety data is based mainly on the results from phase 3 trials and regulatory documents. Denosumab has been associated with an increased incidence of eczema, flatulence, and cellulitis, although no significant differences in the overall incidence of infection were observed.[76] Individuals receiving denosumab appear to have a slightly increased risk of serious infections of the skin, ear, urinary, and GI tracts.[78] RANKL is expressed on activated T and B lymphocytes responsible for the recognition of foreign antigens and inhibition may suppress immune responsiveness. A non-significant increase in the incidence of malignancy (mainly pancreas, GI, reproductive tracts, and breast) has also been observed in those receiving denosumab compared to placebo, although no significant differences in the overall incidence of cancer were demonstrated in the FREEDOM study or its extension. Although no cases of osteonecrosis of the jaw (ONJ) were observed in the original phase III trial,[76] two cases of ONJ were observed in the cross-over group of the extension study.[77] ONJ has previously been reported in RCTs of cancer patients with bony metastases treated with monthly denosumab 120 mg, a dose significantly higher than that used in the treatment of osteoporosis.

Parathyroid hormone analogues

Recombinant parathyroid hormone (PTH) analogues are the only truly anabolic agents available for use in the treatment of osteoporosis, and include both teriparatide (1–34 N-terminal active fragment of human PTH) and Preotact (1–84 PTH). PTH acts on osteoblasts and renal tubular cells to stimulate bone formation via direct action on osteoblasts and increased renal tubular reabsorption of calcium and excretion of phosphate. It also acts indirectly via 1,25-dihydroxyvitamin D production to increase intestinal absorption of calcium. Continuous production of PTH, as seen in hyperparathyroidism, preferentially stimulates bone resorption leading to net bone loss, whereas once daily administration appears to preferentially stimulate net bone formation. The following discussion focuses on the available evidence for teriparatide, which is licensed in Europe and the United States for use in postmenopausal osteoporosis, glucocorticoid-induced osteoporosis, and osteoporosis in men. Teriparatide is licensed at a dose of 20 μg daily via subcutaneous injection for a period of 24 months.

Fracture reduction efficacy for teriparatide was demonstrated in the double-blind, multicentre, randomized controlled Fracture Prevention Trial of 1637 ambulatory women with postmenopausal osteoporosis.[79] The trial was terminated early after a median of 21 months treatment due to safety concerns in animal studies which suggested a dose- and duration-dependent increase in the incidence of osteosarcoma in rats, but despite this, daily subcutaneous teriparatide 20 μg was found to reduce the incidence of new vertebral fracture by 65% and non-vertebral fragility fractures by 53%, with no reduction in hip fractures. Following discontinuation of teriparatide, there was a sustained reduction in the risk of new vertebral fracture along with significantly less non-vertebral fragility fractures in the teriparatide group compared to placebo, whether or not a sequential osteoporosis drug is used.[80] The beneficial effects of teriparatide on BMD have been shown to decline following cessation of treatment, but this can be attenuated by sequential use of an anti-resorptive agent.[81] Teriparatide has also been shown to

reduce the frequency and severity of back pain and improve quality of life. One of the main disadvantages of teriparatide is its high cost and therefore its use is generally restricted to those patients with severe osteoporosis and high risk of vertebral fracture who have failed, are intolerant of or who have contra-indications to bisphosphonates, strontium ranelate or raloxifene.[45,47]

Teriparatide is generally well tolerated, with nausea, limb pain, headache, and dizziness the most commonly reported adverse events. Less common side effects include injection site reactions, hypercalcaemia (>2.76 nmol/litre), and nephrolithiasis. Although routine calcium monitoring is not required as hypercalcaemia is usually mild and transient, teriparatide is not recommended for use in patients with known hypercalcaemia.

Hormone replacement therapy

Until 2003, HRT was considered as first-line therapy for the treatment of postmenopausal osteoporosis. Meta-analysis of RCTs have shown that HRT produces a significant reduction in vertebral and non-vertebral fractures, including hip fracture, although this effect may be attenuated in women over 60 years.[82] The Women's Health Initiative (WHI) trial in the United SDtates[83] demonstrated that combined HRT increased BMD and reduced fracture risk in healthy postmenopausal women; however, data from this and the Million Women Study in the United Kingdom[84] also found significant increases in the risk of breast cancer in women taking combined oestrogen and progestin compared to placebo. HRT has also been associated with an increased risk of VTE and ischaemic stroke and the WHI study concluded that when considering the adverse impact of HRT on other disease outcome such as breast cancer there was no net benefit, even in women considered to be at high risk of fracture.[85]

HRT remains indicated for the prevention of osteoporosis in postmenopausal women at high risk of fractures who are intolerant of other therapies, or in whom they are contraindicated, but is no longer recommended as first-line therapy.[86] However, recent guidance from the National Osteoporosis Society suggests HRT still has a role to play in younger women (under the age of 60). In perimenopausal women with significant osteoporosis, with or without fracture, and no risk factors for breast cancer, heart disease, stroke, or VTE, the risks associated with HRT are low and the benefits of reduced fracture risk may outweigh the risks associated with HRT in these individuals.[87] HRT helps prevent the dramatic bone loss seen at the menopause for as long as treatment is continued and may be followed by bisphosphonate therapy in those patients with an ongoing high risk of fracture for whom lifelong anti-fracture treatment may be required, thereby decreasing duration of exposure to bisphosphonate therapy.

Role of calcium and vitamin D

All patients receiving pharmacological treatment for osteoporosis should be calcium and vitamin D replete. The recommended dietary intake in postmenopausal women is at least 1200 mg/day of calcium and 400–800 IU/day of vitamin D_3. For many patients this is not achievable via diet and sunlight exposure alone, especially in institutionalized individuals or those living in northern latitudes, and additional calcium and vitamin D supplementation is widely prescribed as an adjunct to specific osteoporosis treatment. However, recent studies have raised concern over a possible association between calcium and vitamin D supplementation

and increased cardiovascular risk. Bolland et al. initially reported an association between calcium supplementation alone and an increased risk of myocardial infarction in a meta-analysis of around 12 000 participants from 11 RCTs (mean age >40 years).[88] A subsequent study by the same group using data from the WHI Calcium/Vitamin D Study concluded that personal calcium supplementation, with and without vitamin D, modestly increased the risk of cardiovascular events, especially myocardial infarction.[89] However, there are a number of caveats to the above studies and it is difficult to draw definitive conclusions regarding their safety from the current evidence available. In all osteoporotic drugs trials, the study drug has been combined with calcium and vitamin D supplementation and it is difficult to say if such drugs alone would be as effective in fracture reduction without coadministration of calcium and vitamin D.

The evidence for fracture risk reduction with calcium and/or vitamin D alone is not clear. A meta-analysis and several RCTs have not shown any significant fracture reduction with calcium supplementation alone.[50] The effect of vitamin D on fracture reduction appears to vary depending on analogue, dose, and fracture type. For standard vitamin D preparations (vitamin D_2, vitamin D_3, and 25-hydroxyvitamin D) a number of meta-analyses and a large RCT have not demonstrated a significant reduction in vertebral, non-vertebral, or hip fractures.[50] However, some studies using standard vitamin D at a higher a dose of 700–800 IU/day have demonstrated a reduction in hip and non-vertebral fractures compared to placebo in elderly, institutionalized populations.[90–91] Vitamin D analogues such as 1,25-hydroxyvitamin D and 1-hydroxyvitamin D have been shown in three meta-analyses to significantly reduce the risk of vertebral fracture; however, the evidence for non-vertebral and hip fracture reduction is mixed.[50] A subsequent Cochrane review concluded that although vitamin D alone was unlikely to be effective in preventing vertebral, hip, or any new fracture, there was evidence to suggest that vitamin D with calcium may reduce hip fractures in frail elderly patients in institutional care.[92] Vitamin D has been shown to improve muscle strength and function and reduce the risk of falls amongst the ambulatory or institutionalized elderly, which may contribute to fracture risk reduction,[93,94] with the most recent evidence suggesting that high-dose supplement (≥800 IU daily) is associated with moderate reductions in hip and non-vertebral fractures.[95]

New and emerging treatments

Recent advances in our understanding of bone biology have highlighted a number of potentially new therapeutic targets for the treatment of osteoporosis, acting either through anti-resorptive mechanisms or via an anabolic action on bone formation. Cathepsin K (Cat-K) belongs to a group of lysosomal proteases involved in variety of physiological processes including bone remodelling, immunity, apoptosis and prohormone processing.[96] Cat-K is expressed by osteoclasts and plays a central role in osteoclast-mediated bone degradation. Recent results from a phase 2b clinical study involving 131 postmenopausal women with low BMD[97] found that odanacatib, a selective Cat-K inhibitor, significantly increased BMD at the lumbar spine and hip, along with significant reductions in the markers of bone resorption. In contrast, the Wnt/B-catenin signalling pathway plays an important role in osteoblastic cell differentiation and bone formation and represents a potential target for new anabolic therapies for osteoporosis. The

binding of Wnt to the Frizzled receptors and low-density lipoprotein receptor-related protein (LRP) coreceptors 5 and 6 stabilizes β-catenin, the net result of which is promotion of osteoblastogenesis and suppression of osteoclastogenesis. In the absence of Wnt receptor binding, the β-catenin is phosphorylated and degraded. Wnt activity is modulated by a number of antagonists which act by binding Wnt or preventing its interactions with its receptor.[96] One of these is sclerostin, the product of the *sost* gene. Mutations in the *sost* gene resulting in the absence of sclerostin are responsible for skeletal dysplasias characterized by high bone mass. Antisclerostin antibodies have been shown in a phase 1 study in humans to increase BMD and biochemical markers of bone formation.[98]

Special situations

Osteoporosis in men

Osteoporosis in men is a heterogeneous clinical entity, with secondary causes thought to play a larger role than in women. Although it represents a significant burden on healthcare resources, only a limited number of small RCTs of bisphosphonates and teriparatide have specifically assessed fracture reduction efficacy in men, with the majority of studies having BMD as the primary endpoint. However, changes in BMD and BTMs in response to bisphosphonates and teriparatide appear similar in both men and women,[99] and as these drugs have proven anti-fracture efficacy in postmenopausal women, their effects in terms of fracture reduction are likely to be similar in men. It is on this basis that the European Medicines Agency has granted a licence for the use of such drugs in men.

Alendronate (10 mg daily) has been shown to increase lumbar spine and hip BMD compared to placebo in 241 men with osteoporosis or previous fracture and reduce the rate of vertebral fracture, although the study was not statistically powered to show fracture reduction. The effect on BMD was independent of baseline serum levels of free testosterone, suggesting that bisphosphonates may be effective in men with hypogonadism.[100] Risedronate (35 mg once weekly) has also been shown to increase lumbar BMD from baseline, with a statistically insignificant reduction in vertebral fractures compared to placebo in an RCT of 284 men with low BMD.[101] Zoledronic acid in an RCT of 1065 patients recruited following hip fracture, 24% of whom were male, reduced the risk of both vertebral (1.7% vs 3.8%, p = 0.02) and non-vertebral including hip fractures (7.6% vs 10.7%, p = 0.03) compared to placebo when given within 90 days of hip fracture.[53]

In a randomized, double-blinded, placebo-controlled trial, 151 men with idiopathic or hypogonadal osteoporosis received teriparatide 20 μg/day for a median of 11 months.[102] Significant increases in lumbar spine and femoral neck BMD (5.87% and 1.5% respectively) were observed, independent of free testosterone or oestradiol levels, and changes in BTMs mirrored those seen in postmenopausal women. In the 30 month follow-up study, where subsequent anti-resorptive treatment was permitted, there was a non-significant reduction in the incidence of vertebral fractures in the teriparatide group. The incidence of moderate to severe fracture was significantly reduced by 83% although the study was not powered to show fracture reduction.[103] Despite the lack of definitive evidence of fracture reduction in men, teriparatide appears to produce similar effects in terms of BMD and BTMs as seen in the large anti-fracture studies in women. Thus for men with severe osteoporosis who are intolerant of or have failed bisphosphonate therapy teriparatide is an alternative treatment option.

The role of testosterone in older men at risk of fracture is controversial and there is no clear consensus regarding its use in this group. There is no clear evidence that testosterone prevents fractures and that fact that both bisphosphonates and teriparatide are effective in increasing BMD in men, regardless of gonadal function, suggests that it may be more appropriate to treat this group with an established osteoporotic drug.[99]

Glucocorticoid-induced osteoporosis

Drugs that have a European licence for the prevention of treatment of glucocorticoid-induced osteoporosis (GIO) include alendronate, risedronate, etidronate (postmenopausal women), zoledronic acid, and teriparatide (men and women). In practice the weekly bisphosphonates are the most tried and tested and have evidence of vertebral fracture prevention. The threshold for intervention for prevention is lower in GIO as fractures tend to occur at a higher level of BMD than is the case in postmenopausal women, and often treatment is advised in younger men and women at high risk of fracture.

Cancer-treatment-induced bone loss

Studies which determined the benefit of drugs that have specific effects in the prevention or management of osteoporosis associated with breast cancer treatments, especially the aromatase inhibitors, are limited but the best evidence to date is with the bisphosphonates, specifically intravenous zoledronic acid. Published guidance[104] suggests using any of the oral or intravenous bisphosphonates although subcutaneous denosumab may also prove valuable in the future.

With prostate cancer treatment in men, androgen deprivation produces a major excess fracture risk. Again evidence of bone loss protection is relatively scanty but zoledronic acid again seems to have a benefit and denosumab has a specific licence for use in this situation.

Duration of treatment

Emerging concerns regarding atypical fractures with prolonged bisphosphonate use have focused attention on initiating therapy in those patients who will benefit most in terms of the risk-benefit ratio of bisphosphonate therapy. The WHO FRAX model goes some way to addressing this. In patients currently receiving bisphosphonate therapy, the ongoing need for treatment should be regularly reviewed and formally reassessed after 5 years with a view to continuing therapy in those at highest risk of fracture. After 5–10 years of treatment, good clinical practice would suggest a drug-free period of 1–2 years before resuming treatment in those patients in whom ongoing fracture risk remains high. Although there is some evidence that anti-fracture efficacy persists for alendronate and perhaps risedronate following cessation of treatment, there is no evidence that a drug-free period reduces the risk of atypical fractures and the risks and benefits of stopping bisphosphonate therapy need to be considered on an individual basis.

Monitoring of treatment

The questions as to 'whether to monitor?' or 'how to monitor?' remain contentious. Increasingly, BTMs, especially serum CTX for bone resorption and serum P1NP for bone formation, are being used in specialist centres but they have not become freely available and suffer from the disadvantage of having to be measured in a fasting state. Classically, repeat BMD measurements are used and

have benefit in providing some reassurance to patients that their treatment is being effective. The best site to assess effectiveness of therapy is the lumbar spine but even here for most anti-resorptive therapies 2 years of treatment will be needed before real improvements in BMD will exceed the 'least significant change' measurement error. Changes in the lumbar spine site can be difficult to reliably assess, however, especially in elderly patients where pre-existing fracture, lumbar spondylosis, or aortic calcification may interfere with the reproducibility of repeated measurements. In this situation the total hip site can be used but interpreted with care, recognizing that many treatments have lesser magnitude of effect at that site.

Conclusion

Osteoporosis and fractures are frequent in the community but there is increasing evidence that they can be prevented with judicious use of oral and parenteral drug therapy in particular. Slowly, guidance is emerging on 'who to treat' and 'how long to treat'. With increasing future availability of new drugs with effects on bone resorption and bone formation there will be an increasing need for a stratified medicine approach to target appropriate treatments to individual patients.

CHAPTER 144

Paget's disease of bone

Stuart H. Ralston

Introduction

Paget's disease of bone (PDB) is a common metabolic bone disorder in people of European descent, characterized by focal abnormalities of increased and disorganized bone remodelling which can affect one or multiple bones throughout the skeleton. The characteristic clinical features of the disease were described by Sir James Paget in 1876 and the disease has borne his name ever since.

Epidemiology

Paget's disease predominantly affects older people, with an average age at diagnosis of about 65 years. The risk of developing Paget's disease is strongly age-dependent; the prevalence doubles each decade from the age of about 50 onwards to affect up to 7.5% of men and 5% of women by the eighth decade.[1] (Figure 144.1). Marked ethnic differences in susceptibility exist. The highest rates in the world are in the United Kingdom but the disease is also common in Spain, France, and Italy and in people from these countries who have migrated to other parts of the world such as Australia, New Zealand, the United States, and Canada. Conversely, Paget's is uncommon in Scandinavia and is extremely rare in the Indian subcontinent, China, Japan, and other Asian countries. These ethnic differences in disease susceptibility point to the importance of genetic factors in aetiology, but there is also evidence to suggest that environmental factors play a role. There have been significant reductions in prevalence and clinical severity of Paget's in the United Kingdom and New Zealand over the past 25 years.[2] However for reasons that remain unclear, no changes in prevalence or severity have been observed in Italy over recent years.[3] The reductions in prevalence of Paget's disease that have occurred in some countries because of changes in ethnic make-up of the population due to an influx of migrants from low-prevalence countries such as India and Pakistan and an efflux of members of the indigenous population to other parts of the world. It seems likely that there have also been changes in environmental triggers for the disease over the past 50–100 years. The nature of these triggers are unknown, but possible candidates include a reduced incidence of infections, improvements in nutrition, and reduced mechanical loading and fewer injuries to the skeleton.

Pathophysiology

Bone tissue is normally renewed and repaired throughout the skeleton through the process of bone remodelling. During the bone remodelling cycle, old and damaged bone is removed by osteoclasts and this is followed by infilling of the resorption space by osteoblasts which lay down new bone. This process is markedly accelerated within Pagetic bone lesions. Osteoclasts are increased in number and size and some contain nuclear inclusion bodies which are composed of microcylindrical structures organized into paracrystalline arrays (Figure 144.2). There is marrow fibrosis and increased vascularity of the bone marrow. Osteoblast numbers are also increased and bone formation is elevated, but the bone matrix is laid down in an irregular fashion, leading to the production of woven bone which has reduced mechanical strength. This in turn, impairs mechanical strength, predisposing to the development of deformities, especially when weightbearing bones of the lower limbs are affected. The risk of pathological fractures is also increased. Two factors contribute to the increased in bone turnover that occurs in Paget's disease. First, osteoclast precursors have increased sensitivity to the effects of bone resorbing factors such as calcitriol and the receptor activator of NFκB ligand (RANKL). Secondly, bone marrow stromal cells are better able to support osteoclast formation because of enhanced RANKL expression. There is increasing evidence to suggest that these cellular abnormalities are accounted for by mutations and polymorphisms in the genes that regulate osteoclast differentiation and function as discussed in more detail later in this chapter.
Fig. 144.1 Prevalence of Paget's disease in men and women.

Fig. 144.2 Histological characteristics of Paget's bone lesions: (A) Histological section of a pagetic bone lesion stained with haematoxylin and eosin, The bone is stained pink. A large osteoclast is visible (OCL) next to a row of osteoblasts (OB). There is marked marrow fibrosis. (B) Higher-power image of a different area in the same lesion. Three large multinucleated osteoclasts are visible. Irregular cement lines are evident indicative of woven bone (arrows). (C) Scanning electron microscope image of a nuclear inclusion body in a Paget's osteoclasts (box). (D) The same inclusion body at higher magnification.

Aetiology

Genetic factors play a central role in regulating susceptibility to Paget's disease. Approximately 15% of patients have a positive family history and the risk of developing Paget's is about 7 times increased in first-degree relatives of patients compared with controls.[4] Many families have also been described where the disease is inherited in an autosomal dominant fashion with high penetrance by the age of 70. Furthermore, several rare disorders have been described with clinical features overlapping with Paget's disease that are inherited in a mendelian manner.[5] The features of these diseases are summarized and compared with those of classical Paget's disease in Table 144.1. Familial expansile osteolysis, early-onset familial Paget's, and expansile skeletal hyperplasia are related disorders caused by mutations of the *TNFRSF11A* gene which encodes the receptor activator of NFκB (RANK) which plays an essential role in osteoclast differentiation and function. All mutations affect the signal peptide region of RANK and prevent it being cleaved normally. This causes the abnormal RANK molecules to accumulate within the Golgi apparatus and causes activation of osteoclasts by mechanisms that remain incompletely understood. The syndrome of juvenile Paget's disease is caused by mutations in the *TNFRSF11B* gene which encodes osteoprotegerin (OPG), a decoy receptor for RANKL that inhibits bone resorption. The causal mutations either delete the gene in its entirety or impair the ability of OPG to inhibit RANK signalling. The syndrome of inclusion body myopathy, Paget's disease, and frontotemporal dementia (IBMPFD) is caused

by *VCP* gene mutations. These affect a conserved region of the VCP protein which is involved in ubiquitin binding, but the mechanisms by which this causes osteoclast activation are poorly understood. Classical Paget's disease is a polygenic disorder with at least eight known predisposing genes and loci, many of which are involved in regulating osteoclast differentiation and function through effects on the RANKL–RANK–OPG–NFκB pathway as illustrated in Figure 144.3.

The most important susceptibility gene for the development of classical PDB is sequestosome 1 (*SQSTM1*) which encodes p62, a scaffold protein that is involved in the RANK signalling pathway. Mutations of *SQSTM1* have been reported to occur in 20–50% of patients with a family history of PDB and 5–20% of cases of 'sporadic' PDB. Most causal mutations affect the ubiquitin-associated (UBA) domain of p62 and impair its ability to bind polyubiquitin chains and other molecules in the RANK signalling complex. An important consequence of the UBA domain mutations is that these prevent p62 binding to the deubiquitinating enzyme CYLD and recruiting it to the intracellular RANK receptor complex. The consequence of this is that CYLD can no longer fulfil its normal function of inhibiting RANK signalling by deubiquitinating TRAF6, leading to activation of NFκB signalling and enhanced osteoclastogenesis.[6] Recently, several other susceptibility loci for Paget's disease have identified by genome-wide association studies.[7] These have shown that genetic variants close to the *TNFRSF11A*, *CSF1*, *TM7SF4*, and *OPTN* genes all strongly predispose to Paget's disease. Additional strong susceptibility loci were identified on chromosomes 7q33,

Table 144.1 Features of Paget's disease and related syndromes

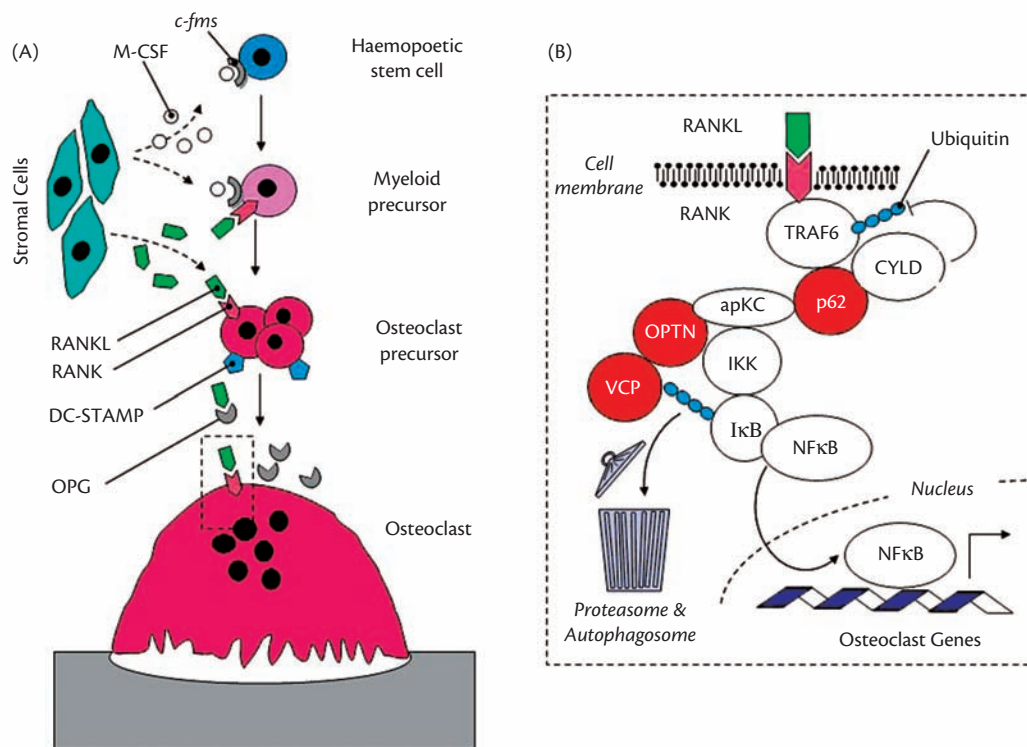
Disease	Age at diagnosis	Inheritance	Genes and loci implicated	Other features
Paget's disease	55–75	Autosomal dominant/ polygenic	SQSTM1 TNFRSF11A CSF1 TM7SF$ OPTN Chr 7q33 Chr 14 Chr 15	
Familial expansile osteolysis	15–20	Autosomal dominant	TNFRSF11A	Premature deafness, tooth loss
Expansile skeletal hyperplasia	15–20	Autosomal dominant	TNFRSF11A	Premature deafness, tooth loss, hypercalcaemia
Early-onset familial Paget's	15–20	Autosomal dominant	TNFRSF11A	Premature deafness, and tooth loss
Juvenile Paget's disease	1–5	Autosomal recessive	TNFRSF11B	Multiple fractures Vascular calcification
Inclusion body myopathy, Paget's disease, frontotemporal dementia	40–50	Autosomal dominant	VCP	Myopathy Dementia


Fig. 144.3 Mediators of osteoclast differentiation and function: (A) Haemopoetic stem cells differentiate down the myeloid lineage in response to M-CSF which is secreted by bone marrow stromal cells and which activates the *c-fms* receptor. Further differentiation down the osteoclast lineage is dependent on both M-CSF and RANKL which by binding to its receptor RANK, promotes osteoclast differentiation and bone resorption by mature osteoclasts. This interaction is blocked by OPG which inhibits bone resorption. Fusion of osteoclast precursors to form mature multinucleated osteoclasts is dependent on DC-STAMP which is upregulated by RANKL. (B) Within the osteoclast, binding of RANKL to RANK activates the NFκB signalling pathway by recruiting TNF-receptor associated factor 6 (TRAF6) to the intracellular tail of the receptor complex. The *SQSTM1* gene product p62 recruits CYLD to the receptor complex by its UBA domain and CYLD negatively regulates NFκB signalling by deubiquinating TRAF6. Mutations affecting the UBA domain of p62 prevent this occurring, thereby activating NFκB signalling. In addition p62 promotes NFκB signalling by binding to atypical protein kinase C which activates IKK. The IKK protein phosphorylates inhibitor of kappa B (IκB) which becomes ubiquitinated and targeted for degradation by the proteasome and/or autophagosome. This allows the p65 component of NFκB to translocate to the nucleus, and activate expression of osteoclast specific genes. The VCP protein is involved in regulating degradation of IκB whereas the optineurin protein (OPTN) inhibits NFκB signalling by an effect on IKK. Both of these proteins also play a role in autophagy, although the relevance of this to osteoclast activation is unclear.

14q32, and 15q24 in which the causal genes are less clear. The *TNFRSF11A*, *CSF1*, and *TM7SF4* genes all play key roles in regulating osteoclast differentiation and function. The importance of *TNFRSF11A* in osteoclast activity has already been discussed. The *CSF1* gene encodes macrophage colony stimulating factor (M-CSF), which together with RANK, is required for osteoclast differentiation. The *TM7SF4* gene encodes dendritic cell specific membrane protein (DC-STAMP) which is required for mononuclear osteoclast precursors to fuse to form mature osteoclasts.[8] The *OPTN* gene is involved in regulating NFκB signalling by modulating inhibitor of kappa B kinase activity (IKK) and is also involved in regulating autophagy. This is the process by which cells dispose of unwanted proteins and organelles.[9] Since the *SQSMT1* and *VCP* genes also play important roles in regulating autophagy, it has been suggested that the osteoclast nuclear inclusions that occur in Paget's disease may be undegraded protein aggregates due to defects in autophagy.[10] It is at present unclear, however, whether abnormalities of autophagy contribute to osteoclast activation in Paget's disease or whether this is a bystander phenomenon. The inherited susceptibility to Paget's disease seems to be mediated by a combination of rare and common variants in genes that regulate osteoclast differentiation and function, although the mechanisms by which these variants cause Paget's remains incompletely understood.

The changes in prevalence and severity that have occurred in many countries over recent years indicate that environmental factors also play a key role in the pathogenesis of PDB. Several potential environmental triggers have been suggested on the basis of epidemiological studies, observational data, or hypotheses, including low dietary calcium intake during childhood, repetitive mechanical loading of the skeleton, zoonotic infections, viral infections, and occupational exposure to toxins. The only environmental trigger for PDB that has been studied experimentally is paramyxovirus infection. This was first suggested to be a cause of PDB when osteoclasts from affected patients were found to have inclusion bodies that were thought to resemble viral nucleocapsids. Since this time, many investigators have attempted to detect evidence of paramyxoviruses in bone and blood samples from Paget's disease patients but the results have been inconclusive.

Disease models

Two types of disease model for Paget's disease have been generated. Some have explored the hypothesis that viral proteins cause PDB, whereas others have generated models in which genetic mutations that cause the disease have been introduced into the germ-line of mice by gene targeting. One of the first disease models was generated by over-expressing the measles virus nucleocapsid protein (MVNP) in mice, driven by the tartrate-resistant acid phosphatase (TRAP) promoter which preferentially targets expression to osteoclasts. Histological analysis of vertebral bone from these mice showed evidence of increased bone turnover.[11] Osteoclast precursors had increased sensitivity to $1,25(OH)_2D_3$ and formed hypernucleated osteoclasts as compared with those generated from wild-type littermates. High levels of interleukin (IL)-6 were found in these cultures and the osteoclast formation was inhibited by antibodies to IL-6, indicating that osteoclast activation in this model was due in part to production of this cytokine. Models of *SQSTM1*-mediated PDB have also been generated. Two groups of investigators independently generated mice in which the proline residue at codon 394 of

the mouse p62 protein is replaced by a leucine residue, mimicking the human P392L mutation.[10,12] Both groups reported that osteoclast precursors from these mice were hypersensitive to RANKL and in one study stromal cells from the mutant mice were reported to support osteoclast formation more efficiently than wild type in association with increased RANKL production. While no evidence of focal bone lesions was detected in one study on the basis of histological analysis of the vertebrae,[13] the other study showed that the P394L mice developed a bone disease with remarkable similarity to Paget's disease.[10] In this model, the mice developed focal bone lesions characteristic of Paget's disease which mainly targeted the hindlimbs, but which seldom targeted the vertebrae. Histological analysis showed evidence of increased bone turnover within the lesions, large hypernucleated osteoclasts, and increased bone formation with production of woven bone. Nuclear inclusion bodies similar to those observed in human Paget's disease were found in some osteoclasts. The difference between studies was most probably due to the fact that microCT analysis was used to localize lesions in one study[10] but not in the other.[13] Targeted inactivation of the *TNFRSF11B* gene in mice results in a generalized state of increased bone turnover associated with multiple fractures, providing a model for juvenile Paget's disease.[14] A model of IBMPFD has also been generated in which the arginine at codon 155 of the VCP protein is substituted by a histidine (R155H), modelling one of the most common human mutations.[15] These mice were reported to develop myopathy, and muscle cells showed increased rates of apoptosis and increased levels of the LC3B protein consistent with an increase in autophagic flux. Inclusion bodies were observed on histological analysis of brain and muscle, mimicking the findings in human IBMPFD. Osteoclast precursors from mutant mice showed increased sensitivity to RANKL and the mice were reported to have focal bone lesions characterized by increased osteoclast and osteoblast activity, again mimicking the human syndrome.

Clinical features

Paget's disease can present in a wide variety of ways. Probably the most common presentation nowadays is as an incidental finding of a raised serum alkaline phosphatase (ALP) or an abnormal radiograph in patients who are undergoing investigation of other diseases. However, patients can also present with specific features of the disease such as bone pain and deformity. Patients with metabolically active Paget's disease may experience bone pain. This can be present at rest and at night but also may be exacerbated by weightbearing or using an affected limb. Frequently, however, pain in Paget's disease does not occur as the result of raised metabolic activity, but instead is due to coexisting disorders such as secondary osteoarthritis, degenerative disc disease, and nerve compression syndromes. Careful evaluation of the patient is therefore necessary to determine the underlying cause of pain so that it can be treated appropriately.

Physical examination is usually normal in Paget's disease but sometimes deformity may be apparent, especially when the disease affects the tibia, skull, or facial bones (Figure 144.4). The skin temperature may be increased over affected bones in patients with metabolically active Paget's disease, but this is usually detectable only over the tibia.

Paget's disease can be associated with several complications including deafness, pathological fracture, secondary osteoarthritis, cranial nerve compression syndromes, and spinal stenosis

(Table 144.2). Although many of these conditions are also common in elderly patients without PDB, epidemiological studies have shown that Paget's patients are 3.1 times more likely to need a hip replacement for osteoarthritis compared with aged matched controls and 1.7 times more likely to need a knee replacement.[1] Other complications that are significantly more common in Paget's disease when

Table 144.2 Complications of Paget's disease of bone

Complication	Estimated frequency
Bone pain	4.6%
Deformity	2.5%
Pathological fracture	0.6%
Osteoarthritis	1.2%
Deafness	1.5%
Spinal stenosis	<0.1%
Nerve compression syndromes	<0.1%
Hydrocephalus	<0.1%
Paraplegia	<0.1%
High-output cardiac failure	<0.1%
Osteosarcoma	0.01%

The estimated frequency of complications is based on the assumption that about 7% of patients with Paget's disease come to medical attention and that the complications in those that do present clinically are similar to those recorded in the PRISM study which was representative of patients being treated by secondary care referral centres in the United Kingdom.

Fig. 144.4 Severe pagetic deformity of the tibia.

compared with controls include hearing loss (1.6-fold increase); tinnitus (1.5-fold); dizziness (1.3-fold), back pain (2.1-fold), osteoarthritis (1.7-fold), and fracture (1.2-fold). Osteosarcoma is a rare complication of PDB, which is estimated to occur in 0.01% to 0.1% of patients. However, most osteosarcomas that occur in adulthood are associated with PDB.[1] Hypercalcaemia can occur in PDB patients who are immobilized. The most common clinical scenario is as the result of dehydration when an affected patient is confined to bed because of an intercurrent illness or postoperatively. High-output cardiac failure can rarely occur as a complication of active PDB due to increased blood flow through affected bone, and a similar mechanism has been proposed to account at least in part, for the development of paraplegia which can occur as a complication of Paget's disease of the spine.

Investigations

The diagnosis of Paget's disease is usually straightforward. A radionuclide bone scan should be performed to localize sites of involvement followed by radiographs of affected bones or areas that are painful. The bone scan appearances in untreated Paget's disease are quite distinctive, showing a homogeneous increase in tracer uptake in affected bones (Figure 144.5). Radiographs show evidence of bone expansion with thickening of the cortex and disruption of the normal trabecular architecture by areas of osteolysis alternating with areas of osteosclerosis. Stress fractures may also be observed, especially when there is deformity of weightbearing lower limbs (Figure 144.5). A routine biochemical screen should be performed with measurement of urea and electrolytes, liver function tests, ALP, calcium and albumin. Serum total ALP levels provide a convenient and sensitive measure of metabolic activity in Paget's disease which is adequate for most patients. Serum total ALP values are raised in 95% of untreated patients with PDB but a normal value does not exclude the diagnosis since ALP can be within the normal range in patients with monostotic disease and in those with metabolically inactive disease. Bone-specific alkaline phosphatase (BSAP) levels track closely with those of total ALP except in patients with chronic liver disease where BSAP measurements would be the preferred method of assessing metabolic activity. Occasionally patients may be encountered where the results of the above investigations are inconclusive. In this situation, bone biopsy can sometimes be required to differentiate between Paget's disease and other causes of osteosclerosis such as prostate cancer metastatic to bone.

Management

The optimal management of Paget's disease requires a multidisciplinary approach. The elevated bone turnover in Paget's disease can be corrected in most cases by treatment with anti-resorptive therapy with one of the many potent bisphosphonates which are now available. Intravenous zoledronic acid in particular can induce biochemical remission of Paget's disease in a high proportion of patients for periods of up to 5 years.[16] In many patients, however, additional measures need to be adopted for pain management and to deal with other complications that respond poorly to bisphosphonates.

Anti-resorptive drugs

Inhibitors of osteoclastic bone resorption are widely used in the treatment of Paget's disease. The main indication is bone pain

Table 144.3 Bisphosphonates used in the treatment of Paget's disease

Drug	Trade name	Dose
Etidronate	Didronel	400 mg/day for 3 months
Clodronate[a]	Loron, Bonefos	400–1600 mg/day orally for 3–6 months or 300 mg/day IV for 5 days
Pamidronate	Aredia	60 mg/day IV for 3 days
Alendronate[a]	Fosamax	40 mg/day for 6 months
Tiludronate	Skelid	400 mg/day for 3 months
Risedronate	Actonel	30 mg/day for 2 months
Zoledronate	Aclasta	5 mg IV

[a]Not licensed in the UK for Paget's disease.
Fig. 144.5 Radiographic and scintigraphic features of Paget's disease: (A) Radiological appearances of advanced Paget's disease showing bone expansion, cortical thickening and loss of normal trabecular architecture, A pseudofracture is visible in the lateral cortex (white arrow). (B) Radionuclide bone scan showing intense tracer uptake in an affected femur. (C) Pathological subtrochanteric fracture in patient with Paget's disease. In this instance the fracture occurred at the site of a pre-existing pseudofracture.

caused by increased bone turnover at an affected site. Repeated courses of treatment can be given in patients who experience a recurrence of symptoms or if the initial course of treatment fails to give an adequate clinical or biochemical response.

Bisphosphonates are generally considered to be the anti-resorptive drugs of first choice in Paget's disease. Several bisphosphonates have been studied in PDB (Table 144.3) and most are effective at reducing the elevations in bone turnover that are characteristic of the disease. The nitrogen-containing bisphosphonates such as pamidronate, risedronate, and zoledronate are much more effective at inhibiting bone turnover in Paget's disease than older bisphosphonates such as etidronate and tiludronate. Despite this, randomized comparative trials have shown only modest differences between different drugs and their effects on bone pain.[17] This is probably because pain in Paget's disease can arise as the result of many different reasons, and not just increased bone turnover. As a reflection of this bisphosphonate therapy has been found to have a limited little impact on quality of life in patients with long-standing Paget's disease who have pre-existing bone deformity.[18]

Bisphosphonates can either be given orally or intravenously. Oral bisphosphonate therapy is an effective treatment for Paget's, but the dosing instructions are complex. Oral bisphosphonates need be taken on an empty stomach with a large glass of water and subsequently the patient must fast for between 30 minutes (risedronate) and 120 minutes (etidronate and tiludronate) to ensure

that intestinal absorption is adequate. The most common side effect with risedronate is dyspepsia, whereas diarrhoea is the most common side effect with tiludronate and etidronate. Pamidronate and zoledronic acid are administered by intravenous infusion. The most common side effect with these bisphosphonates is a transient flu-like illness which is characterized by fever, malaise, muscle, and joint pain lasting 2–3 days, known as the acute-phase response. In some patients these symptoms can be quite severe but they can be ameliorated by coadministration of paracetamol or non-steroidal anti-inflammatory drugs (NSAIDs). It is of interest that the acute-phase response is milder or absent after second and subsequent infusions of intravenous bisphosphonates, indicating that tolerance occurs. Hypocalcaemia can also occur after intravenous bisphosphonate therapy, especially in patients with active Paget's disease where ALP levels are elevated more than five times above normal. The risk of hypocalcaemia is increased in patients with vitamin D deficiency and it is important that this is corrected prior to administration of intravenous bisphosphonates. Some clinicians also prescribe calcium and vitamin D supplements for 1–2 weeks after intravenous bisphosphonates as a prophylactic measure. Bisphosphonates are contraindicated in patients with significant renal impairment and intravenous bisphosphonate therapy has been associated with the development of acute renal failure in patients with pre-existing renal dysfunction. The risk of this can be minimized by ensuring that the patient is properly hydrated at the time of the infusion; by ensuring that the infusion is given at the correct rate; and by avoiding coprescription with other potentially nephrotoxic drugs. Other rare side effects of bisphosphonates include uveitis, skin rashes, atrial fibrillation, osteonecrosis of the jaw, atypical subtrochanteric fractures, and bone and joint pain.

Some bisphosphonates have been reported to promote healing of osteolytic lesions and to restore normal bone histology in Paget's disease. Based on these observations, it has been suggested that bisphosphonate therapy should also be given to asymptomatic patients with the aim of preventing complications like bone deformity, deafness, and fractures. Unfortunately, there is no evidence as yet to show that long-term suppression of metabolic activity in Paget's disease prevents these complications. The only trial that has been performed in an attempt to address this issue is the PRISM study in which patients were treated with intensive bisphosphonate therapy or symptomatic treatment over a 3 year period. This showed no difference between the treatment groups in rates of fracture, requirement for orthopaedic surgery, progression of deafness or in quality of life.[18]

Calcitonin has inhibitory effects on bone turnover and has been successfully used in the treatment of bone pain associated with Paget's disease. It is rarely used nowadays however because of its weak anti-resorptive effects, high cost, and relatively short duration of action. The most common side effects are nausea and flushing.

Monitoring the response to anti-resorptive treatment

The response to anti-resorptive therapy can be conveniently monitored by measurements of total serum ALP activity. Following treatment, ALP levels fall progressively with a nadir at about 3–6 months. Treatment of Paget's disease with aminobisphosphonates such as risedronate and zoledronate is associated with prolonged suppression of ALP levels. In one study, a single infusion of zoledronic acid was reported to suppress ALP levels for periods of up to 6.5 years in some patients with Paget's disease.[16]

Other supportive treatments

Although anti-resorptive therapy can help bone pain, patients with established PDB often require analgesics and anti-inflammatory drugs for adequate symptom control, especially in the presence of complications such as arthritis.[18] Other non-pharmacological approaches such as acupuncture, physiotherapy, hydrotherapy, and transcutaneous electrical nerve stimulation (TENS) may also be used for pain control, and specific problems such as limb shortening and deformity can be helped by aids and devices such as walking sticks and shoe raises. The effectiveness of these strategies has not been specifically evaluated in PDB, but aids and devices were associated with significantly improved health-related quality of life indices participants of the PRISM study.[18]

Orthopaedic surgery

Surgical intervention is frequently required for the management of complications. The most common indication for surgical treatment is joint replacement for osteoarthritis, but others include fracture fixation, osteotomy to correct bone deformity, and surgery to correct spinal stenosis. The operative fixation of pagetic fractures can be technically challenging because of bony enlargement, deformity, hard bone, and increased vascularity, although in general operative treatment for PDB is very useful in improving quality of life for sufferers of the condition, particularly those with advanced osteoarthritis.[19] Bisphosphonate therapy is frequently given prior to elective orthopaedic surgery in the hope that this might reduce operative blood loss, but the effects of bisphosphonate therapy on blood loss have never been studied in a controlled trial. Orthopaedic surgery may also be required in patients who develop osteosarcoma, but the prognosis is poor even with aggressive operative treatment with an overall 5 year survival of about 6%.[20]

CHAPTER 145

Paediatric metabolic bone disease

Nick Bishop

Introduction

Childhood metabolic bone diseases typically present with fracture, bony deformity, bone pain, or short stature, either alone or in combination. To substantiate a diagnosis of osteoporosis, a child must be shown to have a low (more than two standard deviations below the mean) bone mass adjusted for body size with either one lower limb or vertebral fracture, or two upper limb fractures. The fractures should have resulted from low energy or no apparent trauma.[1]

Bone mass is usually assessed by dual energy X-ray absorptiometry (DXA). DXA measurements are significantly impacted by bone size; hence a larger child will have a higher measurement than a smaller child of the same age with the same true volumetric density.

There is evidence from studies of healthy children that supports the concept of body-size-adjusted bone mass being predictive of future fracture risk.[2] There are no prospective studies, however, that clearly link bone density measured by DXA to future fracture risk in the patient groups listed below .[3] There is no uniform method of adjusting for body size when assessing bone mass by DXA, and a large number of methods for undertaking such adjustments have been proposed.[4] Sequential measurements (usually twice yearly) assessed alongside a growth chart are helpful in evaluating bone mass trajectory in response to therapy. Indications for the use of DXA in primary and secondary osteoporosis in children, along with supporting evidence ranked by validity, are given on the International Society for Clinical Densitometry (ISCD) website (www.iscd.org/visitors/pdfs/ISCD2007OfficialPositions-Pediatric.pdf). These include all of the conditions listed in the following sections on primary and secondary osteoporosis, starting either from the age of first fracture, or from age 5 years when reliable measurements can be obtained.

Primary osteoporosis

Osteogenesis imperfecta

See Table 145.1 for classification of osteogenesis imperfecta (OI). The principal features are bone fragility, typically with low bone mass, leading to fractures and bone deformity with growth retardation.[5] Children often have delayed motor development, while ligamentous laxity, dentinogenesis imperfecta, hearing loss, hernias, heart valve defects, and blue scleral hue are variable features. In 90% of cases OI is dominantly inherited due to defects in the type I collagen genes *COL1A1* and *COL1A2*. Mutations in the C-propeptide of COL1A1 can cause Caffey's disease, a segmental hyperostosis of infancy.[6] Recessively inherited OI is now reported for multiple genes that regulate collagen molecule folding (*CRTAP*, *LEPRE1*, *PPIB*),[7–10] chaperone the molecule intracellularly (*FKBP10*),[11] or have a stabilizing role (*SERPINH1*).[12] *SERPINF1* encodes pigment epithelium-derived factor (PEDF), a secreted protein with multiple roles[13–14]; *SERPINF1* is deficient in type VI OI,[15] allowing a biochemical diagnosis by serum measurement of PEDF and possible future treatment with infused recombinant protein. A single case of OI due to mutation in *OSX/FP7* encoding osterix, a transcription factor in the osteoblast differentiation pathway, has been reported.[16] Type V OI is dominantly inherited but the gene defect is not known.[17] It is characterized by disordered control of endochondral bone formation in addition to low bone mass, resulting in a rachitic appearance to the growth plates in early infancy,[18] and later interosseous membrane calcification and hypertrophic callus formation at fracture and osteotomy sites. Surgeons need to be aware of this since perioperative therapy with indomethacin can reduce the risk of massive hyperplastic callus formation, a devastating condition. Approximately 5% of OI cases still have no clear genetic origin identified.

Idiopathic juvenile osteoporosis (IJO)

In idiopathic juvenile osteoporosis (IJO), 15–20% of cases are due to heterozygous mutations in the low -density lipoprotein receptor related protein 5 (*LRP5*) gene.[19] IJO typically presents precocious or early puberty with metaphyseal and vertebral crush fractures. Homozygous mutations result in the osteoporosis pseudoglioma syndrome[20]; affected children have tumour-like eye lesions that consist of non-malignant vitreous hyperplastic tissue. Bisphosphonate therapy can increase bone mass, reduce bone pain and improve vertebral size and shape, and may improve growth.[21–30] Early treatment in more severely affected individuals may reduce the risk of scoliosis which is otherwise reported in 100% of type III OI cases by age 7 years. Neridronate,[24] pamidronate,[25–26,31–34] and zoledronic acid[34] are all used for intravenous therapy. The most widely used bisphosphonate is pamidronate at a dose of 9–12 mg/kg per year,

Table 145.1 Classification of osteogenesis imperfecta

OI Type	Phenotype (during childhood)	Genetic origin
I	Mild motor delay. Bowing of long bones. Vertebral crush fractures. Ligamentous laxity, hernias, mixed conductive/sensorineural deafness, blue sclerae. Subdivided on the basis of the presence or absence of DI (A, absent; B, present)	Typically null allele of COL1A1, resulting from stop, frameshift, or splice site mutations
II	Lethal. Subdivided by appearance of ribs	Missense mutations in COL1A1 or COL1A2 Complete loss of CRTAP, PPIB, or LEPRE1
III	Severe, progressively deforming. Typically have fractures in utero, very poor post-=natal growth. Characteristic facies with small midface and pointed chin. Triangular facial appearance less noticeable with bisphosphonate treatment. Very delayed motor development. Almost all need intramedullary rodding. All have DI. Mutations in LEPRE1 are most often reported in families originating from West Africa, Pakistan, and Ireland	Missense mutations in COL1A1, COL1A2; null allele of COL1A2 Mutations in CRTAP, PPIB, or LEPRE1, SERPINH1, FKBP10, OSX/FP7
IV	Moderately severe. May have fractures in utero, but better post-natal growth than type III. Blue sclerae fade with age; may have DI	Missense mutations in COL1A1, COL1A2
V	Moderately severe. Metaphyseal changes that resemble rickets at birth, progressing to sclerosis in early life, followed by calcification of interosseous membranes in the forearm and lower leg. Characteristic bowing of the forearms. Hypertrophic callus formation following fractures and surgery	Unknown
VI	Severe, progressively deforming. Osteomalacic on bone biopsy, possibly as a result of abnormal matrix deposition—normal lamellar structure is disrupted	SERPINF1, encoding PEDF which can be measured in serum
Bruck 1	Contractures. White sclerae, mild DI. Moderately severe bone disease	FKBP10
Bruck 2	Clinical phenotype as for Bruck 1	PLOD2; bone-specific telopeptide lysyl hydroxylase
Cole–Carpenter	Normal at birth; develop craniosynostosis, ocular proptosis, hydrocephalus and diaphyseal fractures	Unknown

DI, dentinogenesis imperfect.

usually given in 3 monthly cycles. Oral therapy in milder OI cases with risedronate 1 mg/kg per week is safe and effective at increasing bone mass in line with the expected increase for age, but catch-up in moderate–severe cases may require higher doses (2 mg/kg per week).[23] Oral bisphosphonate therapy is less clearly effective than intravenous therapy in more severely affected children at both increasing bone mass and restoring the architecture of previously crush-fractured vertebrae, but has been reported to reduce fracture risk.[23,35]

Children receiving bisphosphonates should have bone densitometry and biochemical testing undertaken at 6 month intervals to ensure that they are responding appropriately to therapy, and to help guide therapy changes.[3] Some children can have their treatment dose reduced as they reconstruct their vertebrae and attain a normal bone mass for age. Others find that dose reduction leads to unacceptable levels of pain. Stopping therapy before growth ceases may increase fracture risk.[36] Serial monitoring of bone formation and resorption markers is used to detect evidence of oversuppression of bone remodelling activity. Vitamin D homeostasis and adequacy should be monitored, as vitamin D inadequacy impairs the skeletal response to bisphosphonate therapy.

Secondary osteoporosis

It is important to note that although fractures and in particular vertebral crush fractures are more common in the disease categories cited, vertebral crush fractures can resolve spontaneously if the underlying disease remits, or if treatment with glucocorticoids is withdrawn or replaced with a different disease-modifying agent.

Inflammatory conditions

Up to 7% of children with inflammatory joint disease of whatever cause—including but not limited to juvenile systemic lupus erythematosus, juvenile dermatomyosistis and polyarticular juvenile idiopathic arthritis (JIA)—have one or more vertebral crush fracture prior to use of glucocorticoids.[37] These fractures are often silent. Vertebral crush fractures also occur during steroid therapy in these children and are not limited to those with crush fractures at presentation. Fractures are generally more common in these children.[38] Recent data from the STOPP consortium indicate an association between falling lumbar spine bone mineral density (BMD) Z-score (for age) and incident vertebral fracture during the first 12 months of glucocorticoid therapy.[39] Vertebral fractures

are typically silent in children with rheumatological disease; detection requires imaging of the spine with radiographic or MRI-based techniques. Bone loss and fractures are more common in Crohn's disease than in ulcerative colitis, both prior to and after commencing glucocorticoids.[40–42] Bone mass loss occurs after the first decade in children with cystic fibrosis with a concomitant increase in fracture risk.[43]

Glucocorticoid effects

There is an increased risk of fracture when taking oral glucocorticoids, irrespective of the underlying condition; four courses of corticosteroids in a 12 month period increases incident fracture by 20%, but this risk appears to resolve 3–6 months after steroid cessation.[44] Corticosteroids reduce cortical bone turnover, resulting in retention of older, more heavily mineralized bone.[45] At a tissue level, corticosteroids increase apoptosis of osteoblast lineage cells, reducing bone formation and possibly impairing the skeletal response to mechanical stimulation. More rapid loss of trabecular bone leads to increased risk of vertebral fracture[39]; however, there has been no quantitation of this risk in relation to either dose or duration of glucocorticoid therapy.

Disuse

Long-bone fractures occur in children with cerebral palsy during handling; the bones are narrow, with thin cortices. In long bones, resistance to fracture is dependent on bone width—a tube that is twice as wide is eight times as strong under three-point bending.[46] Boys with Duchenne muscular dystrophy have low bone mass secondary to disuse and the early introduction of corticosteroids; fractures occur while they are still mobile, but increase in frequency once the patient becomes wheelchair dependent.[47] Intravenous bisphosphonate therapy has been reported to prevent further deterioration of vertebral crush fractures, restore some vertebral height, and relieve pain.[48] In children with epidermolysis bullosa, bone loss occurs due to immobility.

Endocrine disturbance

Low bone mass may not be apparent in children or adolescents with anorexia nervosa, but low bone mass is consistently reported in adult women who were anorexic as teenagers. The exact underlying mechanism is obscure. In Cushing's syndrome, low bone mass and fractures are reported; vertebral crush fractures have been shown to resolve on treatment of the underlying disorder.[49] There is no evidence of low bone mass or fractures during childhood in girls with Turner's syndrome.

Haematology and oncology

Children with acute leukaemia have an increased risk of fracture and bone loss both at diagnosis and during treatment. Up to 16% have one or more vertebral crush fractures at diagnosis, and in many of these children further crush fractures occur. Back pain is a cardinal feature in such children.[50] Studies suggest that chemotherapy alone does not lead to increased later fracture risk, but that the risk is increased in those receiving radiotherapy to the head and spine.

Children with thalassaemia are at increased risk of low bone mass and fracture.[51] Vertebral fractures are also seen post-transplantation, particularly following heart, lung, liver, and intestinal transplantation (infrequently following renal transplantation).[52]

Rare disorders presenting in the neonatal period with fractures

These disorders include:

◆ akinesia
◆ spinal muscular atrophy with arthrogryposis
◆ neurofibromatosis
◆ cytomegalovirus inclusion disease
◆ Caffey's disease
◆ I-cell disease (mucolipidosis II)
◆ Bruck's syndrome (OI with contractures)
◆ infantile hypophosphatasia
◆ severe neonatal hyperparathyroidism.

All of these rare disorders have other features that help distinguish them from OI.

Osteomalacia and rickets

See Table 145.2.

Vitamin D deficiency

The typical clinical features are bowed limbs presenting as genu varum, metaphyseal swelling, bossed forehead, and musculoskeletal pain. The vast majority of cases result from poor sunlight exposure or dietary inadequacy. In recent years the widespread use of sunscreen has increased the incidence of rickets among fair-skinned children, but rickets is still more common in darker-skinned individuals living in colder climates—more so when little skin is exposed because of cultural mores.[53] Vitamin D deficiency results in myopathy and musculoskeletal aches and pains; infants are usually miserable and have delayed motor development that improves quickly with treatment. Investigations should ideally be undertaken on a fasting sample: serum calcium (Ca), phosphate (PO_4), alkaline phosphatase (ALP), parathyroid hormone (PTH), and 25-hydroxyvitamin D (25OHD); wrist and knee radiographs. Expect phosphate to be reduced and alkaline phosphatase increased in active disease; serum calcium is variable. PTH is typically elevated above the upper limit of the adult normal range; it is unusual to see rickets in an individual whose 25OH vitamin D is above 25 nmol/litre and in such cases the possibility of X-linked hypophosphataemic rickets should be considered (see below). The radiological changes in mild rickets can be subtle and limited to widening of the growth plates; such changes are often best seen at the ulna in the wrist, and at the knees. More florid rachitic changes are cupping, splaying and fraying of the metaphyses, with osteopenia (literally, thin-looking bones), and periosteal elevation. Fractures are uncommon without clear rachitic change in infants born at term; however, preterm infants may have fractures without clear rachitic change, reflecting the role of other factors in the genesis of their bone disease (see below).

The threshold for deficiency in asymptomatic individuals without radiological changes is debated widely; a typical cut-off is anywhere from 25 to 50 nmol/litre 25OH vitamin D. Above this, supplementation (200–400 IU/day) is given. Sufficiency is generally accepted as being in excess of 75 nmol/litre, based on the fact that further increases in 25OHD are not associated with a reduction in serum PTH.

Table 145.2 Inherited forms of rickets

Type	Phenotype	Investigations	Genotype
Vitamin D resistant rickets type 1a (VDDR1a)	Motor delay Severe rickets Poor growth Hypocalcaemia Seizures	Low serum Ca, PO_4 Raised serum ALP Raised serum PTH Absent 1,25OH2D	*CYP27B1* (vitamin D 1α-hydroxylase gene) -/-
Vitamin D resistant rickets type 1b (VDDR1b)	Rickets at age 2–7 years	Low serum PO_4 Normal serum Ca Raised serum ALP Low 25OHD Normal 1,25OH2D	Mutations in *CYP2R1* (vitamin D 25-hydroxylase gene) -/-
Hereditary vitamin D resistant rickets	Early-onset severe rickets Hypocalcaemia Alopecia in those with DNA-binding domain defect	Low serum Ca, PO4 Raised serum ALP Raised serum PTH Raised serum 1,25OH2D	*VDR* (vitamin D receptor gene) -/-
X-linked hypophosphataemic rickets (XLH)	Short stature Bone deformities Frontal bossing Craniosynostosis Root abscesses Rachitic change on radiographs	Low serum PO4 Raised serum ALP Normal PTH Inappropriately normal 1,25OH2D	*PHEX* -/-
Autosomal dominant hypophosphataemic rickets (ARHR)	Short stature Bone deformities Frontal bossing Rachitic change on radiographs	Low serum PO_4 Raised serum ALP Normal PTH Inappropriately normal 1,25OH2D	FGF-23 R179 mutation resulting in failure to degrade FGF-23
Autosomal recessive hypophosphataemic rickets (ARHR)	Short stature Bone deformities Frontal bossing Rachitic change on radiographs	Low serum PO4 Raised serum ALP Normal PTH Inappropriately normal 1,25OH2D	*DMP1* -/-
Hypophosphatasia Infantile form	Hypercalcaemia Failure to thrive Motor delay Severe rickets with osteopenia Death	Very low/absent ALP Raised serum calcium Nephrocalcinosis Raised serum pyridoxal-5-phosphate, pyrophosphate Raised urine phosphoethanolamine	*TNSALP* -/-
Hypophosphatasia childhood/adult form	Early tooth loss Small bone fractures in early adulthood Mild rickets Mild motor delay	Low serum ALP Raised urine phosphoethanolamine	*TNSALP* +/-

ALP, alkaline phosphatase; PTH, parathyroid hormone.

Treatment is with ergo/cholecalciferol daily for 2 months. Infants up to 24 months age receive 3000 IU/day (5 µg/day); 2–10 years 6000 IU/day (150 µg/day); 10+ years 10 000 IU/day (250 µg/day). Infants with severe vitamin D deficiency may present with seizures or in heart failure. In such cases, correction of hypocalcemia is needed and further calcium supplementation may be required. With the exception of the infant in heart failure, where calcitriol may improve cardiac function, there is no place for the use of active vitamin D metabolites in the treatment of 'simple' vitamin D deficiency.

Metabolic bone disease of prematurity

The rapidly growing premature infant can outstrip the supply of calcium and phosphate available from either oral or intravenous nutrition. Breast milk should be supplemented with at least

Table 145.3 High bone mass due to increased bone formation

Disorder	Phenotype	Investigations	Genotype
Sclerosteosis 1	High bone mass Gigantism Syndactyly Square jaw Nerve compression	Radiographs show high bone mass, thickened cortices	*SOST* (sclerostin gene) -/-
Sclerosteosis 2	As for sclerosteosis 1	Radiographs show high bone mass, thickened cortices	*LRP4* -/- or +/-
Van Buchem disease	High bone mass Nerve compression	Radiographs show high bone mass, thickened cortices ALP elevated	Deletion of a *SOST*-specific regulatory element
Autosomal dominant osteopetrosis 1	High bone mass Torus palatinus	Radiographs show high bone mass, thickened cortices	*LRP5* +/-

Table 145.4 High bone mass due to reduced bone resorption

Disorder	Phenotype	Investigations	Genotype
Malignant osteopetrosis	Early marrow failure Hepatosplenomegaly Cranial nerve compression Fractures more frequent, heal poorly Rickets	Radiographs show dense bones with failure of remodelling; bones are undertubulated, bone-in-bone appearance in long bones and vertebrae Low RBC, WBC, and platelets Bone biopsy shows increased numbers of multinucleated giant cells without associated resorption cavities Bone biopsy in children with osteoclast formation defects shows few/absent osteoclasts	Loss of factors creating acidification by osteoclasts: *TCIRG1* -/- *CLCN7* -/- Loss of factors leading to osteoclast formation and function: *RANKL* -/- *RANK* -/- *PLEKHM1* -/- *OSTM1* -/-
Intermediate osteopetrosis	Fractures more frequent, heal poorly Renal tubular acidosis, nephrocalcinosis, intracranial calcification,	Increased bone density	Carbonic anhydrase II -/-
Pycnodysostosis	Distal acrolysis Craniosynostosis, raised intracranial pressure. Persistent anterior fontanelle. Fractures more frequent, heal poorly. Growth failure	Growth hormone deficiency in some. Intracranial pressure monitoring, may require craniectomy	Cathepsin K -/-
Autosomal dominant osteopetrosis type 2	Generalized sclerosis Fractures more frequent, heal poorly	Increased bone mass	*CLCN7* +/-

1 mmol/100 mL milk in order to provide sufficient phosphate. Calcium may also need to be added, but care should be taken not to cause coprecipitation. Immobilization adds to the failure to accrete adequate bone mass. Fractures may occur in infants up to 6 months old; particularly at risk are those who are slow (>30 days) to establish enteral feeds, those with conjugated hyperbilirubinaemia, chronic lung disease, or who receive diuretics, and those with clear rachitic changes on radiograph.[54] Vitamin D supplementation in excess of 800 U/day has not been shown to confer any short- or longer-term benefit. There is no place for the use of active vitamin D metabolites. Recent data suggests that despite its lower mineral content, early exposure to breast milk is associated with greater height at skeletal maturity, possibly due to anabolic factors in breast milk such as IGF-1.[55]

Inherited rickets

Rarely, defects of vitamin D metabolism occur; loss of renal 25-hdroxyvitamin D 1-α hydroxylase activity results in vitamin D resistant rickets type I; treatment is with 1-alfacalcidol or calcitriol. Loss of the vitamin D receptor requires treatment with overnight intravenous calcium infusions up to around the age of 2 years, followed by substantial oral calcium supplementation (7 g/day). Alopecia is seen in infants where the receptor DNA-binding domain is defective.[56–57]

The most common inherited form of rickets is X-linked hypophosphataemic rickets (see Table 145.2). Children usually present in the second year of life with bowed legs. In common with the rarer inherited rachitides, increased circulating FGF-23 is found, which promotes phosphaturia and inhibits renal production of the vitamin D metabolite 1,25-dihydroxyvitamin D. Autosomal dominant and recessive rickets as well as tumour-induced osteomalacia and McCune–Albright syndrome/polyostotic fibrous dysplasia also have raised circulating FGF-23 and the expected consequences thereof. Replacement therapy with oral phosphate in divided doses (40–50 mg/kg per day) and 1,25 dihydroxyvitamin D or 1-α calcidol (30–50 ng/kg per day) is currently used in those with rickets; the role of such intervention in McCune–Albright sufferers is unclear.[58] Trials of anti-FGF-23 antibody are under way.

Regular monitoring of serum calcium, alkaline phosphatase, PTH, and urine calcium:creatinine ratio are required. Excessive calcium losses can lead to nephrocalcinosis. Treatment needs to balance the effects of phosphate insufficiency on the growth plate with the effect on PTH production. Osteomalacic lesions contributing to bone softening and bowing deformity only heal when 1,25 dihydroxyvitamin D adequacy is attained, but excess 1-α calcidol can lead to excessive urine calcium losses.

High bone mass disorders

Increased bone formation

Autosomal dominant osteopetrosis type 1 is due to mutations in LRP5 that inhibit binding of inhibitors (SOST and DKK1) of the receptor. Some develop a torus palatinus (a protruding bone appearance on the roof of the mouth.[57] Sclerosteosis and Van Buchem's disease are due to mutations in the gene (*SOST*) encoding sclerostin (sclerosteosis) or in an upstream regulatory region that affects sclerostin production (van Buchem's disease). The main clinical problems result from cranial nerve compression.[59]

See Table 145.3.

Reduced bone resorption

In osteopetrosis[60–62] there is increased bone mass due to failure to resorb bone. Many cases result from mutations in genes that modulate the secretion of hydrogen and chloride ions into the subcellular space beneath the multinucleated giant cell's ruffled border or, less commonly, encode for the pathway resulting in osteoclast formation and activation, the RANK/RANKL pathway. Severe cases present early in life with bone marrow failure and incipient blindness: urgent decompression of the optic nerves may be required to maintain vision. Some respond well to bone marrow transplantation; those with neuropathic features or without osteoclasts generally do not. Milder forms present later in life, with nerve compression and poor fracture healing being significant problems.

Children with pycnodysostosis cases may develop raised intracranial pressure and require surgical intervention.

See Table 145.4.

Disorders of bone mineralization—osteomalacia

Deepak R. Jadon, Tehseen Ahmed, and Ashok K. Bhalla

Introduction

Osteomalacia is a metabolic bone disorder characterized by impaired or defective mineralization of bone matrix following the closure of the growth plates. **Rickets** is a condition of deficient mineralization at the growth plate of long bones in children and adolescents. By comparison, in osteoporosis bone mineralization occurs in normal quantities but there is an overall lack of bone stock.

Epidemiology

Osteomalacia is endemic in some parts of the world such as southern Chile and Argentina due to the low sun exposure at southerly latitudes,[1] and in the Middle East and parts of Asia, secondary to the use of clothing that covers most of the body. In the United Kingdom, nutritional osteomalacia is uncommon among the white population but can be found in elderly housebound subjects.[2] In the Asian population of the United Kingdom, osteomalacia is relatively more prevalent secondary to dietary deficiency, lack of sun exposure, and skin pigmentation.[2] Osteomalacia is rarer in the United States as foodstuffs are commonly fortified with vitamin D. Vitamin D deficiency or insufficiency remains common in both children and adults throughout the world, especially those living in northern latitudes.

Homeostasis of vitamin D, calcium, and phosphate

Vitamin D maintains extracellular calcium ion levels by regulating intestinal calcium absorption, altering parathyroid hormone (PTH) secretion, and releasing calcium from bone (Figure 146.1). The majority of bodily vitamin D (80–90%) is endogenously derived and in the form vitamin D_3 (cholecalciferol). Cutaneous conversion of a cholesterol derivative (7-dehydrocholesterol) under the stimulus of the ultraviolet-B component of sunlight (wavelengths 290–315 nm) generates vitamin D_3. The amount of vitamin D_3 formed depends on the season, latitude, amount of skin exposed, and skin pigmentation. Exogenous dietary sources provide the remainder, as vitamin D_3 and vitamin D_2 (ergocalciferol).[3] Vitamin D_2 is synthesized by UV irradiation of the plant sterol, ergosterol.

Both vitamin D_3 and D_2 are further metabolized in the liver and kidney to 25-hydroxyvitamin D (25(OH)D; calcidiol) and 1,25 dihydroxyvitamin D (1,25(OH)$_2$D; calcitriol), the active metabolite which has properties more in keeping with a hormone than a vitamin. 1,25(OH)$_2$D increases calcium and phosphorous absorption from the small intestine, increases reabsorption of calcium and phosphate in the renal tubules, decreases PTH secretion, and promotes calcium and phosphate release from bone (resorption) into the extracellular compartment. Without vitamin D, only 10–15% of dietary calcium and approximately 60% of phosphorus is absorbed.[3] Increasing calcium and phosphorus concentrations in the extracellular fluid promotes calcification of osteoid to form bone. 1,25(OH)$_2$D synthesis is promoted by PTH, hypocalcaemia, and hypophosphataemia.[2] and suppressed by hypercalcaemia, hyperphosphataemia, impaired renal function, and fibroblast growth factor 23 (FGF23).[2,3] An individual's vitamin D status is reflected in the circulating levels of 25(OH)D, rather than its active metabolite 1,25(OH)$_2$D.

Aetiology and classification

Calcium and inorganic phosphate are the key precursors for bone mineralization and growth, and their deficiency forms the basis of rickets and osteomalacia classification: hypocalcaemic rickets is caused primarily by calcium deficiency; hypophosphataemic rickets/osteomalacia is caused primarily by phosphate deficiency. Rickets and osteomalacia have multiple aetiologies (Box 146.1) with much overlap, and these are discussed individually later in this chapter.

Clinical features

Detailed history-taking can give indications of poor calcium and vitamin D dietary habits, concurrent or previous illness, drug history, and family history. The key clinical features of osteomalacia
Fig. 146.1 Vitamin D metabolism.

Box 146.1 Causes of rickets and osteomalacia

Vitamin D related rickets/osteomalacia

- Nutritional: low dietary intake and/or sun exposure and skin pigmentation

- Gastrointestinal malabsorption: coeliac disease, gastric and small bowel surgery, inflammatory bowel disease and pancreatitis

- Defects in vitamin D metabolism: chronic liver disease, chronic renal failure, and abnormalities of vitamin D receptors (see below)

- Anti-epileptics

- Vitamin D receptor/enzyme deficiency:

  - Non-functioning 25 hydroxylase

  - Absent 1α-hydroxylase: pseudo-vitamin D deficiency (vitamin D dependent rickets type 1)

  - Non-functioning VDR: hereditary vitamin D resistant (vitamin D dependent rickets type 2)

Phosphate deficiency

- Hereditary hypophosphatemic rickets:

  - X-linked hypophosphataemic rickets (XLH)

  - Autosomal dominant hypophosphataemic rickets (ADHR)

  - Autosomal recessive hypophosphataemic rickets (ARHR)

  - Hypophosphataemic rickets with hypercalciuria (HHRH)

- Tumour-induced osteomalacia (TIO)/oncogenic osteomalacia

- Renal tubular phosphate wasting

- Fanconi's syndrome

- Distal renal tubular acidosis

- Dent's disease

- Lowe's syndrome

- Furosemide

- Renal tubular damage

Calcium deficiency

- Very low calcium intake in children

Miscellaneous

- Aluminium intoxication

- Cadmium intoxication

- Etidronate overdose

- Hypophosphatasia

are bone pain and tenderness, muscle pain and weakness, skeletal deformity, and fracture.

Presentation of osteomalacia

The bone pain of osteomalacia is diffuse, affects bone rather than joints, is exacerbated by weight bearing and use of local muscles, and affects the spine, rib cage, shoulder girdle, and pelvis.[1,4] Pain is usually symmetrical, starting in the lumbar spine and spreading to the pelvis, hips, upper thighs, ribs, and upper back. Percussion at these sites elicits tenderness. The localization of pain to the axial rather than the peripheral skeleton is thought to be due to the greater proportion of unmineralized osteoid that accumulates in trabecular bone *vs* cortical bone.[4] Pain is thought to occur due to unmineralized bone matrix becoming hydrated, resulting in stretching of the periosteum.[3] Deformities due to softening of the adult skeleton include kyphosis, scoliosis, coxa vara, pectus carinatum, protrusio acetabulae, and triradiate pelvis.[1]

Osteomalacia usually causes mild proximal weakness. More pronounced weakness in the hip girdle results in a waddling gait. In severe cases patients may be confined to a wheelchair or bed bound, and be more prone to falls. Muscle atrophy is often mild relative to the weakness. Muscle tone is often reduced, but reflexes tend to be preserved.[4] Patients may report difficulty rising from a sitting position or climbing stairs. Muscle strength demonstrates correlation with 25(OH)D levels, especially at lower levels of 25(OH)D.[5]

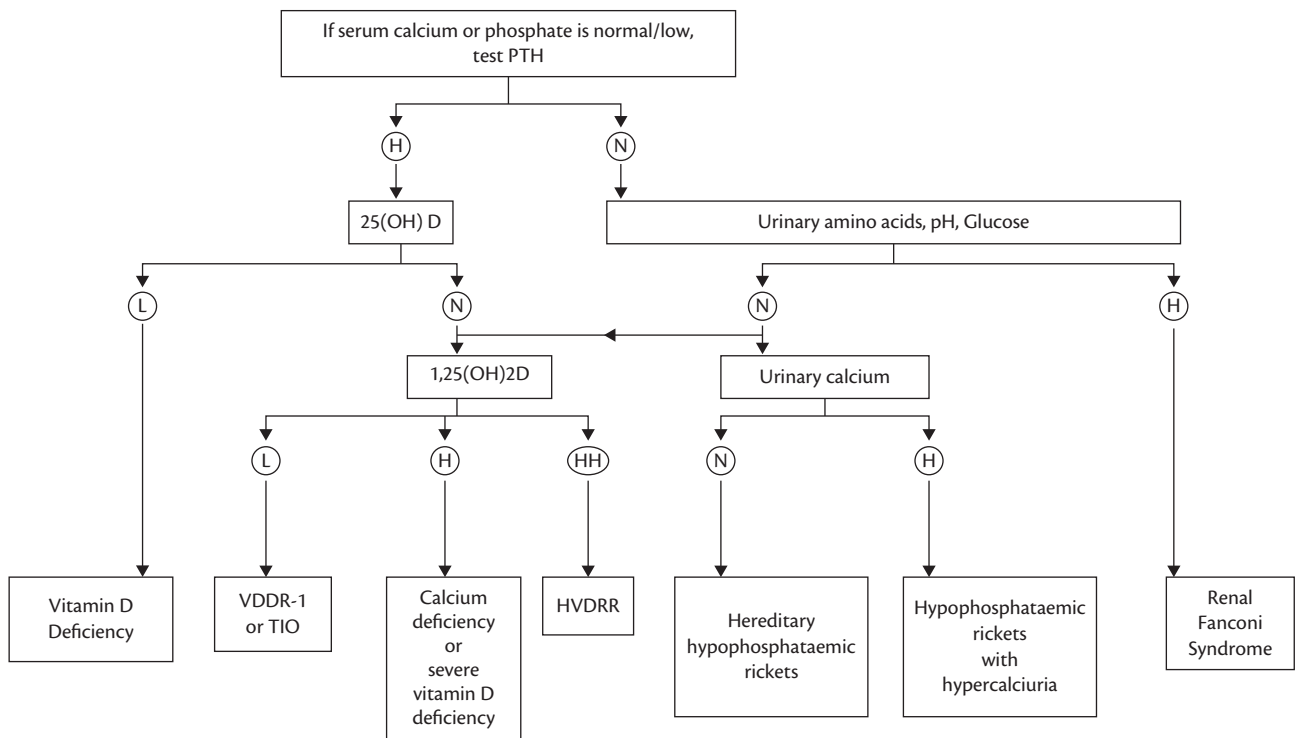
Oligoarticular joint effusions and joint pain occur rarely and raise the differential of a seronegative inflammatory arthritis. Joint effusions in osteomalacia are due to local microfractures or pseudofractures.[1] In adolescence, osteomalacia may present with significant hypocalcaemia manifesting as cramp or tetany.[2]

Investigation

The clinical diagnosis of osteomalacia should be corroborated by biochemical and radiological assessments (Figure 146.2).

Biochemistry

The biochemical picture varies according to the underlying cause and stage of disease (Table 146.1). Vitamin D deficiency is diagnosed when measuring serum 25(OH)D. Adults with osteomalacia secondary to vitamin D deficiency show elevated alkaline phosphatase (ALP) as one of the first manifestations, alongside low/normocalcaemia, hypophosphataemia, and reduced urinary calcium excretion. Serum ALP is produced by overactive osteoblasts during mineralization of bone and growth plate cartilage. It leaks into the extracellular compartment, resulting in elevated serum ALP concentration that accurately reflects disease activity.[6]

PTH levels increase as 25(OH)D levels decrease. The excess PTH leads to increased bone resorption and cortical bone thinning, resulting in an increased risk of fracture. Bone turnover markers rise.


Symbol		
Ⓛ	Low	PTH = Parathyroid hormone

Fig. 146.3 Antero-posterior plain radiograph of the pelvis. A patient with osteomalacia demonstrates a Looser's zone just distal to the left lesser trochanter of the femur and bilateral superior pubic rami fractures.

Imaging

There may be osteopenia with poor definition of unmineralized trabecular osteoid. However, the best known radiographic feature of osteomalacia is the characteristic Looser's zone (see Figure 146.3), first described by Emil Looser in 1920. Looser's zones (pseudofractures) are narrow radiolucent lines 2–5 mm in width with sclerotic borders perpendicular to the cortex that mimic the appearance of a fracture. They most commonly occur in the ribs, pubic rami, and lateral scapula. In addition, they can be found on the inferior aspects of the femoral neck, lesser trochanters, metatarsals, and medial aspects of the shafts of long bones.[1] They can lead to complete fractures and significant bony deformities.

Secondary hyperparathyroidism causes cortical thinning and subperiosteal erosions involving the phalanges, distal ends of the

clavicles, and pubic symphysis.[7] Secondary and tertiary hyperparathyroidism can manifest as the 'rugger jersey' sign; alternating bands of increased/decreased bone density of vertebral bodies on a lateral lumbar spine plain radiograph.[2] It occurs due to weakened trabecular bone being condensed adjacent to the vertebral endplates. Intervertebral discs compressing softened endplates in osteomalacia give rise to biconcave or 'codfish' vertebrae.[7]

Hypophosphatasia and hypophosphataemia can cause chondrocalcinosis and calcific enthesopathy that can mimic features of seronegative spondyloarthropathies.[1] In hypophosphatasia, Looser's zones tend to occur on the outer cortex of long bones.

Bone mineral density (BMD), assessed by DEXA, may show low values consistent with osteopenia or osteoporosis as the amount of unmineralized bone (osteoid bone) is high in osteomalacia. A rapid increase in BMD occurs after therapy has been started.[8]

Radioisotope bone scans can detect Looser's zones and fractures more reliably than plain radiographs.[9] When present at multiple sites, the uptake may mimic metastatic cancer. Bone scans may also show generalized increased uptake in the skeleton, particularly of the skull.

Bone biopsy is rarely needed, but remains the gold standard for diagnosis of osteomalacia, particularly in those patients whose biochemical and clinical picture is uncertain. The changes on biopsy include thickened osteoid seams and excessive osteoid volume.[2] However, these features can occur in other disorders with high turnover such as Paget's disease, thyrotoxicosis, and hyperparathyroidism.[4] Tetracycline bone labelling is helpful as it demonstrates reduced or absent mineralization activity in osteomalacia.

Vitamin D deficiency osteomalacia

Vitamin D deficiency is the commonest cause of osteomalacia. It results in impaired intestinal calcium absorption, with subsequent hypocalcaemia, normal phosphate, and elevated PTH. Later, the secondary hyperparathyroidism reduces renal phosphorus reabsorption leading to hyperphosphaturia, normalizing serum calcium levels and further reducing calcium deposition in bone, leading to rickets and osteomalacia. The final stage is of low calcium, low phosphate, and tertiary hyperparathyroidism.

The definition of vitamin D 'insufficiency' and 'deficiency' varies even among experts. In the United Kingdom the definition of vitamin D sufficiency in most centres is either 50 nmol/litre or more, or 75 nmol/litre or more. Levels below 25 nmol/litre in the United Kingdom generally reflect vitamin D deficiency and concentrations of 25–50 nmol/litre may indicate vitamin D insufficiency.

In winter months at latitudes of 52° or more (i.e. most of the United Kingdom), the ultraviolet (UV) light intensity is inadequate for the cutaneous synthesis of vitamin D; during the remainder of the year, effective UV light occurs mostly between 1100 and 1500 hours, when most people are indoors, at work, or at school. During the winter and spring, 16% of adults in the United Kingdom will have severe vitamin D deficiency (<25 nmol/litre).[10] In the United Kingdom's South Asian community the prevalence of severe vitamin D deficiency during the winter and spring has been estimated at 50%.[11] Causes of vitamin D deficiency leading to osteomalacia in adults are as follows.

◆ **Primary vitamin D deficiency**: Inadequate sun exposure, resulting from social, economic, cultural, and health-related factors, combined with reduced dietary intake is the most common cause. Housebound elderly patients and those with pigmented skin produce lower amounts of vitamin D.[12]

◆ **Secondary vitamin D deficiency**: Malabsorption disorders are the second most common cause of vitamin D deficiency and osteomalacia. Malabsorption is usually secondary to a reduced effective surface area for absorption as in small bowel and gastric surgery, or due to an abnormal absorptive surface, as in coeliac disease and inflammatory bowel diseases. Disorders causing fat malabsorption (e.g. pancreatic insufficiency) can also lead to vitamin D deficiency, as vitamin D is fat-soluble.

◆ **Defects of vitamin D metabolism**: Abnormal hepatic hydroxylation is a rare cause of vitamin D deficiency and osteomalacia. In comparison, impaired renal hydroxylation of 25-hydroxyvitamin D (secondary to reduced renal function, loss of renal mass, and renal tubular disorders) is the most common cause of osteomalacia after primary vitamin D deficiency and malabsorption disorders.

◆ **Iatrogenic causes**: Drugs such as phenobarbitone and phenytoin can induce cytochrome P450 enzymes and increase catabolism of 25(OH)D.

Management of vitamin D deficiency

The aims of management are to reduce symptoms, fracture risk, bone deformity, and sequelae. There are no universally agreed protocols for managing vitamin D deficiency. Deficiency can be prevented by adequate sun exposure to the face and arms for a mean of 15–30 minutes, between 1100 and 1500 hours, 2–3 times per week. Such a recommendation may not be effective at different times of the year and will depend upon both latitude and skin pigmentation. Patients with osteomalacia should be given vitamin D and calcium supplementation. One regime is to use 60 000 IU of cholecalciferol weekly for 8–12 weeks, followed by 1000–2000 IU daily as maintenance therapy.[13] Additionally, 1 g calcium should be given daily. 25(OH)D levels should be checked to monitor successful replacement. If necessary, 24 hour urinary calcium and serum PTH can be used to monitor treatment.[7] The aim should be to bring the 25(OH)D concentration to around 50 nmol/litre. In a very symptomatic patient calcitriol may be used in the short term in addition to vitamin D_2 or D_3.

In malabsorption-related osteomalacia, higher doses of vitamin D and calcium may be needed. Patients with liver disease and impaired synthesis of 25(OH)D can be treated with calcidiol supplements if they do not respond to vitamin D_2 or D_3 replacement. Patients with renal disease and impaired synthesis of $1,25(OH)_2D$ can be treated with calcitriol as well as vitamin D. Vitamin D intoxication is rare, with serum levels up to 220 nmol/litre having been reported as safe.[14] Preparations containing up to 1000 IU/pill of vitamin D_3 are available over the counter in many pharmacies and healthfood stores. High-strength preparations must be prescribed by a medical practitioner. Some studies suggest that treatment with vitamin D_2 is less efficient than vitamin D_3 and may require more frequent dosing. Symptoms improve within the first month of therapy and serum calcium improves after week 4. There may be an initial increase in ALP before reaching a steady state.[15]

Other presentations of osteomalacia

Phosphate deficiency is associated with a variety of disorders (listed in Box 146.1) of which X-linked hypophosphataemic rickets is the commonest form. They share many phenotypic features and often present in childhood (see Chapter 145). For differential diagnoses for osteomalacia see Box 146.2.

Tumour-induced osteomalacia

Tumour-induced osteomalacia (TIO; or oncogenic osteomalacia) is a rare acquired paraneoplastic syndrome of renal phosphate wasting that shares many features with genetic forms of hypophosphataemic rickets. It is most often caused by benign mesenchymal tumours but has also been noted in association with carcinomas, sarcomas, osteoblastomas, neurofibromatosis, fibrous dysplasia, and schwannomas among others.[7,16] The tumours have a predilection for the craniofacial region and extremities.[17] Tumour by-products impair phosphate transport in renal epithelial cells of the proximal renal tubule and may reduce calcitriol synthesis through altered 1-α-hydroxylase activity.[18] FGF23 is thought to have a critical pathogenic role since at least two studies have shown reduction in elevated FGF23 levels after surgical tumour resection.[19] Other proposed mediators of disease include MEPE and frizzled related protein-4 (FRP4).[20]

TIO may present at any age, although most patients are adults. Presentation is with similar symptoms to X-linked hypophosphataemic rickets (XLH) with longstanding progressive muscle and bone pain. Children with TIO present with rickets, gait disturbance, growth retardation, and skeletal deformities. TIO may be differentiated from other hypophosphataemic syndromes by the severe associated muscle weakness and lack of family history, given that this is an acquired rather than inherited disorder.

Biochemical testing demonstrates severe hypophosphataemia, phosphaturia, inappropriately low plasma $1,25(OH)_2D$ concentrations, and normocalcaemia.[16] Small tumours within bone can be difficult to localize and therefore the time from symptom onset to identification of the responsible tumour can be prolonged. MRI is the commonest imaging modality. Sensitivity can be improved by combining with indium-111-labelled octreotide scintigraphy, given that tumours usually express somatostatin receptors.[2] Selective venous sampling for FGF23 can identify target regions for imaging with MRI.

Tumour resection effectively normalizes biochemistry and allows bone healing. Pharmacological therapies are similar to those used in XLH and are given until the tumour is resected, or indefinitely if the tumour is unresectable or non-localizable. There is conflicting evidence for the use of octreotide, an anatagonist of the somatostatin receptors expressed by tumours, in patients with unlocalizable tumours.[21] Prognosis after tumour resection is good, with only a limited burden of nephrocalcinosis.

Vitamin D deficiency

See section above, 'Vitamin D deficiency osteomalacia'.

Hypophosphatasia

Hypophosphatasia is an inherited condition characterized by impaired mineralization of bones and teeth. It is caused by inactivating mutations of the *TNSALP* gene resulting in deficiencies of serum and bone ALP activity.[22] Consequently, inorganic pyrophosphate accumulates extracellularly and impairs skeletal mineralization. The prevalence of severe hypophosphatasia has been estimated to be 1/100,000; however, the prevalence of milder forms is likely to be much higher.[23] Six clinical forms are recognized[22,23]:

- The **perinatal form** is lethal and is characterized by markedly impaired mineralization of bone.
- In the **prenatal form**, in-utero mineralization defects are noted and can mimic osteogenesis imperfecta but then seem to spontaneously improve towards the end of pregnancy.
- The **infantile form** manifests during the first 6 months of life and often results in premature death.
- The **childhood form** manifests after the first year of life and presents with skull deformities, enlarged joints, short stature, delay in walking, and a waddling gait. Patients also exhibit premature loss of dentition.
- **Odontohypophosphatasia** is characterized by dental disease without features of skeletal disease.
- **Adult hypophosphatasia** presents in middle age with stress fractures, pseudofractures, osteomalacia, chondrocalcinosis, and osteoarthropathy. There is often a history of premature loss of teeth.

A diagnosis can be made by a combination of clinical features, radiological findings, biochemical assays (such as reduced serum activity of ALP, elevated urine levels of phosphoethanolamine and raised serum levels of pyridoxal-5-phosphate), and genetic screening. There is currently no curative treatment for hypophosphatasia and management therefore consists of symptomatic treatments such as non-steroidal anti-inflammatory drugs (NSAIDs). There have been reports of successful treatment with PTH as well as bone marrow cell transplantation and these represent avenues for further research.[23]

Hypophosphatasaemia

This is an acquired state of low ALP that can be readily differentiated from hypophosphatasia, and occurs under conditions of starvation, hypothyroidism, severe anaemia, Wilson's disease, coeliac disease, and glucocorticoid and chemotherapy exposure.

Renal osteodystrophy

Renal osteodystrophy is the result of two major processes: secondary hyperparathyroidism and rickets or osteomalacia from a deficiency of

1,25(OH)$_2$D. Kidneys play a central role in mineral metabolism and patients with renal failure may develop abnormalities in bone metabolism early in the course of their disease. These abnormalities may be linked to elevated levels of FGF23 that serve to work in a compensatory fashion to maintain normal serum phosphate levels.[24] FGF23 also acts to inhibit 1-α-hydroxylase reducing levels of 1,25(OH)$_2$D. This is thought to act as the initial step in the development of secondary hyperparathyroidism.[24] Later in the course of chronic renal failure, a hyperphosphataemic state occurs, further inhibiting renal 1-α-hydroxylase activity, resulting in further decreases of 1,25(OH)$_2$D and reduced intestinal calcium absorption. These changes exacerbate the secondary hyperparathyroidism. Rapid bone remodelling ensues and can manifest as osteitis fibrosa cystica.[7]

In addition to the above changes, some patients exhibit abnormal mineralization of bony matrix leading to osteomalacia. This has been seen with the excessive use of aluminium hydroxide as a phosphate binder, although alternative methods to reduce serum phosphate are now more commonly used.[7] Osteomalacia can also occur in patients receiving dialysis if supplies of vitamin D and calcium are inadequate. 25(OH)D levels should be checked regularly to help to ensure an adequate maintenance level. Patients with stage 4–5 chronic kidney disease require 1,25(OH)$_2$D supplementation as they are unable to make enough themselves. This helps to reduce PTH levels and the risk of renal osteodystrophy.[3]

Adult Fanconi's syndrome

Adult Fanconi's syndrome is a rare disorder characterized by generalized wasting of amino acids, glucose, phosphate, uric acid, and bicarbonate from the proximal renal tubules.[25] It can be inherited or acquired and can cause renal failure and bone disease as well as other metabolic changes. Anti-retroviral drugs have been recognized to cause renal tubular dysfunction and Fanconi's syndrome.[26] Patients present with typical clinical and radiological features of osteomalacia. Hypophosphataemia, low 1,25(OH)$_2$D levels (not universal), and acidosis (due to bicarbonate leak and uraemia) contribute to the development of osteomalacia.[27] Secondary hyperparathyroidism may also contribute in some cases.

Treatment involves correcting the biochemical defects by administering phosphate and 1,25(OH)$_2$D, while withdrawing any offending agent.

Conclusion

Osteomalacia is characterized by inadequate mineralization extending beyond the growth plate into the osteoid bone. Although common causes of osteomalacia such as vitamin D deficiency have been recognized since the 17th century, considerable advances have been made over the last decade in our knowledge of gene mutations responsible for inherited osteomalacia and the mechanisms underpinning TIO. In time, this may improve preventive and therapeutic choices. However, the vast majority of cases of osteomalacia continue to be caused by vitamin D deficiency. It is imperative that we all have a low threshold for investigating patients who present with typical features and suggestive risk factors, so they can be treated effectively.

Bone tumours

Thomas Beckingsale and Craig Gerrand

Introduction

Bone tumours comprise a heterogeneous mix of post-traumatic, developmental, benign, and malignant lesions. They can be sub-classified according to their histological matrix as bone-forming, cartilage-forming, or fibre-forming, although some do not produce a specific matrix (non-matrix-producing).[1] Perhaps the most important distinction is between malignant tumours, which have a predisposition to invasive and destructive local growth and distant metastasis, and benign tumours, which do not metastasize, although some can demonstrate locally aggressive behaviour (Table 147.1).

Primary malignant tumours of bone (bone sarcomas) are rare and so a high index of suspicion must be maintained to ensure timely diagnosis and avoid mismanagement.[2] Delays in diagnosis are common, and earlier diagnosis would undoubtedly lead to improved outcomes in terms both of survival and of less-damaging surgery being required.[2] Symptoms of bone pain should never be dismissed, especially unilateral 'growing pains' in children.

Radiographic investigation is mandatory to exclude bony malignancy, avoid delay in diagnosis, and prevent incorrect treatment such as arthroscopy or steroid injection when there is an underlying tumour. If radiography indicates that bone cancer is a possibility, an urgent referral should be made to a bone cancer multidisciplinary team (MDT).[3]

Guidance

In the United Kingdom, the National Institute for Health and Clinical Excellence (NICE) publishes guidelines for referral of suspected cancer, and informs the organization of cancer services, which are appointed by the National Commissioning Group (NCG).[2,3] In the United States of America, the National Comprehensive Cancer Network (NCCN) issues clinical practice guidelines for the treatment of bone sarcomas.[4]

Aetiology

Primary malignant tumours of bone are rare entities, with an incidence in England of around 0.85 per 100 000 for men, and 0.60 per 100 000 for women. They account for just 0.2% of all malignant tumours, but 4% of malignancies in children under the age of 14. Males are affected more than females, with a ratio of 13:10.[5] The three most common malignant tumours of bone are osteosarcoma, Ewing's sarcoma, and chondrosarcoma. The incidence of osteosarcoma has a bimodal distribution with the first (larger) peak in adolescence and a second peak in old age. The incidence of Ewing's sarcoma also peaks in adolescence but it is extremely rare after the age of 30 years. Chondrosarcoma increases in incidence with age. Absolute numbers of bone sarcomas are rising annually with the ageing population.[5] More than one-third (34%) of bone sarcomas occur in the long bones of the lower limbs, 14% occur in the bones of the pelvis, sacrum, and coccyx, and a further 10% occur in the scapula and long bones of the upper limb.[5] Relative survival from bone sarcomas has improved steadily over the last 30 years and is currently 58% for males and 59% for females in England.[5]

Presentation

Bone tumours, both benign and malignant, can present with unexplained pain and swelling. Swelling may initially be due to soft tissue oedema, but later can be from bony enlargement and soft tissue extension. Pain from bony lesions is typically worse at night and can often be mistaken for 'growing pains' in children. Patients often present after a coincidental injury, which, although not causative, draws attention to the swelling. Acute presentation can also follow pathological fracture through the lesion in 5–10% of cases. Occasionally, neuralgia or paraesthesiae may be the presenting complaint due to nerve compression from an enlarging lesion. Malignant tumours are associated with cachexia and weight loss, with acute pyrexia on occasion. Symptomatic metastasis to the lung can, rarely, lead to presenting complaints of shortness of breath, chest pain or haemoptysis. Unexplained bony pain mandates careful clinical examination and radiography to look for possible bony tumours. The following 'red flags' should raise suspicion:

◆ pain—worse at night
◆ swelling
◆ cachexia, weight loss, pyrexia
◆ pathological fracture
◆ respiratory symptoms from metastases to the lung.

Other than pathological fracture, these symptoms are all common in general rheumatological practice, and hence a high index of suspicion is required to prevent missed or delayed diagnoses.

Table 147.1 Bone tumours

				Metastatic disease

Principles of investigation

Radiography

Radiography is used to make the initial diagnosis. The bone in which the lesion originates, the location within that bone (epiphyseal, metaphyseal, or diaphyseal), and the relationship to the medullary cavity or cortex (central or eccentric), give clues to the diagnosis. For example, unicameral bone cysts originate in the metaphysis of the proximal humerus in 50% of cases.

The effect of the lesion on the bone, and the response of the bone to that lesion, can give useful information about the local behaviour of the tumour. Benign lesions have a narrow zone of transition, which is well defined and 'geographic' (like the edge of a landmass on a map), indicating that the tumour is growing slowly enough to be walled off at its margins. Malignant tumours have a wider zone of transition, indicating aggressive and rapid enlargement, seen as a permeative lesion with poorly demarcated borders. Endosteal scalloping and cortical resorption may also be seen.

The periosteum reacts to the presence of tumour by forming reactive new bone at the edge of the tumour where it is elevated, seen as a Codman's triangle. New bone formation may also be seen as 'sun-ray spicules' perpendicular to the tumour, as in osteosarcoma, or may be seen in concentric layers, like 'onion-skin', reflecting phases of tumour growth, classically in Ewing's sarcoma.

MRI and CT

MRI is used to delineate the local extent, stage and relationships (with regard to neurovascular structures, compartments, and joints) of the tumour. Pathological detail is shown, as well as the presence or absence of skip lesions and lymphadenopathy. The extent of local oedema is also shown, allowing surgical planning for adequate margins.

CT scanning can be a useful adjunct to MRI, giving further local information about the tumour. This is particularly useful for bony tumours where, for instance, it may demonstrate the nidus of an osteoid osteoma, or endosteal scalloping and matrix formation in cartilaginous tumours. However, CT is primarily used for systemic staging, assessing for the presence of metastases, or looking for a primary tumour when indicated.

Isotope bone scan and positron emission tomography

Isotope bone scanning is used to screen the entire skeleton for the presence of bony metastases or multifocal disease (e.g. polyostotic fibrous dysplasia). PET scanning gives metabolic information and is often combined with a CT scan to provide anatomical detail. Currently it is rarely used in orthopaedic oncology as a primary investigation, but it can be useful to detect recurrent or metastatic disease.

Biopsy

Biopsies are performed to make a histological diagnosis, grade the tumour, and plan treatment. It is recommended that they be performed by the surgical team who will perform the definitive tumour resection because the biopsy track must be excised during the definitive procedure.

Staging

Local staging follows MRI scan to show local extent of the tumour, the size of an associated soft tissue mass, and the involvement of critical anatomical structures. MRI scanning allows biopsy planning and should precede it. Systemic staging involves CT chest (the most common site for metastases), and whole-body bone scan. Tumours are staged according to the American Joint Committee

on Cancer (AJCC) system. They are staged depending on the histological grade of the tumour, the size of the tumour, and the presence or absence lymphatic spread or metastases.[4]

Principles of treatment for malignant tumours

The three most common primary malignant tumours of bone are osteosarcoma, chondrosarcoma, and Ewing's sarcoma. Because of the wide range of presentations and treatments and the need to carefully coordinate treatment, malignant bone tumours should be treated within the setting of a MDT comprising pathologists, radiologists, surgeons (orthopaedic, plastic, general, and thoracic), clinical and medical oncologists, paediatric oncologists, and specialist nurses. Wherever possible, patients should be entered into clinical trials. Some chemosensitive tumours (e.g. osteosarcoma or Ewing's tumours) require a combined approach to treatment, classically with adjuvant (preoperative) chemotherapy, local therapy (usually surgery), then adjuvant chemotherapy.

Reconstructive/limb-salvage surgery

The aim of surgery must be complete removal of the tumour with a surrounding cuff of normal tissue. Margins are defined as

- **intralesional**, where the resection passes through the tumour and macroscopic tumour deposits are left in the wound

- **marginal**, where the tumour is excised with an intact pseudocapsule but the reactive zone around the tumour (an area of oedema and neo-vascularity characterized by the presence of inflammatory cells and micronodules of tumour) is violated, possibly leaving microscopic satellites of tumour within the wound

- **wide**, where the tumour is excised with a cuff of normal surrounding tissue

- **radical**, where the entire anatomical compartment in which the tumour resides is excised en bloc, in theory removing the entire tumour.[6]

As a rule, safe margins must not be compromised for a preferred functional or reconstructive outcome.

Patients who undergo limb salvage have a slightly higher local recurrence rate than those who have an amputation, but the overall survival of the two groups is indistinguishable. Hence, limb salvage has become the norm with rates of 90% in most centres.[7,8] Amputation is now generally reserved for tumours that extensively involve neurovascular structures, or where safe margins cannot be achieved.

The greatest experience of megaprosthesis use is in long bones, especially the femur, tibia, and humerus, and extendable prostheses are available to accommodate growth in children. The 10 year implant survival rates are around 75%, depending on anatomical site and length of resection. However, with revision procedures, durability of limb salvage can be as high as 90% at 20 years. The durability of implants has been improved by the use of hydroxyapatite collars, aiding long-term implant fixation to the bone, and the menace of infection, the most common reason for implant failure and secondary amputation, has been reduced by silver-coating the implants, rendering them resistant to bacterial adhesion and biofilm formation.[8]

Radiotherapy

Osteosarcomas and chondrosarcomas are poorly radiosensitive, and hence radiotherapy does not form part of their treatment protocol. On the other hand, Ewing's sarcoma is radiosensitive, and radiotherapy can occasionally form the mainstay of treatment for these tumours when they arise in areas where surgical access for resection is difficult, for example in the pelvis.

Chemotherapy

Survival from osteosarcoma and Ewing's sarcoma has, greatly improved since the advent of effective chemotherapy over the last 30 years. There is presently no widely available systemic agent for the treatment of chondrosarcoma, the treatment of which remains primarily surgical.

Radiologically detectable metastases are found in about 30% of patients at the time of diagnosis, but it is likely that a much greater percentage have clinically undetectable micrometastases. Neoadjuvant chemotherapy allows early and effective treatment of these micrometastases. Such neoadjuvant also has the added benefit of reducing the inflammation around the tumour, and sometimes in the size of the tumour itself, both of which ease and facilitate surgical resection.

Randomized trials have demonstrated increased disease-free and overall survival for osteosarcoma and Ewing's sarcoma with the use of multiagent chemotherapy. The treatment protocol for osteosarcoma includes doxorubicin, cisplatin, and high-dose methotrexate, whereas the standard treatment protocol for Ewing's sarcoma includes vincristine, doxorubicin, cyclofosfamide, ifosfamide, and etoposide.[9] The response of the tumour to neoadjuvant chemotherapy, measured in osteosarcomas as percentage necrosis on histology of the resected specimen, is prognostically significant. Greater than 90% histological necrosis is considered a good response and is associated with an improved survival rate. Osteosarcomas that respond well to neoadjuvant chemotherapy are treated with the same agents after surgery, but etoposide and ifosfamide are added for poor responders after surgery.

Bone-forming tumours

Post-traumatic lesions

Florid reactive periostitis

Florid reactive periostitis is a rare, reactive process that occurs most commonly in the hands and feet, and usually presents with progressive swelling, erythema, and pain around the metacarpophalangeal joints. Ossification occurs in the soft tissues around the short tubular bones, but in the early stages of the disease this may not be visible on radiographs. Treatment is with rest, non-steroidal anti-inflammatory drugs (NSAIDs), and corticosteroids, which may decrease the size of the lesion. Surgical excision is occasionally required with low rates of local recurrence.[10]

Developmental or hamartomatous lesions

Bone islands

These are solitary enostoses and are seen radiographically as small areas of increased density, 1–2 mm in diameter, within areas of cancellous bone.

Osteopoikilosis

Osteopoikilosis is a rare, clinically benign, and usually symptomless condition of multiple bone islands, which is inherited as an autosomal dominant trait. It sometimes presents with cutaneous nodules, suggesting a generalized mesenchymal defect. Histological examination of the cutaneous nodules reveals fibrous tissue, resembling scleroderma-like lesions.

Melorheostosis

Melorheostosis is a rare condition characterized by irregular cortical hyperostosis, described as looking like 'melting wax dripping down the sides of a candle'. Para-articular fibrosis and vascular malformations are common early manifestations and may precede the osseous abnormalities. The condition can lead to leg-length discrepancy and joint contractures, resulting in deformity and pain. Surgical management has generally proved disappointing.[11]

Benign tumours

Osteoid osteomas

Osteoid osteomas are benign, painful lesions, more than 50% of which present in the cortical diaphyses of the femur or tibia. Other common sites of presentation include the hands, feet, and spine. They are usually less than 1 cm in diameter, and are seen as a central, lucent nidus within an area of cortical sclerosis on radiographs and CT scans. An isotope bone scan shows markedly increased uptake. The classic history is of severe night pain, relieved dramatically by NSAIDs, which, on occasion, are the only treatment modality required. Traditional surgical treatment is by en-bloc excision or 'burr-down' technique, but CT-guided radioablation is the more modern approach.[12]

Osteoblastomas

These are very similar in appearance to osteoid osteomas but they are larger, usually greater than 1 cm, and present more commonly in the spine, usually in the vertebral arch, where they can lead to radicular or myelopathic symptoms. Treatment is by curettage and grafting or en-bloc excision.

Malignant tumours

Osteosarcoma

Osteosarcoma[13] is the second most common primary bone tumour, myeloma being the first, but the most common sarcomatous tumour of bone. It makes up 20% of all primary bone tumours, but 55% of all bone tumours in children and adolescents. Presentation is most common around the knee with 35% arising in the distal femur and 20% arising in the proximal tibia. The incidence has a bimodal distribution with a first large peak during the growth spurt in adolescence, and a second smaller peak after the fifth decade because of Paget's sarcoma and radiation sarcoma, which carry a poor prognosis. Osteosarcoma is associated with retinoblastoma and a number of progeroid and precancerous syndromes such as Li–Fraumeni, Rothmund–Thompson, and Bloom. Ninety-five per cent of osteosarcomas are intramedullary, of which 90% are high grade. The remaining 5% are surface lesions, of which 90% are low grade.

Radiographs of 'classic' osteoblastic, intramedullary osteosarcoma show a sclerotic, destructive lesion in the metaphysis of a long bone, invading the cortex and extending into the soft tissues with a 'sunburst' pattern. Elevated levels of alkaline phosphatase, in the absence of metastases, are suggestive of larger primary tumours, whereas elevated lactate dehydrogenase levels suggest a more biologically active tumour. Both are associated with a poorer prognosis.

Treatment of osteosarcoma is with neoadjuvant chemotherapy, involving an anthracycline (doxorubincin), a platinum (cisplatin), and high-dose methotrexate, surgical resection, and adjuvant chemotherapy. Etoposide and ifosfamide are added to the chemotherapeutic regime during adjuvant treatment for tumours that have responded poorly to the standard regime during the neoadjuvant period. Radiologically detectable metastasis is present at diagnosis in 30% of cases and is associated with a poorer prognosis. Another key factor in prognosis is the response of the tumour to chemotherapy, where a good response (>90% necrosis) carries a better prognosis.

Muramyl tripeptide (MTP) is a novel agent being trialled as an addition to the standard chemotherapy regime. MTP is not directly tumoricidal, but works by stimulating the immune system, causing macrophages to exhibit cytotoxic anti-tumour activity. A randomized trial showed that 6 year overall survival improved from 70% to 78% when MTP was added to the standard chemotherapy regime for osteosarcoma.[14]

Cartilage-forming tumours

Developmental or hamartomatous tumours

Solitary osteochondromas

These are osteocartilaginous exostoses, whose formation follows mutation within the *EXT* genes, leading to aberrant growth of a fragment of epiphyseal growth plate. The fragment continues to grow by enchondral ossification, resulting in a subperiosteal, cartilage-capped, bony projection. They most commonly present in the metaphyses of long bones around the knee, with more than one-quarter of them arising in the distal femur. They usually manifest clinically during the second decade due to symptoms secondary to local irritation, trauma, or fracture, and their growth usually ceases after physeal closure. Osteochondromas may, rarely, present in the epiphysis where the condition is known as dysplasia epiphsealis hemimelica, or Trevor's disease. Radiographs show either a flattened (sessile) or stalked (pedunculated) juxta-articular protuberance, the cortices of which are contiguous with the adjoining cortical bone, growing away from the adjacent joint. Malignant transformation to a chondrosarcoma is extremely rare in solitary osteochondromas. Symptomatic exostoses are treated by surgical excision through the base of the lesion. Recurrence is rare, but is more common if the cartilage cap is incompletely excised.

Multiple hereditary exostoses

Otherwise known as diaphyseal aclasia, multiple hereditary exostoses are an autosomal dominant trait, resulting in multiple osteocartilaginous exostoses secondary to mutation in the *EXT* genes. It is the most common skeletal dysplasia and it results in short stature, bony deformity, and disfigurement. The ulnae are often shortened, leading to Madelung-like deformities. Radiologically and macroscopically the resulting exostoses are similar to solitary osteochondromas but histology often reveals a more disorganized structure. Malignant change, too, is more common than in solitary osteochondromas and occurs in around 1–5%.

Enchondromatosis

Enchondromatosis or Ollier's disease is a non-familial condition of multiple intraosseous cartilaginous tumours, which is often unilateral and confined to a single limb. Histologically, tumours are more cellular and myxoid that solitary enchondromas. The risk of malignancy is high, with a 10% risk of developing a bony malignancy. However, the overall risk of malignancy is 25% if associated visceral and brain tumours are included. Enchondromatosis in conjunction with multiple soft tissue and visceral haemangiomas is known as Maffucci's syndrome and the risk of malignancy approaches 100%.

Benign tumours

Enchondromas

These are common, solitary, asymptomatic, intramedullary, cartilaginous tumours, which arise in the tubular bones of the hand in more than 50% of cases. They often present after pathological fracture, particularly in the bones of the hands and feet. Histologically lesions in long bones may be difficult to distinguish from low-grade chondrosarcomas, and malignant transformation, although very rare, can sometimes occur is such lesions. Radiographs show enchondromas as well-defined lucent lesions, with a short zone of transition and a matrix of stippled or 'popcorn' calcification. These lesions are usually treated by curettage with or without grafting.

Malignant tumours

Chondrosarcomas

These are malignant, cartilaginous tumours, the diagnosis of which critically depends on the clinical, radiological, and histological findings, as it can be difficult to distinguish enchondromas from low-grade chondrosarcomas on histological grounds alone. Incidence increases with age, most presenting after the fifth decade. Fifty per cent of lesions arise in the femur and pelvis, presenting with persistent pain and swelling. Radiographs show lucent metaphyseal or diaphyseal defects with endosteal scalloping and 'popcorn' calcification. T2 weighting on MRI scan reveals a bright lesion due to the high water content of the cartilaginous matrix.

Chondrosarcomas are resistant to radiotherapy and chemotherapy, and hence treatment is surgical. Low-grade tumours rarely metastasize and are often treated by intralesional curettage, whereas high-grade lesions require wide surgical excision. Prognosis is largely dependent on the grade of the tumour and the presence or absence of metastases. Low-grade (grade I) chondrosarcomas are distinguished from enchondromas by their location within long bone and the pelvis, and by microscopic evidence of haversian invasion. They are very rarely metastatic and have a greater than 90% 5 year survival. Grade II tumours histologically show definite increased cellularity and nuclear size, as well as focal myxoid change. They are metastatic in more than 10% of cases and have a 5 year survival of 80%. High-grade III tumours are distinguished by their marked hypercellularity, cellular atypia, and high mitotic activity. They are aggressive, rapidly enlarging lesions, which are metastatic in over 70% of cases, and have a 5 year survival of only 30%. Ten per cent of tumours undergo dedifferentiation in one area, becoming highly malignant sarcomas with spindle cells and bizarre giant cells, similar to fibrosarcoma or malignant fibrous histiocytoma. Radiographs show an area of lucency within the classic 'popcorn' calcification. Presentation is often with pathological fracture in elderly patients, and prognosis is dismal.

Chordomas

These arise from remnants of the embryological notochord, and hence present exclusively in the axial skeleton, with around 50% arising in the sacrococcygeal region. They are a slow-growing lesion, presenting usually in the fifth decade, but are metastatic in around 50% of cases to lymph nodes, lung, liver, and bone.

Fibre-forming tumours

Developmental or hamartomatous tumours

Non-ossifying fibromas

These are very common, asymptomatic lesions, present in up to 35% of normal children. Radiographs show a well-demarcated, solitary, eccentrically placed, metaphyseal lucency with a sclerotic margin. Presentation is usually as an incidental finding, but may follow pathological fracture. Treatment is by observation unless there is a significant risk of pathological fracture, as these lesions usually resolve by adulthood.

Fibrous dysplasia

This is a common fibro-osseous lesion, usually arising monostotically in a long bone of the lower-limb. The lesion is often discovered as an incidental finding but can also present with swelling or pathological fracture, usually in adolescence. Radiographs show a well-demarcated lesion with fusiform expansion, ground-glass calcification, and cortical thinning. In the proximal femur, the lesion can sometimes lead to multiple, sequential pathological fractures, resulting in a 'shepherd's crook' deformity.

Malignant tumours

Fibrosarcomas

These are rare, malignant spindle cell tumours, arising in the ends of long bones around the knee 50% of the time. They present most commonly in the third to sixth decades. Radiographs show a poorly demarcated, lucent lesion with a mottled appearance, cortical destruction, and extension into the soft tissues. Treatment is by wide excision and reconstruction.

Malignant fibrous histiocytomas

Malignant fibrous histiocytomasare rare tumours, arising in the metaphyses of long bones around the knee in adults. Radiographs show a poorly demarcated, lucent lesion with cortical erosion but minimal periosteal new bone formation. Histology reveals a spindle cell tumour with a distinctive storiform or 'starry night' pattern. Treatment is as for osteosarcoma with chemotherapy, wide excision and reconstruction.

Adamantinomas

Adamantinomas are rare, slow-growing, low-grade spindle cell tumours arising in the tibia in over 90% of cases. Radiographs show a multicystic lucency with cortical thinning and bony expansion. The lesion is generally only locally aggressive but can metastasize in up to 20% of cases late in the disease process. Treatment is with wide excision and reconstruction.

Non-matrix-producing tumours

Reactive or post-traumatic lesions

Unicameral bone cysts

These are solitary, cystic lesions arising in the metaphyses of long bones in childhood and adolescence. The classic site is the proximal humerus, where 50% of such lesions arise. A further one-quarter arise in the proximal femur, where pathological fracture can be difficult to manage. Presentation is usually with fracture, pain (which usually indicates impending fracture), or as an incidental finding. Pathological fractures through these lesions usually heal well, but the cysts only partially resolve. Radiographs reveal a well-demarcated lucent area with a sclerotic margin. The classic 'fallen leaf' sign indicates a fracture, at least partially, through the lesion. Treatment is usually by observation for the majority, but surgical intervention is indicated for those at risk of pathological fracture. Options described include minimally invasive decompression and curettage (the authors' preferred method), curettage and grafting, surgical fixation through the cyst with an intramedullary nail, or corticosteroid injection.

Aneurysmal bone cysts

These are solitary, expansile, multiloculated, eccentrically placed, cystic lesions, usually arising in long bones or the spine and presenting with pain usually before the third decade. Radiographs show an expansile lesion, as described above, with a trabeculated appearance, and MRI shows multiple fluid levels. In many cases the lesion is a secondary, reactive lesion to another benign lesion such as an osteoblastoma, chondroblastoma, or giant cell tumour. It is important to distinguish this benign entity from telangiectatic osteosarcoma, which can have aneurysmal change within it. Treatment is with curettage and grafting, but recurrence rates can be high, approaching 50%.

Developmental or hamartomatous tumours

Haemangiomas of bone

These are solitary, asymptomatic lesions usually arising in the lumbar vertebral bodies and are comprised of thin-walled, cavernous blood vessels. Radiographs show accentuated, thickened vertical trabeculae, described as 'jail bar' striations. No treatment is required, but pathological collapse can occur. Widespread disease is occasionally seen as skeletal haemangiomatosis, which has no familial tendency and is self-limiting.

Benign tumours

Giant cell tumours of bone

These rare, solitary, locally aggressive lesions are seen at the epiphyseal ends of long bones, with 50% arising around the knee. The incidence is 1–2 per million of population per year. Radiographs show an aggressive, juxta-articular, lytic lesion. Frequently there is near-complete cortical destruction and an associated soft tissue mass. Histology reveals spindle-shaped tumour cells and multinucleated giant cells, which are indistinguishable from osteoclasts. It is essential to differentiate the lesion from a giant-cell-rich osteosarcoma. Treatment is by curettage and grafting with the use of a surgical adjuvant such as liquid nitrogen and/or polymethylmethacrylate cement. Agents that interfere with osteoclast recruitment, such as bisphosphonates and RANK-ligand inhibitors, can also

play a useful role in difficult cases. Recurrence rate is high after surgical curettage alone. Malignant transformation and metastasis is another rare but well-recognized complication, which appears to be more likely in locally recurrent tumours.

Malignant tumours

Ewing's sarcoma

Ewing's sarcoma is a malignant, small, round blue cell tumour of bone, which can, very rarely, arise in the soft tissues. It presents most commonly in the metaphyses and diaphyses of the long bones either side of the knee or in the pelvis. Symptoms are of pain and swelling associated with the lesion, but erythema, pyrexia, a leucocytosis, and a raised erythrocyte sedimentation rate (ESR) can also be present at diagnosis, incorrectly leading the unwary to a diagnosis of infection. Radiographs show a lytic, moth-eaten appearance to the bone with a laminated, 'onion peel' periosteal bone reaction. MRI shows the extent of the tumour and the degree of soft tissue extension. Investigations for Ewing's sarcoma must also include a whole-body isotope bone scan and a bone marrow biopsy to rule out metastatic or multifocal disease, which is associated with a poorer prognosis. Genetically, reciprocal translation between chromosomes 11 and 22 is seen (t(11;22)(q24;q12)). Systemic treatment by chemotherapy is with doxorubicin, vincristine, cyclofosfamide, ifosfamide, and etoposide. Local management is with radiation, surgery, or both. Overall 5 year survival is 66% but is as high as 75% if the tumour responds well to chemotherapy, and as low as 20% if the tumour responds poorly.

Immunohaematopoietic tumours and metastatic bone disease

It is beyond the scope of this chapter to describe all the haematological malignancies and secondary malignancies that may involve bone. These include plasmacytomas, multiple myeloma, lymphoma, and leukaemia. Treatment of immunohaematopoietic tumours usually involves chemotherapy and radiotherapy, but rarely involves surgery. Adjuvant treatment for metastatic bone disease depends largely on the sensitivities of the primary lesion. Surgery for immunohaematopoietic and metastatic tumours is generally reserved for the treatment of impending or completed pathological fractures.

CHAPTER 148

Avascular necrosis

Stefan Rehart and Martina Henniger

Introduction

Avascular necroses are acquired skeletal diseases with typical development and localization. The actual frequency is unknown. The joint surface is not necessarily involved. There are three major forms: aseptic osteonecrosis, septic osteonecrosis, and post-traumatic osteonecrosis. Many bones may be affected by osteonecrosis, and many sites have eponyms associated (Table 148.1).

Table 148.1 Sites and names of the common eponymous osteonecroses

Site	Name
Vertebral body	Calvé
Vertebral plate	Scheuermann
Synchrondrosis ischiopubica	Van Neck
Sternal end of clavicle	Friedrich
Distal part of the ribs	Tietze
Caput humeri	Hass
Capitulum humeri	Panner
Trochlea humeri	Hegemann
Caput radii	Hegemann
Distal radial epiphysis	De Cuvelan
Os scaphoideum	Preiser
Os lunatum	Kienböck
Metacarpal head	Dietrich
Basis of the middle- and end phalanges	Thiemann
Femoral head and neck in early childhood	Calvé–Legg–Perthes
Apophysis of calcaneus	Haglund
Talus	Vogel
Os naviculare pedis	Köhler (I)
Metatarsal head II–V	Freiberg–Köhler (II)
Basis of the base phalanx of the great toe	Thiemann
Os cuneiforme laterale	Lance
Basis metatarsal V	Iselin

For various, often unknown, reasons there is direct or indirect damage of the bone vascularization. Certain diseases or factors facilitate the occurrence of aseptic osteonecroses. More than 50% of all commercial scuba divers, 30% of all patients with systemic lupus erythematosus (SLE) and 29% with type 1 Gaucher's disease develop osteonecrosis.[1,2] Ischaemia of bone cells leads to cell death of bone, cartilage, and bone marrow cells, which are subsequently destroyed. The defects may be without consequence or lead to severe, irreversible damage to bones and joints depending on the extent and localization. In general, every bone at any age can be affected.

Aetiology and epidemiology

Certain fractures and/or dislocations as well as infections can lead to arterial injury and to post-traumatic or septic osteonecrosis. However, the cause of aseptic osteonecrosis is less clear and its incidence seems to be very complex, including multifactorial causes. The most likely pathophysiological mechanism is an intravascular coagulation with spreading of the fibrin thrombus. Because the osteonecrotic lesions do not widen, but stay about the same size or shrink slightly, the osteonecrosis is apparently the result of only one ischaemic event, not of repeated ischaemic reinfarction.[3]

Risk factors for osteonecrosis are listed in Box 148.1.[4]

Pathogenesis

Osteonecrosis results from a direct or indirect injury, or damage to the vascular flow (injury/embolism/mechanical disturbance of arterial blood supply or venous backflow obstruction). Circulatory deficiency results in bone and bone marrow cell death (osteocytes, haematopoetic cells, adipocytes). Osteonecrosis develops only in the bone marrow, which consists mainly of adipocytes in patients with sickle cell anaemia and Gaucher's disease. The necrotic tissue triggers repair, during which necrotic parts may be resorbed by macrophages and osteoclasts. A reactive surface develops at the boundary with healthy bone. When there is a revitalization of the necrosis due to ingrowth of blood vessels and connective tissue from the healthy surroundings substituting for abnormal and biomechanically weak bones, smaller lesions can heal. If this healing remains incomplete, due to the anatomical position, the subchondral bone will break from repeated microtrauma and various significant defects will result.

Box 148.1 Risk factors for osteonecrosis

- Thrombophilia: APC resistance, protein C deficiency, protein S deficiency, anti-thrombin III deficiency, hyperhomocysteinemia
- Hyperlipoproteinemia and fat embolism: alcoholism, diabetes mellitus, hyperlipidaemia type I and IV, elevated C-reactive protein, obesity, pregnancy, decompression disease, haemoglobinopathies, burns, fractures
- Hypersensitization reactions: host-vs-graft disease, anaphylaxis, anti-phospholipid syndrome, immune complexes, serum sickness, SLE, transfusion incidents
- Hypofibronolysis: dysfibrinogenaemia, plasminogen deficiency, decreased tissue plasminogen activator, elevated plasminogen activator inhibitor type 1
- Infections: endotoxic bacterial reactions, bacterial lipopolysaccharides, bacterial mucopolysaccharides, 'Schwartzmann reaction', toxic shock syndrome, viral infections
- Proteolytic enzymes: pancreatitis, snake bites
- Tissue factor release: inflammatory intestinal diseases, malignancies, neural trauma, pregnancy
- Other prethrombotic conditions: acidosis, anorexia nervosa, oestrogen, smoking, Gaucher's disease, haemolytic uraemic syndrome, haemolysis, hyperfibrinogenaemia, hyperviscosity, shock, lipoprotein, nephrotic syndrome, polycythaemia, sickle cell crisis, thrombocytosis, thrombocytopenia purpura, vascular changes

The pathophysiological sequence is very flexible in time and takes weeks to years. The progression of the disease can be classified into five pathophysiologic stages, as described in the Association Research Circulation Osseous (ARCO) classification.[5]

Association Research Circulation Osseous (ARCO) classification

Initial stage (ARCO 0)

The initial stage is an ischaemic attack, which is still reversible and usually asymptomatic. At most, pathological perfusion can be shown by means of a dynamic contrast MRI scan. Histologically, only minimal changes can be found.

Reversible early stage (ARCO I)

Next comes an oedema of the bone marrow with extended medullary cavity necroses, the start of repair processes, and gradual replacement of necrosis through growth of fibrous vascular tissue. In the MRI scan a subchondral necrotic lesion with medullar cavity oedema and other unspecific signal changes of the repair process can be seen, but still without signs of a reactive interface.

Non-reversible early stage (ARCO II)

Histological transformation processes, in the sense of bone resorption and formation in the bone marrow and the trabecular, are found. Vascular granulation tissue attempts to repair the necrotic area on the inside of the sclerotic zone, which is directly opposed to the area of vital bone tissue. In the MRI scan the so-called 'MR double

line sign', which is pathognomonic for osteonecrosis, appears in the T2-weighted image. It corresponds to the reactive interface. In plain radiographs only blotchy changes with sclerotic edges are visible.

Transitional stage (ARCO III)

Mechanical failure of the affected bone area leads to subchondral microfractures. It usually begins at the margin of the defect and is a consequence of insufficient repair. On radiographs, a small subchondral crescent sign is visible. If the fracture gap is filled with synovial fluid the subchondral fractures can also be seen as an MR crescent sign.

Late stage (ARCO IV)

In the late stage there are secondary arthritic lesions (calcification, resorptive cysts) and deformations, which can be detected by any imaging method.

Diagnosis

The diagnosis cannot be made on the basis of laboratory tests. Sometimes the erythrocyte sedimentation rate (ESR) can be increased. Laboratory examinations are used to exclude a septic event and detect risk factors (coagulation disorders, sickle cell anaemia, hyperlipoproteinaemia).

Several imaging techniques are available for diagnosing AVN.

Radiography

In plain radiography there may be minimal changes that are very difficult to make out. Here, the radiograph serves mainly to exclude other pathologies.

Later on, if the necrosis leads to perifocal osteoporosis or the vital bone surrounding the necrosis reacts with bone formation/sclerosis, changes also become perceptible on radiographs. Due to osteolysis of necrotic bone and sprouting of new blood vessels, bright spots and intensifications in the bone can be seen. Later, fractures and progressive collapse as well as increasing arthritic changes are seen.

Scintigraphy

In early stage (ARCO I), when conventional radiographs do not yet show lesions, a cold spot can be seen in 99 m-technetium scintigraphy. In due course, when repair processes begin (ARCO II), specific hot spots or cold in hot spots are found. Simultaneously, multifocal bone diseases can be excluded through scintigraphy.

MRI

Today MRI is the most sensitive and specific method for diagnosis and assessment in respect of lesion size and the stage of osteonecrosis (Figures 148.1 and 148.2). The characteristic image is a hypointense oval zone or a hypointense crescent sign in a subchondral position. In most cases the pathognomonic MR double line sign is found in T2-weighted images. This corresponds to the reactive interface between healthy and necrotic bone. A line of low signal intensity is found at the face of healthy bone, whereas at the interface with necrotic area there may be a line of high signal intensity.

CT

CT scanning has a higher sensitivity and specificity than conventional radiography, but it is inferior to MRI, particularly in the early stages. However, in the diagnosis of subchondral fractures,[6]

Fig. 148.1 Lunate malacia (Kienböck's disease): (a) Radiograph (secondary finding: former radius fracture). (b–d) MRI.

often the deciding factor for therapy, CT becomes increasingly important as it has a higher sensitivity than MRI and conventional radiography.

Common localizations

Humeral head necrosis

Occasionally humeral head necrosis occurs spontaneously, but far more commonly it is associated with the risk factors listed in Box 148.1. Usually, osteonecrosis of the humeral head becomes symptomatic later than a comparable finding in the hip and knee joint. This is easy to understand as it has less weight loading

and maybe decreased conformity of the glenoid in comparison to the acetabulum. Clinical signs are pain at rest and nocturnal pain, and later also an active and passive painful restriction of movement.

Staging will be done on the basis of conventional radiography and MRI (see above). The size and location of the osteonecrosis as seen in MRI allows a prognosis concerning the further clinical course.[7]

In ARCO stages I and II conservative therapy is used. This essentially consists of mechanical load reduction. To avoid stiffening of the joint, at least passive physiotherapeutic movement therapy should be applied.
Fig. 148.2 MRI of scaphoid osteonecrosis (Preiser's disease).

When symptoms persist and there are signs of collapse of the humeral head, surgical therapy is indicated.[8] Joint-preserving and joint-replacing surgical techniques are available. In early stages decompression can be achieved by means of a core decompression. This leads to pain relief and possibly to revascularization. Further joint-preserving techniques are a vascular bone transplant or removal of necrosis with subsequent spongiosa transplant, similar to necrosis of the femoral head. However, there is not a large number of cases and re-examinations for the assessment of efficacy.

In more advanced stages with explicit joint destruction, joint replacement methods are used. The choice of implant depends on condition of the bone (bone quality, glenoid destruction), the state of the soft tissues (particularly the rotator cuff), and the individual requirements of the patient.

Lunate malacia—Kienböck's disease

Necrosis of the lunate bone was first described by Peste in 1843.[9] In 1910 the Viennese radiologist Kienböck published a paper focusing on lunate malacia and its subsequent results.[10] Even today its pathogenesis is not fully understood. Important aetiological factors may be vibration and microtraumatization, for example when working with compressed air apparatus and power saws; arterial injury; negative ulnar variance, and hence increased pressure stress; venous backflow obstruction due to wrist dorsal extension; systemic diseases; or corticosteroid therapy (for multiple sclerosis, rheumatoid arthritis, dermatomyositis, SLE, systemic sclerodermia or sickle cell anaemia). Single traumatic events with perilunar luxation or luxation-fracture are not a very likely cause.[11] Symptoms consist of pain that is difficult to localize—especially in the form of diffuse pain in the wrist in dorsal extension—as well as a loss of strength as time goes by. Clinically, synovitis and local swelling is found in combination with defined pain in palpation.

Diagnostically, in early stages specific changes in the MRI are detected At this point conventional radiology may still be completely without pathological findings. Only later are increased sclerosis and intraosseus cysts found; still later, the continuous collapse of the lunate as well as ongoing perilunar osteoarthritic defects are seen.

The stages are defined according to Lichtman and Ross or to Decoulx, modified after Martini and Schiltenwolf[12]:

- **Stage I**: morphologically normal radiographic appearance; enhancement in the MRI scan; diffuse pain.
- **Stage II**: radiology reveals increased sclerosis of the spongy trabecular structures and an inhomogenous appearance. The height of the lunate is still normal. If subchondral proximal fractures are detectable (CT) the findings are staged as IIb. The MRI shows homogeneity (oedema), inhomogeneity (partial necrosis), or lack of enhancement (complete necrosis) of the contrast fluid. Clinically, pain persists.
- **Stage IIIA**: radiologically fractures and the progressive collapse of the lunate without rotational dislocation of the scaphoid and normal carpal height are seen.
- **Stage IIIB**: fractures and the complete collapse of the lunate in combination with a rotational dislocation of the scaphoid, together with a positive ring sign, are seen on radiographs.
- **Stage IV**: advanced collapse of the lunate and the entire carpus with massive osteoarthritis occurs.

Therapy depends on the stage of the disease:

- In **stage I** immobilization is indicated. Should that not be sufficient, corrective interventions with regard to the length of the radius or the ulna are considered. In general, the technically easier radius shortening (rather than ulna lengthening) is preferred.
- In **stage II** length-levelling operations are definitely indicated.[13] Alternatively, revascularizing interventions may be possible (arterial-vessel based bone transplants, e.g. os pisiforme). Unfortunately in many cases the collapse of the lunate cannot be prevented in this way.
- In **stage IIIA** partial arthrodeses of the wrist are performed; length-levelling operations may still be possible.
- In **stage IIIB** reconstruction of the wrist height with an STT arthrodesis (fusion of the scaphoid with the trapezium and the trapezoideum) or an SC arthrodesis (fusion of the scaphoid with the capitate) is chosen.
- In **stage IV** partial arthrodeses, proximal row resection, or the total fusion of the wrist are performed.

Femoral head necrosis

Men are affected four times more than women in this context, especially in the third to the fifth decade. In 30–70% of cases the disease affects both sides. Without therapy the prognosis is poor; in more than 85% a collapse of the femoral head is noticed, in combination with severe secondary destruction of the joint.

Clinically, most of patients in early stages do not complain of any symptoms. Later in the course of this illness pain, limping, and increasing deficits in the function of the hip (range of motion) can be seen.

Conventional radiographs reveal the necrosis only in the advanced stages, when irreversible damage has occurred (ARCO II), but for reasons of differential diagnosis they are always to be done in any case. MRI is the method of choice in diagnosing the necrosis. Therapy and prognosis depend on the stage, dimension, and the location of the lesion. In the so-called precollapse stage

(ARCO 0–II), prevention of weightbearing of the hip in question by the use of crutches for several weeks may prove favourable. Further conservative therapy options are magnetic field, shock wave, or hyperbaric oxygen therapy as well as medication with cytokines, vasodilation with calcium antagonists, prostaglandin analogues, or osteoprotective bisphosphonates.[14] The efficacy of these measures is confirmed by case-reports only.[15] Should conservative measurements fail, or if the disease is at an advanced stage (>ARCO II), surgical interventions may be planned. The choice of these depends on the stage, the size, and location of the osteonecrotic area, as well as the diameter of the impression of the femoral head and the involvement of the acetabulum. Further dependencies are the individual perioperative risks of the patient (age, general condition, comorbidities, etc.).

Core Decompression

The most common operation is core decompression of the femoral head, an intervention introduced by Arlet and Ficat 30 years ago. The best results are achieved with small to medium-sized defects in the precollapse stage.[16] This procedure reduces the intraosseus pressure and improves the arterial blood supply.[5] The release of pressure provides immediate pain relief for the patient. The assumption that reparative power in the necrotic area is increased by the increase in regeneration of the vessels has not been proven by MRI and histomorphological findings, so this surgical intervention is considered controversial.[17] However, lack of success subsequently offers access to further operative procedures without severe disadvantages.

Corrective osteotomy

The principle of the osteotomies consists in the removal of the defective site from the main load transmission area. Most suitable for this are small, medially located lesions in the pre- and postcollapse stage. Most frequently varus osteotomies, combined flexion osteotomies, and technically very demanding high transtrochanteric rotation osteotomies are performed. As well as the possibly quite high complication rates for this kind of surgery, the deterioration of the background for the arthroplasties that are generally later indicated has to be taken into account.

Bone transplantation

This method may be discussed when joint-preserving interventions of large defects in the postcollapse stage are foreseen. It is important to differentiate between vascularized and non-vascularized bone transplants. Most commonly the arterial-blood-supplied fibula graft is used in the autologous bone marrow impaction technique, introduced via a transtrochanteric bone channel. The operation is time-consuming and technically very demanding. So far it is not clear whether any reparative capacity may be gained by it.

Arthroplasty

Joint replacement is indicated in ARCO stages III and IV, together with unfavourable factors such as additional risk factors, underlying disease, large defects, fast progression of the disease, or non-compliance of the patient in combination with high demands.[18]

Osteonecrosis of the femoral condyle—Ahlbäck's disease

Osteonecrosis of the femoral condyle was first described by Ahlbäck in the 1960s.[19] The aetiology is still not known. Generally the medial femur condyle is affected, but the lateral femur condyle as well as the medial tibia plateau may also be involved. The peak age is 60 years, and women are three times more affected than men. Patients usually complain about sudden, very intense knee pain in the medial or lateral joint space. Clinically, limping and pressure pain in the according area are found, but also intra-articular swelling or a reduction of the range of motion of the knee may be determined. Radiography, scintigraphy, and MRI may be of help in securing the diagnosis (Figure 148.3).

According to Aglietti, five stages may be differentiated in radiographs[20]:

◆ **Stage I**: normal radiograph.

◆ **Stage II**: flattening of the concerned femur condyle.

◆ **Stage III**: typical lesion with subchondral brightening of variable size and depth, surrounded by sclerosis.

◆ **Stage IV**: the brightening zone is demarcated by a sclerotic wall area. The subchondral bone collapses and is noted as a calcified plate.

◆ **Stage V**: secondarily osteoarthritic changes are diagnosed; a deviation of the axes of the leg may be present.

The prognosis as well as the choice of therapy depends on the size of the defect, the relation of the defect size to the width of the condyle, and the stage. For early stage disease with lesions less than 3.5 cm^2 in size affecting less than 40% of the femur condyles, the prognosis is reasonably good.[21]

Conservative treatment is suitable for lesions with a good prognosis. This includes physical therapy, painkillers, and anti-phlogistic medication and possibly raising the outer edge of the shoe by 4 mm for the discharge of the medial condyle.[21]

Poor prognosis qualifies for surgical interventions. These consist of arthroscopic cleaning, smoothing, and drilling out of the necrotic focus. Occasionally the lesions are emptied out and replaced with fresh or frozen grafts. Another possibility is replacement with tricortical iliac crest transplants with periosteum. Further operative treatment is tibial head correcting osteotomy, or unicompartmental medial joint arthroplasty. (Severe) secondary osteoarthritic destruction requires total joint arthroplasty.[21]

Fig. 148.3 Radiograph of osteonecrosis of the medial femoral condyle (Ahlbäck's disease).

Juvenile osteochondrosis and osteonecrosis

Osteochondrosis and osteonecrosis occur during growth in adolescence, in various locations at different ages. Affected areas are epiphyses, metaphyses and apophyses of the long bones, and enchondrally ossified bones of the wrist and foot. Here, too, the aetiology remains unknown. One hypothesis is that there is a transient mismatch between the arterial blood supply and the process of ossification during skeletal growth. In general, apart from aseptic osteonecrosis of the foot (Freiberg–Köhler and Köhler II disease) boys are more often affected than girls. The effects may be uni- or bilateral or occur simultaneously in different skeletal locations.[22] Pathophysiology, symptoms, and the course of the illness extend over months or years and—despite the various locations—are quite similar.

The disease occurs in four stages:

- **Initial stage**: the necrosis of the osteocytes and the bony parts of the joints by means of disturbance of the blood supply may be noted. Relative to that, the further growth of the cartilage represents a mismatch in front of the concomitant joint swelling, which can be seen radiologically as an apparent widening of the joint space.
- **Condensing stage**: radiologically the impaction of the bony parts of the joints can be seen because of the sintering of necrotic parts of the bones combined with hypermineralization.
- **Fragmentation stage**: resorption of the necrotic parts occurs, while simultaneously reparative processes act with the formation of osteoid and fibrocartilage. Radiologically, flocculent resolution of the bone is noticed with osteolytic and sclerotic areas and the deformation of parts of the joint.
- **Reparative stage**: new vital bone is formed and the fibrocartilage is remodelled to lamellar bone. The radiographs show aligned bone marrow structures.

Without therapy, various degrees of deformity occur after the healing process. The involvement of the joint surfaces represents a prearthrotic deformity. The destruction of the epiphyseal plate in children and adolescents leads to growth defects, which further increase the deformities. The most common osteonecroses of childhood and adolescence are localized in the lower extremity.

Juvenile osteochondrosis of the femoral head—Perthes' disease

The disease consist of the aseptic ischaemic necrosis of the ossification centre of the femoral head because of the perturbation of the blood supply in children of 4–8 years of age. Boys are four times more likely to be affected than girls. In terms of aetiology, disruption of the arterial blood supply, the intra-articular or intraosseus pressure increase, growth disturbance (retardation of the patient's skeletal age), coagulation defects, and genetic factors have all been proposed.

Clinically, from limping, pain, and a decrease in the range of motion of the hip joint (especially abduction and internal rotation) can be seen. The diagnosis is conformed by means of conventional radiographs and particularly by MRI.

The Caterall classification, which serves as a judgement tool for prognosis and therapy, divides the disease into four groups, corresponding to the extent of the epiphyseal participation. The epiphysis is considered to be divided into four quadrants.

- **Group I**: the anterolateral quadrant is affected.
- **Group II**: the anterior one-third or one-half of the femoral head is affected.
- **Group III**: up to 75% of the femoral head is affected; only the dorsal part remains intact.
- **Group IV**: the entire femoral head is affected.

Groups I and II generally show a better prognosis, groups III and IV a poor one. Additionally the so-called 'head at risk signs' are considered:

- lateral calcification of the epiphysis
- metaphyseal involvement
- Gage sign: a V-shaped brightening in the area of the lateral epiphysis and the adjacent metaphysis
- horizontal positioning of the epiphyseal plate
- lateral subluxation (of the femoral head out of the acetabulum).

Therapy depends on the clinical findings and the age of the child. The goal is to maintain the containment, the correct orientation of the femoral head in the acetabulum, and the spherical femoral head.

The onset of the disease before the age of 7 years is compatible with a reasonably good prognosis, and generally leads to conservative treatment. This usually means physiotherapy for many years. The orthoses used in the past did not lead to additional success. For groups III and IV, 'head at risk signs', children older than 7 years, or deterioration of the range of motion with physiotherapy, a surgical intervention should be considered. The best time for surgery is in the condensation or early fragmentation stage. Intertrochanteric osteotomy of the femur to centre the femoral head and to improve the abduction and adduction via the medialization of the femur with the resulting relaxation of the iliopsoas muscle is the usual choice. Alternatively pelvis osteotomies may be used for a better roof of the femoral head.

Osteochondrosis dissecans

Osteochondrosis dissecans is a subchondral osteonecrosis which in due course demarcates and may later show dissection with loose bodies in the joint. Mostly convex articular surfaces are affected, especially the femur condyles, the talus, and the capitulum of the humerus (Panner's disease) (Figure 148.4). Usually osteochondrosis dissecans occurs in older children, adolescents, or young adults. Boys and athletes are prone to the disease. In 30–40% the illness is bilateral. In general the symptoms consist of pain, limping (if a joint of the lower extremity is affected), and restricted range of motion. Should dissection already be present, entrapment may occur. Diagnostically, conventional radiographs and MRI are indicative.

In the knee joint the necrotic area is situated in the lateral part of the medial femur condyle in most cases. Scintigraphy is suited for the course of observation. Diagnostically, the chondral surfaces are best investigated by means of arthroscopy. Initial signs of a dissection beginning are changes of the colour (yellowish cartilage) or the findings when pressing the cartilage with a probe.

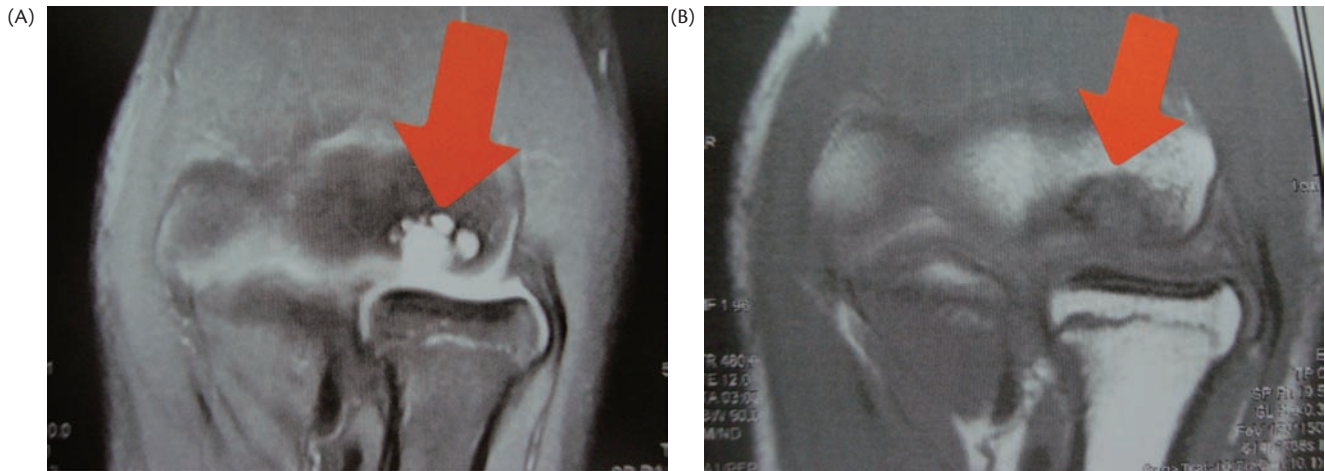
The aetiology remains unknown, although recurrent trauma may possibly play a key role.


Fig. 148.4 MRI of osteochondrosis dissecans of the capitulum of the humerus (Panner's disease) in a 12 year old boy.

In the upper ankle joint most often the anterolateral surface of the talus, rarely the posteromedial part, is affected. The peak is found in the second decade of life, and boys are affected more often. In 10–25% the finding is bilateral. A common cause seem to be trauma (single events as well as repetitive microtrauma), but also deterioration of local blood supply, metabolic disorders, overweight, and family predisposition. Osteochondrosis dissecans increases the risk of developing osteoarthritis later. The prognosis depends on the age (the younger the better) and on the presence of a dissecate. In younger children with small necrotic areas and few complaints, the indication is for a conservative treatment with leg relief (crutches for 6–10 weeks/orthoses), physiotherapy, relative protection, and abstention from sports activities. Every 3 months a MRI reinvestigation is appropriate. In the presence of intact chondral surfaces, procedures for revascularization of the defect by means of retrograde bone marrow plastic or retrograde punching of the sclerotic area are indicated. In the case of a beginning dissection, debridement of the defect in combination with a solid refixation of the dissecate via screws, fibrin glue, or resorbable pins is appropriate. Autologous bone–cartilage grafting (dorsal femur condyle or lateral patella—alternatively, homologue from a cadaver) is necessary when large or non-vital defects are given. Older cartilage defects may benefit from Pridie drilling (anterograde for the ingrowth of vessels and the induction of surface-covering fibrocartilage). In case of deviation of the leg axes, osteotomies for the reduction of weightbearing by the knee may be considered.

Osteochondroses of the capitulum of the humerus (Panner's disease) generally affect boys in the 5–12 years age range. Here, too, repetitive microtrauma (frequent valgus loading of the elbow in tennis or throwing sports) and local disturbances of microcirculation seem to be the main reason for their development. The clinical signs are non-specific. Visible and palpable swelling of the joint, extension deficit, and rarely entrapment can be found. The diagnosis is normally confirmed by radiographs and MRI.

Therapy is mostly conservative. Temporary immobilization (dorsal cast of the arm) with the elbow situated in 90° flexion for a period of 3–4 weeks and anti-inflammatory medication are prescribed. Should more severe and persisting symptoms be demonstrated, arthroscopy may be indicated. The prognosis of the disease is benign, only rarely an extension lag of the elbow persists.

Bisphosphonate-associated osteonecrosis of the jaws

In recent years an increasing number of articles concerning bisphosphonate-associated osteonecrosis of the jaws have been published in the literature. The bisphosphonates are used mainly in the therapy of osteoporosis, Paget's disease, and tumour-induced hypercalcaemia, as well as skeletal metatases. The incidence of bisphosphonate-associated osteonecrosis of the jaws is estimated to be approximately 2–9%.[23–25] Risk factors are malignant disease, the relative potency of the medication in question (the highest risk for osteonecrosis of the jaws is represented by high-potency medications such as zoledronic acid) and the form of application, the duration of the therapy, extraction of teeth, or other oral surgical procedures such as root canal treatment.

Symptoms of a bisphosphonate-associated osteonecrosis of the jaws are non-specific and extend from non-symptomatic affections to extreme pain with loss of sensation. Clinically, signs similar to infections such as reddening, swelling, putrid secretion, and formation of abscesses may be seen, as well as exposed bone in the jaw with a yellow-brown colour and very hard composition. The surface of this may appear rough, typically in the area of extraction alveoli or in the alveolar crest, in the toothless jaw, or in the lateral area of the lower mandible teeth.

Diagnostically, in addition to panoramic radiographs to show the extent of the lesion and the accompanying infection, CT or MRI is indicated. A biopsy is recommended for a definite conformation of diagnosis and in order to exclude malignant tumours. The most important therapy concept, other than systemic antibiotics, is prevention. Before the use of bisphosphonates, dental presentation, with extraction of teeth not worthy of preservation, and the therapy of infectious sites, is imperative. Patients who are taking bisphosphonates regularly should see their dentist frequently.[26]

CHAPTER 149

Renal osteodystrophy

Thomas Bardin and Tilman Drüeke

Introduction

Renal osteodystrophy (ROD) is a term that encompasses the various consequences of chronic kidney disease (CKD) for the bone. It has been divided into several entities based on bone histomorphometry observations. ROD is accompanied by several abnormalities of mineral metabolism: abnormal levels of serum calcium, phosphorus, parathyroid hormone (PTH), vitamin D metabolites, alkaline phosphatases, fibroblast growth factor-23 (FGF-23) and klotho, which all have been identified as cardiovascular risk factors in patients with CKD.[1,2] The term CKD mineral and bone disorder (CKD-MBD) has been proposed by the KDIGO group (Kidney Disease: Improving Global Outcome).[3] It is meant to describe the entire systemic disorder of mineral and bone metabolism associated with CKD manifested by either one or a combination of the following: (1) abnormalities of calcium, phosphorus, PTH, or vitamin D metabolism, (2) abnormalities in bone turnover, mineralization, volume, linear growth, or strength, (3) vascular or other soft tissue calcification.[3]

Renal osteodystrophy

ROD can presently be schematically divided into three main types by histology: (1) osteitis fibrosa as the bony expression of secondary hyperparathyroidism (sHP), which is a high bone turnover disease developing early in CKD; (2) adynamic bone disease (ABD), the most frequent type of ROD in dialysis patients,[4,5] which is at present most often observed in the absence of aluminium intoxication and develops mainly as a result of excessive PTH suppression; and (3) mixed ROD, a combination of osteitis fibrosa and osteomalacia whose prevalence has decreased in the last decade. Pure osteomalacia has become exceptional in CKD patients.

Skeletal resistance to PTH is an important and early feature of CKD, which has been evidenced by the lower than normal hypercalcaemic response to PTH infusions in CKD patients. It can be explained by several factors (Box 149.1).[6–7] As PTH is the main stimulant of bone turnover, higher than normal serum levels of PTH are required to maintain normal bone turnover in CKD patients with PTH resistance.[8]

Secondary hyperparathyroidism

Osteitis fibrosa due to sHP is a naturally occurring type of ROD and develops early on in the course of CKD. A cross-sectional study of a large unreferred CKD patient cohort in the United States found increased serum 'intact' PTH levels (>65 pg/mL; normal, 10–65 pg/mL) in 12% of patients with an eGFR greater than 80 mL/min, and 56% of those with an eGFR less than 60 mL/min.[9] The international KDIGO CKD-MBD guideline recommends starting serum PTH measurements when the creatinine clearance decreases below 60 mL/min (CKD stage 3) in order to avoid, by implementing appropriate measures, the deleterious consequences of a progressively worsening sHP.[10]

Pathophysiology of secondary hyperparathyroidism
Endstage chronic kidney disease

Numerous factors explain the development of sHP in most patients with advanced CKD when preventive measures are not undertaken (Figure 149.1). Classical aetiological factors, which have been the main therapeutic targets for many years, include hyperphosphataemia, insufficient 1,25-dihydroxyvitamin D (1,25 diOH D) production, and a negative calcium balance. Hyperphosphataemia plays an important part in advanced renal failure.[11] It induces hypocalcaemia by favouring soft tissue precipitation of calcium in the form of calcium phosphate, decreases the activity of renal 1α-OH-vitamin D hydroxylase and directly stimulates parathyroid cell proliferation and PTH secretion. Decreased renal synthesis of 1,25 diOH D is due to nephron reduction, hyperphosphataemia, metabolic acidosis, and the presence of uraemic toxins.[12] It leads to decreased intestinal calcium absorption, which favours hypocalcaemia and in turn enhanced PTH secretion. Reduced tissue expression of the vitamin D receptor (VDR) due to uraemic toxins and other mechanisms further contributes to enhanced parathyroid cell proliferation and

---

Box 149.1 Main mechanisms of uraemic bone resistance to PTH

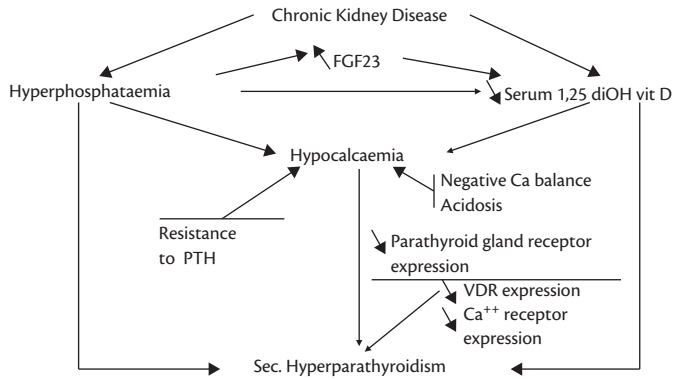
- Decrease of 1,25-dihydroxyvitamin D production
- Decrease of osteoblast PTH receptors
- Progressive increase of serum osteoprotegerin, which impairs bone response to PTH (osteoprotegerin being very high in dialysis patients)
- Presence of PTH fragment 7–84 in uraemic serum, having opposite effects to those of PTH, i.e. lowering serum calcium and inhibiting bone resorption.


Fig. 149.1 Pathophysiology of secondary hyperparathyroidism in endstage kidney disease.

PTH oversecretion by a transcriptional mechanism.[13] The reduced VDR expression, together with reduced calcium sensing receptor (CaR) expression,[14] particularly in nodular areas of the hyperplastic parathyroid glands, is indicative of the presence of clonally growing, tumoural sHP,[15] which has escaped physiological control and become refractory to medical treatment. In 24% of parathyroid tumours removed from dialysis patients who underwent parathyroid surgery for refractory sHP, chromosomal abormalities were observed, characterized by both allelic losses and gains.[16]

Early stages of renal disease

In early CKD, a different sequence of mineral disturbances is involved in the pathophysiology of sHP. The predominant role of FGF-23 has been progressively recognized in recent years. It now appears that an increase in serum FGF-23 levels is the first reaction of the organism to prevent an increase in serum phosphate during the early stages of CKD, some time before the well-known increase in PTH secretion.[17] Owing to these two defence mechanisms, phosphate retention secondary to a progressively reduced renal excretory capacity is avoided until CKD stages 4–5 (corresponding to creatinine clearances <30 to <15 mL/min), and hyperphosphataemia becomes a late event. FGF-23 is secreted by osteoblasts and osteocytes and targets FGF receptor–α-klotho complexes in the kidney to inhibit both renal phosphate reabsorption and production of 1,25 diOH D. The latter effect favours sHP. A study of the disturbances of mineral metabolism in early CKD has suggested that inappropriate postprandial calciuria with episodic hypocalcaemia may represent an additional mechanism contributing to sHP.[18] Another important mechanism is the early decrease in renal 1,25 diOH D synthesis as a consequence of increased serum FGF-23 levels, reduced nephron mass, and impaired substrate availability.[19] Vitamin D deficiency is frequent in CKD patients and may also contribute to sHP via reduced 1,25 diOH D synthesis.[19] Last but not least, the occurrence of skeletal resistance to PTH also plays a role.[6,7] Of note, in CKD there is also a partial resistance to the action of FGF23, owing to downregulation of both FGF receptor-1 and α-klotho in various tissues, including the parathyroid gland and the kidney.[20,21]

Clinical, biochemical, imaging, and pathological features of secondary hyperparathyroidism

Clinically, sHP is most often asymptomatic although severe disease can cause mechanical bone pain, arthralgias, myalgias, and an erosive enthesopathy which put the patient at risk of tendon rupture. Systemic features include asthenia, pruritus, pancreatitis hypertension, cardiac failure, and erythropoietin-resistant anaemia. Cardiovascular mortality is increased, even when sHP is moderate in predialysis CKD stages.[22]

Laboratory features include increased serum levels of PTH and bone turnover markers such as total and bone alkaline phosphatases, osteocalcin, and several products of type I collagen metabolism products.[23] Serum phosphorus is increased only in CKD stages 4–5.[9] Serum calcium levels are variable. They may be low initially, but hypercalcaemia develops in case of severe sHP. Serum 25-OH-vitamin D (25OHD) levels are generally below 30 ng/mL, indicating vitamin D insufficiency or deficiency.[24]

Radiography shows subperiostal bone resorption which is particularly well expressed at the radial border of the second phalanges of the second and third fingers (Figure 149.2) where radiographic and histological features are best correlated. Resorption of the third phalangeal ends is an early feature of severe sHP and can lead to distal osteolysis translating clinically into a pseudo-hippocratism (Figure 149.3). Subchondral bone resorption (Figure 149.4) causes widening of pubic symphysis and sacroiliac and acromioclavicular joint spaces. In the axial skeleton, bone resorption and formation frequently coexist, leading to a 'salt-and-pepper' appearance of the skull (Figure 149.5) and the so-called 'rugger jersey' vertebrae in which condensed plates contrast with low density of the central parts. In severe cases, bone condensation can result in a rare pseudo-pagetic aspect, which, in contrast to true Paget's disease, involves the whole axial skeleton. Brown tumours due to sHP should be differentiated from amyloid erosions which always involve articular areas. Soft tissue calcifications, in particular vascular (Figure 149.6), valvular, periarticular (Figure 149.7), cutaneous, and eye calcification, may develop and should be taken into account for management.

Fig. 149.2 Subperiosteal bone resorption at the radial aspect of the second phalanges in secondary hyperparathyroidism.

Fig. 149.3 Severe secondary hyperparathyroidism with massive lysis of third phalange.

Fig. 149.4 Subchondral bone resorption at the sacro-iliac joint and pubic symphysis.

Fig. 149.6 Vascular calcification in female adult haemodialysis patient with severe secondary hyperparathyroidism: (a) before parathyroidectomy (PTX); (b) 12 months after PTX.

Bone scan demonstrates an increased uptake of technetium-99m pyrophosphate or bisphosphonate in the axial skeleton resulting for increased bone turnover.[25] It also can pick up large extraskeletal calcifications.

Parathyroid gland imaging is useful for the indication of parathyroidectomy, especially in the case of recurent sHP. Ultrasound is the first-line technique but generally misses ectopic glands. CT and/MRI can be used to visualize ectopic glands but often cannot differentiate parathyroid tissue from lymph node or thyroid nodule. Scintigraphy using $^{99\,m}$Tc sestamibi coupled with ^{123}I is the most specific technique. It allows detection of parathyroid tissue with a false-positive rate inferior to 5%.[26]

Transiliac bone biopsy is seldom indicated at present in clinical practice. It should, however, be done more often in CKD patients with unexplained fractures, persistent bone pain, unexplained hypercalcaemia, unexplained hypophosphataemia, possible aluminium toxicity, and prior to therapy with bisphosphonates.[10] Histomorphometric features of hyperparathyroidism (HP) (Figure 149.8) include increased bone resorption and formation and bone marrow fibrosis.[27]

Management of secondary hyperparathyroidism
Target PTH

Because of the skeletal resistance to PTH, greater than normal serum levels of PTH are required for normal bone turnover. In dialysis patients, the 2003 American KDOQI guidelines recommended serum 'intact' PTH to be maintained between 150 and 300 pg/mL.[8] The more recent (2009) international KDIGO guideline recommends serum PTH levels to be maintained in the range of approximately 2–9 times the upper normal normal limit of the assay and to intervene only in case of significant changes in PTH levels.[10] This wider PTH target range followed changes in the immunoassays used, the awareness of major interassay and intraindividual variability of PTH measurements,[28,29] and the demonstration that normal bone turnover was not accurately predicted by the KDOQI targeted values (see below).

Calcium intake

Because the most active form of vitamin D is reduced in CKD, intestinal calcium absorption is low. It is generally recommended that calcium intake should be up to 2 g per day including intake with food and administration of calcium supplements or calcium-containing phosphate binders. The KDIGO guideline suggests caution in prescribing the latter in presence of extraskeletal calcification and/or adynamic bone and strongly recommends refraining from their administration in the presence of hypercalcaemia [10]

Control of hyperphosphataemia

Reduction of serum phosphorus towards the normal range in patients with endstage kidney failure has become a major objective.[10] Therapeutic means include a decrease in dietary phosphate intake to 800–1000 mg/day, but without inducing a protein deficiency state. It should be implemented as soon as hyperphosphataemia occurs. However, rigid dietary restriction is rarely followed in the long term and carries the risk of malnutrition. Renal replacement therapies allow elimination of phosphate, which can be improved by increasing dialysis performance. The most efficacious means remains the use of oral phosphate binders which reduce the availability of phosphate for intestinal absorption (Box 149.2). Aluminium-containing binders are a potential source of aluminium intoxication and are contraindicated except for short periods of time.[10] By the 1990s, they had been replaced by calcium-containing binders. When taken with meals, calcium salts have been said to form poorly absorbed complexes with dietary phosphorus, but much of the unbound calcium is nevertheless absorbed. Calcium carbonate provides bicarbonate, which is useful against metabolic acidosis, and has been widely used in France. Large doses, especially when prescribed together with vitamin D sterols, are a source of hypercalcaemia and extraskeletal calcification. KDOQI therefore recommended that doses of elemental calcium should not exceed 1.5 g/day. Aluminium-free, calcium-free phosphate binders should be preferentially used when calcium-containing chelators are not sufficient or contraindicated. Sevelamer hydrochloride (Renagel) was the first to be developed. It appears as effective as calcium carbonate, while inducing less hypercalcaemia and cardiovascular calcification.[30] Sevelamer carbonate has been introduced more recently in an attempt to increase serum bicarbonate. Lanthanum carbonate is an alternative which has shown similar efficacy in reducing hyperphosphataemia.[31] However, these new phosphate binders are costly and their superiority over calcium-containing binders in delaying the progression of vascular calcification and hard clinical outcomes remains a matter of debate.

Native vitamin D and vitamin D derivatives (Box 149.3)

Vitamin D depletion is found in about one-half of endstage renal disease patients.[24] It is associated with poor survival in CKD patients.[32] However, such associations based on retrospective, uncontrolled studies do not prove a causal relationship. The effect of native vitamin D supplements on hard patient outcomes remains so far uncertain. It seems nevertheless reasonable to correct vitamin D insufficiency/deficiency in CKD patients.[10] This may increase serum 1,25 diOH D even in dialysis patients with only minimal or no excretory kidney function,[33] suggesting that vitamin D depletion, together with poor renal or extrarenal 1-α-25OH vitamin D hydroxylase activity plays a role in the pathogenesis of sHP. Once sHP has developed, active vitamin D derivatives such as alfacalcidol or calcitriol are indicated in order to halt its progression. These drugs are generally given orally but the IV route during dialysis sessions is also possible. Note that excessive doses

- Alfacalcidol (1α hydroxy vitamin D_3)
- Paricalcitol (19-nor-1α,25 dihydroxy vitamin D_2)
- Doxercalciferol (1α-hydroxy vitamin D_2)

---

of active vitamin D derivatives increase the serum Ca × P product and may induce ABD by oversuppression of PTH secretion. Serum calcium, phosphorus, and iPTH levels should be closely monitored and these compounds should be avoided in case of hypercalcaemia, extraskeletal calcification, and low PTH levels.[10] Vitamin D analogues such as paracalcitol (19-nor-1α,25 $(OH)_2D_2$), maxacalcitol (22-oxa-calcitriol), and doxercalciferol (1α-$(OH)D2$) can also be used and decrease PTH secretion to a similar degree. However, the claim that they are less hypercalcaemic and induce ABD less often remains unproven.[34]

Calcimimetics

The finding that the calcium sensing receptor (CaR) is expressed in parathyroid cells and the discovery of drugs able to activate this receptor (CaR agonists or calcimimetics) has opened a new avenue in the management of sHP. Cinacalcet-HCl (Mimpara) has been approved for the management of sHP in dialysis patients. Cinacalcet is administered orally. In most instances, a dose of 30–60 mg/day is sufficient. Randomized controlled trials (RCTs) have shown that cinacalcet allows to reach target PTH values in 56% of patients, compared with only 10% of control patients receiving optimal standard therapy.[35] In contrast to the latter, cinacalcet not only decreases serum PTH levels but also reduces serum calcium and phosphorus. The occurrence of transient hypocalcaemia is an indication for increased calcium and/or vitamin D sterol intake, thereby improving cinacalcet effectiveness. Cinacalcet use has been found to be associated with a lower frequency of parathyroidectomy, bone fractures, hospitalization rate for cardiovascular causes, and an improvement in quality of life. An RCT is under way aimed at confirming such beneficial effects prospectively. The most frequent side effects, in addition to hypocalcaemia, are nausea and vomiting. In the majority of patients, these adverse effects disappear after prolonged administration.

Parathyroidectomy

Parthyroidectomy (PTX) should be considered when facing sHP refractory to medical management. Before the availability of calcimimetic drugs, PTX, which is rarely performed in non-dialysis patients, was indicated in dialysis patients at a yearly rate of approximately 1–3%, which increased with dialysis vintage. The most frequent indications were the persistence of very high serum PTH level (>800 pg/mL) after a 6–8 week trial of active vitamin D sterol treatment or the coexistence of refractory hypercalcaemia and/or hyperphosphataemia with soft tissue calcifications contraindicating the use of vitamin D derivatives. The degree of parathyroid gland hyperplasia was also taken into accounts, as very large glands often contain areas of monoclonal growth and are less sensitive to medical management.[15] Calcimimetics, which can now be prescribed in settings where vitamine D derivatives are contraindicated, appear to lower the rate of parathyroidectomy; however, this needs to be confirmed by long-term trials which should also evaluate the cost-effectivenes of calcimimetics as compared to PTX.

Aluminium-induced bone diseases

Aluminium osteopathy is a dramatic disease. It is associated with bone pain and frequently leads to fractures of various bones, including the upper ribs which are rarely affected by other causes of bone frailty. The elimination of aluminium contamination of the dialysis fluid and the avoidance of aluminium-containing phosphate binders has practically led to the disappearance of aluminium intoxication in developed countries. Classically, there were two types of aluminium-induced osteopathy: osteomalacia and ABD. They shared three pathological features, including (1) presence of aluminium deposits at the mineralized bone–osteoid interface, (2) a major decrease in osteoblast number along bone trabeculae, and (3) a massive slow-down of mineralization speed.[36] Aluminium-induced osteomalacia, characterized by an additional accummation of non-mineralized osteoid (Figure 149.9), was the first recognized type. It was clinically the most severe form and arose after massive aluminium intoxication through contamination of the dialysate in a number of dialysis centres.[37] ABD, which differs from osteomalacia by the lack of excess osteoid, was identified later. It usually resulted from less severe aluminium intoxication following chronic ingestion of aluminium-containing phosphate binders. In general, it was clinically less severe although it could also be associated with proximal limb pain, myopathy and fractures. The main mechanism by which aluminium is involved in decreased bone turnover was believed to originate via aluminium deposits in the parathyroid glands. The resulting impairment of PTH production would then lead to low bone turnover. PTX has been shown to worsen the consequences of aluminium intoxication on bone and is contraindicated in the presence of significant aluminium intoxication.

The diagnosis of aluminium intoxication can be made by aluminium staining of a bone biopsy or by measuring excessive levels of aluminium in the blood, either spontaneously or after deferoxamine infusion. Management relies on the cessation of the intoxication and on regular infusions of deferoxamine.

Non-aluminium-associated adynamic bone disease

ABD, in the absence of aluminium intoxication, has become the most frequent type of renal osteodystrophy in both haemodialysis and peritoneal dialysis patients since the end of the 20th century.[5,38,39] The main aetiological factor appears to be excessive iatrogenic PTH suppression, resulting in serum PTH levels too low to maintain normal bone turnover. The disease should be preventable by targeting serum PTH levels at values 2–9 times above the normal range.[10] This should go along with a normal bone turnover despite the resistance of the uraemic skeleton to PTH. Other factors of ABD include diabetes mellitus and old age.

In dialysis patients, the diagnosis is suspected when serum 'intact' PTH levels are below 150 pg/mL and serum bone turnover markers are decreased.[10] However, levels of PTH within the target range have been observed in patients with histological evidence of ABD.[5] The imperfection and lack of standardization of presently available assays to measure PTH are probably one of the reasons for this failure.[28] The so-called 'intact' PTH assays not only recognize the whole
Fig. 149.9 Aluminium-associated osteomalacia.

hormone but also its 7–84 fragment and other fragments, which accumulate in renal failure and may contribute to the pathogenesis of ABD. The 7–84 fragment has been shown to exert an effect on serum calcium opposite to that of whole PTH and is believed to play a part in the skeletal resistance to the hormone in CKD. Reliable measurement methods of serum levels of the whole PTH molecule and of the 7–84 PTH fragment, respectively, are needed to improve the diagnosis, treatment, and prevention of ABD.

Its prevalence has been estimated to be 5–30% in non-dialysis CKD patients, and to reach even higher levels in dialysis patients, with variations according to dialysis technique: 32–40% in haemodialysis patients and 48–65% in those treated by peritoneal dialysis.[4,39] The latter difference can be explained by generally higher serum calcium levels in peritoneal dialysis patients with easier suppression of PTH secretion.

Non-aluminium-associated ABD is most frequently asymptomatic. The risk of hypercalcaemia and of extraskeletal calcifications is important in case of excessive prescription of oral calcium and/or vitamin D sterols, reflecting decreased bone buffering capacity. Consequences in terms of bone fragility remain debatable. In children, adynamic bone exposes to delayed skeletal growth. Management is difficult. Prescription of calcium-containing phosphate binders should be limited in patients with ABD to avoid a positive calcium balance and vascular calcifications. This favours the use of non-aluminium-, non-calcium-containing chelators to control hyperphosphataemia. Lowering the calcium concentration of the dialysate allows the stimulation of parathyroid gland activity.

Hyperphosphataemia

Hyperphosphataemia is a very frequent feature in CKD stages 4–5 and 5D (dialysis). It is observed in association with all types of renal osteodystrophy. A nationwide American study has shown that an increase of serum phosphorus above 5.0 mg/dL was associated with a significant increase in relative mortality risk, which was independent of serum PTH and calcium.[40] A recent review has concluded that the risk of death increased by 18% for every 1 mg/dL increase in serum phosphorus. Hyperphosphataemia is a source of sHP and a major contributor to extraskeletal, in particular vascular calcifications (see below). The control of hyperphosphataemia is a major objective of CKD patient management. The recent KDIGO guideline suggests lowering the serum phosphorus levels of CKD stage 5D patients towards the normal range.[10]

Extraskeletal calcification

Periarticular deposits of basic calcium phosphate are frequent in end stage kidney disease patients (Figure 149.7). They are favoured by hyperphosphataemia and hypercalcaemia, dialysis vintage, and high active vitamin D sterol doses. Deposits are frequently multiple and may induce acute inflammatory episodes.[41]

The prevalence and incidence of vascular and valvular calcification are also greatly increased in CKD patients. The calcification often appears at a much younger age than in the population at large. This has been well illustrated by several studies, including the one by Goodman et al.[42] who demonstrated an elevated frequency (21/39) and rapid progression of coronary artery calcification in children and young adults on dialysis, and by Shroff et al.[43] who observed an increase in arterial calcium load already in the predialysis stage of uraemic children. An increase in coronary calcification has also been observed in the earlier stages of adult CKD patients. This matter is a subject of considerable interest as vascular calcification has been shown to contribute to the poor cardiovascular outcome of patients wih CKD.[44]

Vascular calcification (Figure 149.10) most often involves the intima, where it associates with atherosclerotic plaques. It occurs at all stages of CKD and increases with the progression of CKD.[45] Atherosclerotic plaques have been shown to be more calcified in patients with CKD stages 4–5 and 5D than in age-matched controls. Vascular calcifications of CKD patients may also involve the media. They generally occur only at the stage of dialysis, with particularly high prevalence in CKD patients with diabetes. Medial calcification leads to arterial stiffness via the loss of vessel wall elasticity and associates with a marked increase in the relative risk of mortality, as does intimal calcification linked to atherosclerosis.[44]

A number of factors are associated with the development of vascular calcifications in CKD patients. Decreased concentrations of several inhibitors such as fetuin A and pyrophosphate, together with increased concentrations of promoters such as calcium, phosphate, vitamin D, and many others all play a role. Vitamin K deficiency has also been incriminated more recently. Vitamin K favours gamma-carboxylation and thus activation of matrix gla protein, another important inhibitor of vascular calcification. Arterial calcification is also a cell-mediated phenomenon involving the transformation of vascular smooth muscle cells into chondroblast- and osteoblast-like cells. In-vitro studies have shown that hyperphosphataemia plays a major role in this active process, as the elevation of phosphorus concentration in the culture medium resulted in the increase of various soluble mediators, appearance of osteoblasts, and calcification of the artery wall. Bone and mineral disorders including hyperphosphataemia, hypercalcaemia, renal osteodystrophy, and its management by calcium and vitamin D supplements play an important part. Of interest, studies have shown an inverse relationship between bone mineralization status and arterial calcification in patients with CKD, as has long been demonstrated in general population. A study pointed out the importance of bone activity in the occurrence of vascular calcification in association with a high calcium load which was shown to have a particularly important influence on aortic calcification in presence of ABD. A likely explanation was that the adynamic bone lost its buffering capacity

for calcium, therefore favouring hypercalcaemia and extraskeletal calcifications in response to large amounts of ingested calcium.

Osteoporosis

Bone mineral density (BMD) decreases in parallel with the progression of CKD.[46] Several transversal studies have shown a decrease of BMD in haemodialysis patients, in particular at the distal forearm as lumbar osteoarthritis and aorta calcification can lead to an overestimate of BMD at the lumbar spine. However, BMD imaging is not considered to be useful in patients with CKD stages 5–5D since a marked decrease in mineral density does not allow one to differentiate between severe ostitis fibrosa and ABD.[10] In difficult cases a bone biopsy is still recommended.

Fracture rate is increased in dialysis patients, as shown by a national American study which observed a relative risk of femoral neck fracture of 4.44 in men and 4.40 in women in dialysis patients as compared to an age- and sex- matched control population.[47]

Studies have identified various risk factors of fracture in dialysis patients.[48] These include duration of survival under dialysis, presence of peripheral arteriopathy, and, most importantly, factors known to play a role in the population at large: age, sex, white skin colour, impaired muscle strength, low body mass index, and cigarette smoking. Low BMD increased fracture risk in some, but not all studies. Early menopause, which is frequent in CKD, is another important factor of decreased BMD in women on maintenance dialysis. Steroid treatment that patients may have received for the management of their renal disease or during a previous kidney transplantation also plays an obvious role. Whereas aluminium-induced osteomalacia was clearly associated with an major fracture risk, the role of the two presently observed major types of renal osteodystrophy—sHP and non-aluminium-associated ABD—is more difficult to ascertain.

Some authors failed to observe an influence of serum PTH in their important American registry study, whereas other investigators observed an increased fracture rate in patients with low serum PTH levels, a negative correlation between serum PTH level and BMD, or an elevated fracture rate in patients with sHP. Vascular calcification is also associated with vertebral fractures.

Management of osteoporosis in endstage kidney disease patients is a difficult challenge. General measures such as exercise and satisfactory nutritional status are frequently difficult to implement. Excessive long-term phosphorus restriction through a low-protein diet may increase the risk of osteoporosis.[49] Vitamin D-deficient patients should be supplemented with vitamin D. Serum calcium levels should be maintained within the normal range according to KDOQI and KDIGO guidelines, and the KDOQI guidelines recommended a total elemental calcium intake of not more than 2 g/day to reduce the risk of extraskeletal calcification in patients with CKD stages 3–5.[10] Serum PTH levels should be kept in the target range.

Oestrogen replacement in young women with early menopause is usually advised, but the risk of breast cancer and cardiovascular toxicity should be carefully weighed against their use. Bisphosphonates, which may induce ABD, and strontium ranelate are not approved in these patients. Raloxifene has been found to improve BMD in postmenopausal women on haemodialysis therapy,[50] but is known to increase the risk of arteriovenous thromboembolism.

CHAPTER 150

Skeletal dysplasias

B. P. Wordsworth

Introduction

The human skeleton is not just a supporting frame for the rest of the body but also acts as an accessible mineral store. Bone is metabolically active throughout life and metabolic disturbances may have wide-ranging consequences that are not restricted to altering its mechanics. The study of some genetic bone diseases has already provided remarkable insights into the normal regulation of bone metabolism. In some cases this has been translated into new treatments for conditions, such as osteoporosis and Paget's disease.

Most of the conditions described in this chapter are monogenic disorders but only a small sample is covered here. For a fuller description of these and other related disorders the reader is directed not only to the references but also to the online compendium, Mendelian Inheritance in Man (www.ncbi.nlm.nih.gov/omim).[1–5] Some of these disorders are associated with abnormalities of bone mineral density while others cause abnormalities of stature which is often disproportionate. These changes may be quite subtle and have to be judged carefully against the range of the normal human phenotype.

Skeletal dysplasias are developmental disorders of the chondroosseous tissues commonly resulting in short stature, which is often disproportionate. The underlying mutations are often in the structural genes encoding components of the matrix but may also involve growth factors or cell signalling. In contrast, the dysostoses tend to affect single bones or groups of bones, reflecting the transient nature of the many different signalling factors to which they are responsive during development.

Abnormalities of bone density (high or low) may be due to primary deficiency of bone matrix synthesis (e.g. osteogenesis imperfecta and hypophosphatasia) but may also reflect an imbalance between bone formation and resorption. This may be caused by abnormalities of bone formation (e.g. hyperostosis/sclerosteosis and osteoporosis pseudoglioma syndrome) or bone resorption (e.g. classic osteopetrosis and fibrous dysplasia). Linear growth is often not affected by these conditions.

Deformity and short stature

Faced with the small child in clinic it can be a difficult task to decide who and when to investigate further. Short stature (defined as less than 0.4th centile) can be divided into proportionate and disproportionate forms, of which the most frequent is caused by short

limbs. About three-quarters of children with short stature either have familial short stature or constitutional delay of growth and puberty; others have chronic disease (10%), syndromic short stature (6%), chromosomal abnormalities (5%), or hormone deficiencies (1–2%). It is important to recognize that only 1% have true skeletal dysplasias. Particular attention should be paid to children whose height progressively crosses the centile ranges. There may be associated deformities, including knock knees, bowed legs, enlarged epiphyses, and bossing of the skull, that may heighten suspicion of an underlying growth disorder. Particularly in the more severe cases, skeletal surveys may be very valuable so long as they are interpreted by experts.

Osteogenesis imperfecta: the brittle bone syndrome

Osteogenesis imperfecta (OI) affects about 1 in 20 000 births but exists in several quite distinct clinical forms. Type 2 OI is a leading cause of lethal short-limbed dwarfism. It was among the first of the skeletal dysplasias for which the underlying genetic mutation was found.

Pathophysiology

OI is a genetic disorder of type I collagen and affects those tissues which contain it. These include particularly bone and dentine but also the sclerae, joints, tendons, heart valves, and skin.

In the so-called 'mild' type 1 OI the quantity and quality of bone is reduced, typically by about 50%. In the extraskeletal tissues, the sclerae are thin (often blue or grey in colour), there is often a degree of ligmamentous laxity, some hyperextensibility of the skin, and occasionally incompetence of the heart valves. The teeth may also be affected (dentinogenesis imperfecta) in which case they tend to be brittle and opalescent.

Clinical features

Type 1 OI (OMIM 166200) is the most frequent form (60%) and least serious. Fractures, which usually heal without deformity, are not present at birth but typically start during childhood, becoming less frequent after adolescence as peak bone mass is achieved. In later life fractures tend to recur although in some unusual cases the initial fracture tendency may even be delayed until the early menopause. Life expectancy is near normal.

Type 2 OI (OMIM 166210) is one of the most common forms of lethal short-limbed dwarfism, but not all infants with fractures at birth succumb immediately. A few survive the perinatal period, later merging with type 3 OI (severe, progressively deforming).

Patients with type 3 OI (OMIM 259420) are likely to survive but present major management problems because their disability is severe and progressive. Although intramedullary rods may be tried in some cases such patients rarely walk, even after multiple operations, and have very short stature (Figure 150.1).

Type 4 OI (OMIM 166220) is intermediate in severity between types 1 and 3 but the sclerae are white, in contrast to type 1 disease. It is more commonly associated with dentinogenesis imperfecta and craniocervical abnormalities than type 1 OI, particularly in those with multiple wormian bones in the skull. Life expectancy is only modestly reduced in type 4 disease in contrast to more severe type 3 disease.

Diagnosis

In the first few years of life non-accidental injury is the main differential diagnosis. Although this may be suggested by multiple fractures at different sites and of different ages, there are no pathognomonic signs. Some fractures, such as metaphyseal 'corner' fractures and posterior rib fractures, are more often seen in non-accidental injury, but any type of fracture can also occur in OI. The distinction between OI and non-accidental injury is legally important and can be difficult. In adult life, mild OI may go unrecognized. Genetic testing is useful in some cases where the clinical diagnosis is in doubt since mutations in one or other of the type I collagen genes (*COL1A1* or *COL1A2*) can be detected in around 90% of cases. A small minority of cases of lethal or severe OI are caused not by collagen mutations but by recessive genes involved in the post-translational processing of collagen which can be identified in appropriate situations by serial DNA sequencing.

Fig. 150.1 Severe type 3 OI with profound pelvic deformity, slender deformed long bones and ununited fractures of the femur.

Treatment

Bisphosphonates have been increasingly used in the treatment of OI in recent years, particularly in infants with the more severe forms of OI in whom regular intravenous pamidronate has proved effective in increasing bone density although its effects on reducing fracture rates are somewhat less secure. Oral bisphosphonates should be considered in those with less severe disease, and vitamin D levels should be checked routinely given the high prevalence of insufficiency or even deficiency in those with OI. Fractures should heal normally in those with type 1 OI but non-union and malunion are relatively common in the more severe forms. Craniocervical surgery may be need in those with marked invagination of the foramen magnum to prevent hydrocephalus.

Chondrodysplasias

In these conditions the abnormalities of the bone are secondary to defects in endochondral ossification. Many of these conditions are due to mutations in collagens or other cartilage matrix components. Radiographs are essential to determine whether the metaphyses of the long bones or the epiphyses are primarily affected. The presence of spinal involvement in many of these disorders may be quite subtle. Most patients with skeletal dysplasias have some degree of restricted growth, and most are short-limbed. Achondroplasia is the best-known example but there are many different types, most of which are rare and require expert advice to be distinguished.

Achondroplasia

In achondroplasia (OMIM 100800), there are abnormalities in the epiphyseal growth cartilage. These reflect the underlying activating mutation in the *FGFR3* receptor that exerts a negative influence on longitudinal growth by inhibiting proliferation of chondrocytes in the growth plate. Radiological features include metaphyseal irregularity and flaring in the long bones, irregular and late-appearing epiphyses, a narrow pelvis in its anteroposterior diameter, with short iliac wings and deep sacroiliac notches. The spine shows progressive caudal narrowing of the interpedicular distance which is commonly associated with significant spinal stenosis. Spinal surgery for decompression of stenosis is commonly required, often at multiple levels. Eventual height can vary between about 80 and 150 cm. Significant increase in height can be achieved by limb lengthening procedures (often in several stages) but this should be carefully assessed in individual cases.

Epiphyseal dysplasias

These are characterized by prominent involvement of the growing end of the long bones (epiphyses) that typically results in reduced limb growth and variable short-limbed short stature. There are many different forms which vary considerably in their severity and the degree to which the spine is also involved (spondyloepiphyseal dysplasias). Many are caused by abnormalities in matrix components, including type II collagen (the most abundant cartilage matrix protein), type 9 collagen, COMP (cartilage oligomeric matrix protein), matrilin 3, and proteoglycans

Type II collagenopathies

These particularly illustrative examples of epiphyseal dysplasias exhibit a wide variety of phenotype, ranging from the lethal achondrogenesis type II (OMIM 200610), through intermediate forms,

spondyloepiphyseal dysplasia congenita (OMIM 183900) and Kniest dysplasia (OMIM 156550), to milder variants, including classic Stickler's syndrome (OMIM 108300). The different underlying mutations in type II collagen illustrate the variation in effect of different mutations in the same gene (see 'Osteogenesis imperfecta' above). Abnormalities of linear growth may lead to angular limb deformity (Figure 150.2) and premature osteoarthritis occurs commonly in these disorders.

Other epiphyseal dysplasias

These conditions include various forms of multiple epiphyseal dysplasia, some of which have very characteristic radiographic appearances (Figure 150.3). Epiphyseal dysplasias have been linked to mutations in type 9 collagen (OMIM 600204 and 600969), type 11 collagen (OMIM 604841), and abnormal proteoglycan sulphation (OMIM 226900). The latter can also cause much more severe forms of dysplasia known as achondrogenesis type 1B (OMIM 600972) and diastrophic dysplasia (OMIM 222600), respectively.

Spondyloepiphyseal dysplasias

This heterogeneous group of disorders exhibits prominent spinal involvement and the short stature is partly due to shortness of the trunk. In the dominantly inherited pseudoachondroplasia (OMIM 1777170), short stature is pronounced in childhood and adult life but does not become apparent until about the second birthday. In contrast to achondroplasia the face appears normal. Hypermobility

is marked and early osteoarthrititis quite typical, particularly in the hips. Hip joint replacement is often required in early adult life.

Spondyloepiphyseal dysplasia (tarda) is most commonly an X-linked recessive condition (OMIM 313400) caused by mutations in *SEDLIN*, a gene which appears to play an intracellular role in trafficking from the endoplasmic reticulum to the Golgi apparatus. The spine is disproportionately short with a characteristic 'heaped up' appearance to the centre and posterior parts of the vertebral bodies (Figure 150.4). Premature arthritis in the hips is particularly troublesome in early to middle life.

Metaphyseal dysplasias

In these disorders the growth plate itself is involved, with variable restriction of growth. For example, in metaphyseal chondrodysplasia Schmid type (OMIM 156500) there are mutations in type X collagen, which is transiently expressed by chondrocytes in the hypertrophic zone. Varus deformities of the hip and knees are common and surgical procedures to correct deformity may be necessary. These may be coupled with some leg lengthening since staure is typically somewhat reduced (Figure 150.5). It can be distinguished from nutritional rickets by the normal vitamin D levels. Other more severe forms of metaphyseal chondrodysplasia include the Jansen type (OMIM 156400) in which hypercalcaemia and very short stature is caused by mutations in the parathyroid hormone (PTH) receptor, and the McKusick type (OMIM 250250) in which abnormalities also include sparse hair growth and immune deficiencies.

Fig. 150.2 Long leg views of a child with Stickler syndrome demonstrating repair of osteochondritis dissecans in the distal femoral epiphysis. Th bilateral valgus deformities of the knees were subsequently successfully corrected by medial distal femoral epiphysiodesis.

Fig. 150.3 The characteristic double layered patella characteristic of EDM4, a recessive form of multiple epiphyseal dysplasia caused by mutations in a solute carrier important in the sulfation of proteoglycan.

Fig. 150.4 Lateral thoracolumbar spine showing moderate flattening of the vertebrae (platyspondyly) and 'heaping up' of the posterior aspect of the vertebral bodies characteristic of the X-linked form of spondyloepiphyseal dysplasia tarda.

Fig. 150.5 Varus deformities of the hips and knees in a patient with Schmid type metaphyseal chondrodysplasia. The metaphyses are clearly widened and splayed at all the major large joints in the lower limbs.

Multiple hereditary exostoses

This condition (OMIM 133700) has also been referred to as diaphyseal aclasis in the past and is one of the more common abnormalities of bone structure. The mutant gene (exostosin) is involved in cell surface expression of heparan sulphate proteoglycan and appears to function as a tumour suppressor gene. Clinically it is characterized by a juxtaepiphyseal disorder of bone growth, limited to bones developed in cartilage, which gives rise to cartilage-capped exostoses that point away from the joint. Stature is usually normal. Surgical removal of large exostoses may be required if there is mechanical interference with joint function. After skeletal maturity is reached there is a significant risk of malignant change in these exostoses that has been estimated at around 1–5% (lifetime risk). Any increase in size should raise the suspicion of malignant change which can be most effectively screened using ultrasonography to measure the thickness of the cartilage cap on the exostosis.

Dysostoses

These disorders of skeletal development can be distinguished from the true skeletal dysplasias because of the distinct patterns of bone groups that are affected. Those with predominantly axial involvement include vertebral segmentation defects (Klippel–Feil anomalies) and spondylocostal dysostosis (OMIM 277300). Mild varieties tend to be inherited in dominant fashion while the more severe types are recessive. Other forms have more prominent involvement of the limbs. In some cases this may involve the hands with variably short digits (various forms of brachydactyly) and/or fusion of the phalanges (symphalangism). Webbing of the fingers (synphalangism) may also occur to a varying degree. In dyschondrosteosis (OMIM 127300) there is mesomelic shortening of the limb in which the radius and tibia appear relatively short, causing a Madelung deformity in the forearm. It is of particular interest that the mutant *SHOX* gene is in the pseudoautosomal region of the sex chromosomes and females are considerably worse affected than males.

Nail–patella syndrome (OMIM 277300)

This dominantly inherited condition is associated with dystrophic nails, hypoplastic patellae, iliac horns, and a tendency to progressive nephrosis which causes renal failure in 20% of cases. The mutant *LMX1B* gene is involved in dorsoventral patterning of the developing limb and in the processing of type 4 collagen found in the basement membrane of the renal glomerulus.

Cleidocranial dysplasia (OMIM 119600)

In this rare condition involvement of the membrane bones is prominent; the clavicles are hypoplastic or absent, the fontanelles remain open, there are supernumerary teeth and wormian bones may be apparent on skull radiographs. It is caused by mutations in *RUNX2,* a key transcription factor in osteoblast differentiation and cartilage hypertrophy at the growth plate.

Disorders of bone density

Bone density reflects the balance between bone formation and resorption. Consequently, disorders of either can result in quantitative and qualitative disturbances of bone. Wnt signalling pathways and bone morphogenetic proteins are involved in osteoblast

activation but natural antagonists, including sclerostin, dickkopf, and noggin, modulate these effects. Mutations in many of these have now been described that affect bone density. Likewise abnormalities of osteoclast function are also implicated.

Osteopetrosis

Patients with osteopetrosis (Albers–Schönberg disease) have increased bone density and abnormal bony architecture. Pathological fractures are an important consequence. The classic forms of osteopetrosis reflect failure in the function of the osteoclasts, particularly relating to the generation of an acid milieu in the resorption pit. This can result from mutations in an osteoclast-specific proton pump, chloride channels or carbonic anhydrase that is necessary to generate hydrogen ions in the osteoclast (OMIM 259730). There is substantial variation in the severity of the condition; some forms are lethal in infancy from bone marrow failure (OMIM 259700) while others (Figure 150.6) may produce relatively few symptoms throughout life (OMIM 166600). The mild forms vary widely in severity. The bones are relatively fragile despite being dense since they lack the normal capacity for remodelling along lines of maximum stress. Pyknodysostosis (OMIM 265800) causes a particular form of osteopetrosis with short stature, homogeneous increased bone density, wormian bones and acro-osteolysis. In this disorder mutations of the proteolytic enzyme cathepsin K render osteoclasts inefficient at bone resorption.

Other causes of increased bone density

Other forms of increased bone density reflect increased bone formation by overactivity of osteoblasts induced by excess Wnt signalling through the LRP5 receptor. These include familial high bone mass and various types of endosteal hyperostosis (e.g. OMIM 144750). Sclerosteosis (OMIM 269500) is another hyperostosis in which there are inactivating mutations of the natural bone morphogenetic protein (BMP) inhibitor sclerostin. Diaphyseal dysplasia or Camurati–Englemann disease (OMIM 131300) is caused by activating mutations in TGFβ. It is characterized by enlarged long bones and proximal myopathy.

Melorheostosis (literally 'flowing limb') is a rare form of hyperostosis with a typically segmental distribution. It is thought to reflect local genetic mosaicism in the developing embryo and can cause severe soft tissue contractures as well as local enlargement of the affected bones (Figure 150.7).

Fibrodysplasia ossificans progressiva (OMIM 135100)

FOP is rare, with an incidence of less than 1 per million. Diagnosis depends on the combination of developmental abnormalities of the skeleton and progressive widespread myositis, leading to ossification in the major skeletal muscles. Initially there is oedema and cellular infiltration throughout the muscle, with myofibrillar breakdown. Later endochondral ossification leads to mature bone, within which is haemopoietic marrow. The upper paraspinal trunk is typically first affected, and the peripheral skeleton and associated

Fig. 150.6 Radiograph of the pelvis and lumbar spine of a young woman with typical dominantly inherited osteopetrosis caused by a CLCN7 chloride channel defect. There is obvious heterogeneous increased density of the bones with a classic endobone ('bone within bone') appearance in the iliac wings.

Fig. 150.7 Sclerosis and thickening of the bones of the fourth and fifth rays of the hand in a child with melorheostosis.

soft tissues are often spared. Typically, the affected muscle and/or associated fascia becomes swollen and hard, sometimes following injury; after a week or two these features subside, but the apparent improvement may be followed by ossification within the muscle and progressive joint fixation. Myositis usually begins in the upper paraspinal muscles in early childhood. By late childhood or adolescence ossification will have usually occurred widely in the trunk but also within the muscles around the shoulders, hips, and less commonly knees, to fix these joints and to complete the disability. The large, striated muscles are affected; ossification does not involve the small muscles of the hands and feet, the diaphragm, the cardiac, or the smooth muscles. Ossification in the muscles around the jaw may fix it almost completely. The diagnostic skeletal abnormalities affect the big toes, to a lesser extent the thumbs and the cervical spine (Figure 150.8). There is no effective treatment to prevent or reverse the abnormal ossification. Surgical removal of ectopic bone is technically difficult and may ultimately worsen the disability.

Reduced bone density

Various forms of inherited osteoporosis have been described in addition to OI. One of these is the osteoporosis pseudoglioma syndrome (OMIM 259770), in which reduced Wnt signalling as a result of inactivating mutations in the LRP5 receptor leads to reduced osteoblast activity and failure of the normal development of the eye. Of interest, LRP5 has also been shown to be a key regulator of bone mass in the genral population.

Hypophosphatasia

This rare disorder has similarities with rickets and osteomalacia. It is due to alkaline phosphatase deficiency which leads to defective mineralization of bone and varying degrees of fracture risk. In the adult form, progressive stiffness, pain in the bones, and apparent

'stress' fractures can occur (Figure 150.9). Approximately 50% of such patients have a childhood history of bone disease or premature loss of deciduous teeth. Recurrent poorly healing metatarsal fractures occur. Partial fractures of the long bones characteristically occur on the convex outer surface (in contrast to Looser's zones in osteomalacia). Calcium pyrophosphate chondrocalcinosis is also common and may be associated with arthropathy (pseudogout). More severe (lethal and childhood) variants are also described, reflecting correspondingly more severe deficiency of alkaline phosphatase.

Other conditions affecting the skeleton

Fibroblast growth factor 23 related disorders

FGF-23 is a crucial factor in determing phosphate excretion from the kidney. It may accumulate under certain circumstances to cause a renal phosphate leak and osteomalacia. This is exemplified by oncogenic osteomalacia where excess production of FGF-23 by a vascular tumour (eg. haemangiopericytoma). Widespread bone pain and pathological fractures may result.

Vitamin D-resistant rickets

Typically this is an X-linked dominant disorder (OMIM 307800) in which FGF-23 acculmulates as a result of mutations in the metalloproteinase PHEX which normally inactivates FGF-23. Affected individuals are short, develop angular limb deformities that often require corrective surgery, and may develop Looser's zones (cf. vitamin D deficient rickets). In adult life there is excessive bone deposition giving the appearance of buttressing of the long bones, spinal stenosis, and widespread enthesopathy (Figure 150.10). Treatment in the child is with regular phosphate supplementation and 1α-hydroxylated analogues of vitamin D. A rare form of autosomal dominant hypophosphataemia exists in which the cleavage site for
Fig. 150.8 Classic shortened monophalangic great toe in an adolescent with FOP (A). The cervical spine shows typical small vertebral bodies and poor develop of the intervertebral joints. There is extensive ossification in the soft tissues (B).

Fig. 150.9 Chronic fractures through base of the fourth metatarsal (arrowed) in a patient with the adult type of hypophosphatasia.

Fig. 150.10 Widespread enthesopathy in a patient with X-linked hypophosphataemia. There is extensive ossification of the hip joint capsule causing severe impingement syndrome.

PHEX in FGF-23 is missing, thereby also causing active FGF-23 to accumulate (OMIM 193100).

Marfan's syndrome

In Marfan syndrome the fundamental genetic defect lies in fibrillin, one of the key microfibrillar components of elastic tissues. Accurate diagnosis is dependent on the presence of major involvement of **at** **least two** organ systems and/or a definite history of the condition in a first-degree relative.[6]

Pathology

Deficiency of the microfibrillar architecture of elastic tissues is undoubtedly responsible for some of the clinical features of Marfan's syndrome. However, it is now recognized that dysregulated tissue growth factor beta (TGF-β) signalling also plays an important part. Latent TGF-β is normally sequestered in the connective tissue matrix bound to latent TGF-β binding protein, which itself binds to fibrillin in the matrix. Abnormal fibrillin microfibrillar architecture allows excessive amounts of activated TGF-β to be released with adverse consequences for organogenesis and growth. These effects can be neutralized in animal models by anti TGF-β antibodies and also angiotensin receptor antagonists, which are now entering clinical trials in humans.

Clinical features

Marfan's syndrome is dominantly inherited. Its main effects are on the skeleton, cardiovascular, and ocular systems. In the typical patient with Marfan's syndrome, overall height is increased and the limbs are long relative to the trunk. Long, thin fingers (arachnodactyly) are common. Scoliosis is common, may be severe, and worsens with the pre-adolescent growth spurt (Figure 150.11). Anterior chest-wall deformity (pectus carinatum/pectus excavatum) is often associated with scoliosis. Dislocation of the lens is the main ocular feature of Marfan's syndrome, but the most severe complication is

Fig. 150.11 Complex thoracolumbar scoliosis in a patient with Marfan's syndrome stabilized with spinal rods.

dilatation of the ascending aorta leading to aortic incompetence and/or dissection.

Treatment

There is no specific treatment yet for the underlying defect, but many of the clinical manifestations require attention. Once the diagnosis is established it is generally recommended that treatment with beta-blockers should be initiated to retard the rate of dilatation of the proximal aorta. Regular monitoring of the aortic root by echocardiography is desirable since dissection is much more likely to occur if it exceeds 5 cm in diameter, at which point aortic root/valve repair should be considered. Life expectancy is considerably reduced, although this depends on the severity of cardiac involvement. Earlier intervention and improvements in elective cardiac surgical techniques have had a significant impact on survival in those with more severe forms of the disease.

Scoliosis may be progressive and severe. Bracing is largely ineffective and operative stabilization, ideally in adolescence, may be necessary. Epiphysiodesis may be considered in either sex where predicted height is in excess of that deemed to be socially acceptable. Surgical correction of chest-wall deformities should be undertaken only in the most severe cases because of the possibility of complicating potential surgical field for later cardiac surgery. Milder chest-wall deformities often become less obvious with age because of the accumulation of subcutaneous fat. Tailored footwear is necessary for many individuals with foot deformities, but these will sometimes need surgical correction.

Ehlers–Danlos syndrome

This heterogeneous syndrome includes individuals with the common clinical features of abnormal velvety hyperelastic skin, easy bruising, hyperextensible joints, and lax ligaments (see also Chapter 170). The Villefranche nosology[7] lists seven types of Ehlers–Danlos syndrome (EDS) but many individuals do not accurately fit comfortably into any of these. Classic EDS is caused by mutations in type V collagen, vascular EDS by mutations in type III collagen, oculoscoliotic EDS by mutations in lysyl hydroxylase, which causes abnormal cross-linking of collagen trimers, and the arthrochalasia/dermatosparaxis forms of EDS result from abnormal processing of the N-terminal domain of type I collagen. Individuals with EDS are more susceptible to ligament rupture but the results of surgical repair are unpredictable. The vascular form of EDS (type 4) carries a particularly adverse prognosis; it is associated with catastrophic rupture of blood vessels and other hollow viscera (see further reading). Mortality and morbidity in pregnancy is particularly severe. The most commonly diagnosed form of EDS is type 3 (benign joint hypermobility syndrome) which is clinically and pathologically highly heterogeneous. It is sometimes, but by no means invariably, associated with widespread joint pains and should be carefully distinguished from the more severe variants (e.g. vascular and oculoscoliotic types) which carry an adverse prognosis. Genetic testing is only rarely required for EDS.

Alkaptonuria

In this rare condition (<1:150 000), enzyme deficiency causes accumulation of homogentisic acid in the tissues. The most important effects of this disease are on the spine and later on the larger joints. The intervertebral discs lose height and later calcify (Figure 150.12).

Fig. 150.12 The appearance of the thoracolumbar spine in a 40 year old woman with alkaptonuria. There is universal calcification of the intervertebral discs and gross loss of disc height throughout.

The spine becomes rigid and short and the lumbar lordosis is lost. In the large joints, such as the knees, shoulders, and hips, there are effusions and loose bodies. No effective medical treatment for the condition exists but monitoring of the heart valves is recommended as these may also be involved and become incompetent in later life.

Mucopolysaccharidoses

Failure of the normal lysosomal breakdown of complex carbohydrates or glycosaminoglycans leads to their accumulation in the tissues. Hurler's, Hunter's, and Morquio's syndromes are such examples. See also Chapter 170.

Hurler's syndrome (OMIM 607014)

This is the most severe type of mucopolysaccharidosis and causes death at an early age. The physical features include proportionate short stature, a typical facial appearance, a short neck with a lumbar gibbus and chest deformity, and a protuberant abdomen. Similar but less severe features are seen in Hunter's syndrome.

Morquio's syndrome (OMIM 253000)

In this disorder the orthopaedic manifestations are striking, but intelligence is normal. Characteristically the neck is short, the sternum is protuberant, and there may be a flexed stance with knock knees. Importantly, the odontoid may be hypoplastic, leading to atlantoaxial instability, compression of the long spinal tracts, and paraplegia.

Gaucher's disease

This is a rare lysosomal storage disorder in which glucocerebroside-containing macrophages accumulate in the bone marrow, spleen, liver, and other organs. The skeletal manifestations are often severe and disabling. They vary from a characteristic but clinically insignificant failure of remodelling in the lower femora (Erlenmeyer flask appearance) to diffuse and localized bone loss and osteosclerotic and osteonecrotic lesions, which cause pain and pathological fracture, often requiring precocious joint replacement surgery.

Fibrous dysplasia

Fibrous dysplasia of bone is a condition in which areas of immature fibrous tissue are found within the skeleton. Monostotic and polyostotic fibrous dysplasia are both caused by activating mutations in the *GNAS1* gene, encoding a component of the G-protein signalling system. However, these mutations are not in the germ-line (which would be lethal) but occur somatically in the developing embryo. The extent of involvement reflects the degree of mosaicism present in the affected individual.

Monostotic fibrous dysplasia

This disorder is relatively common in orthopaedic practice and reflects late postzygotic mosaicism. The lesions may occur in any bone and the most frequent presenting symptom at any age is a fracture, often of the upper end of the femur. There is a smooth-walled translucent area within the bone, often with thinning of the cortex and sometimes with associated deformity. The differential diagnosis is from other causes of bone cysts, including Paget's disease and hyperparathyroidism with osteitis fibrosa cystica. The large size of some of the defects in the shafts of the long bones may make conventional stabilization of fractures very difficult. Bisphosphonates may be effective in many cases where there is clear evidence of increased osteoclast activity.

Polyostotic fibrous dysplasia

The bone lesions tend to increase in size and number but less rapidly after growth has ceased. The skeletal lesions may cause complications such as spinal cord compression, and may be associated with hypophosphataemic osteomalacia. Radiologically, the bones are deformed, the cortex may be difficult to detect, and the medullary bone takes on a 'ground glass' or 'smoky' appearance (Figure 150.13). This variant of fibrous dysplasia is often associated with involvement of many additional tissues in the McCune–Albright syndrome. Classic features include skin pigmentation, precocious puberty, hyperthyroidism and, sometimes, pituitary gigantism. Of interest, diffuse idiopathic skeletal hyperostosis (DISH)-like new bone formation may also occur in disorders associated with inactivating mutations in *GNAS*, such asa pseudohypoparathyroidism (Figure 150.14).

Miscellaneous bone disorders

Vitamin C (ascorbic acid) deficiency (scurvy) is reflected in weakness of collagen-containing tissues, notably causing haemorrhage and fractures. Extensive subperiosteal haemorrhage leads to pain and immobility; the legs are held in a 'frog-like' position. Radiographs in infancy show a widened zone of provisional calcification in the metaphyses and failure of new bone formation.

Prolonged parenteral nutrition can produce a form of bone disease similar to osteomalacia. The main symptom is periarticular bone pain, particularly in the ankles. The radiographic appearances suggest osteoporosis.

Fig. 150.13 Polyostotic fibrous dysplasia affecting the pelvis in a 65 year old woman. The cystic lesions are particularly obvious in the right hemipelvis and proximal femur.

Fig. 150.14 DISH-like new bone formation bridging the lumbar vertebrae in a patient with pseudohypoparathyroidism.

Deposition of excess fluoride in the skeleton can result from an excess in the diet (endemic fluorosis), from industrial exposure (during the manufacture of aluminium, steel, and glass, and from exposure to the dust of fluoride-containing rock), and from the administration of sodium fluoride in treatment. There is a generalized increase in bone density (with loss of the normal corticomedullary junction), and the tendons, ligaments, and sometimes muscles may be mineralized. Compression of the spinal cord and its roots, with progressive neurological disability has been described.

The prolonged use of vitamin A (retinoids) for the treatment of skin disease, such as psoriasis and ichthyosis, leads particularly to calcification of the spinal ligaments, causing stiffness and reduced mobility. There is a resemblance to Forestier's disease (DISH).

Chronic vitamin D overdosage leads to soft tissue calcification, especially in the arteries and kidneys. After several years, progressive stiffness in the spine, major joints, and feet lead to difficulty in walking. Radiographs show ligamentous calcification. Lead poisoning in the growing skeleton produces a radiologically dense line near the growth plate.

Shoulder

Andrew J. K. Östör

Introduction

The shoulder is the most complex and enigmatic joint in the body and disorders in and around the joint are frequent. The prevalence of shoulder pain in the community approximates 30% and represents the second most common musculoskeletal complaint presenting to primary care after back pain.[1,2] Subacromial impingement syndrome is the commonest source of shoulder pain, with rotator cuff tendinopathy underlying this in the majority of cases.[3] The differential diagnosis of shoulder pain is vast, however, encompassing both intrinsic and extrinsic aetiologies, and thus an open mind must be maintained when assessing shoulder discomfort or dysfunction (Table 151.1).

The impact of shoulder pathology on the individual, including interference with work and leisure activities, is enormous, particularly in older people.[3,4] The resultant economic strain on society due to healthcare utilization and lost productivity is enormous.[5,6] Despite this the field is plagued by a poor understanding of the epidemiology, assessment, diagnosis, and management of shoulder conditions. This chapter deals with the more common disorders affecting the shoulder which are likely to be encountered in clinical practice.

Anatomy

The shoulder complex is a multiaxial spheroidal joint comprised of three articulations (glenohumeral, acromioclavicular (AC), sternoclavicular) and two virtual ones (subacromial, scapulothoracic) (Figures 151.1–151.3] The glenohumeral joint represents the 'true' shoulder joint and comprises the articulation between the glenoid of the scapula and the humeral head. In order to increase the surface area of the glenoid a cartilaginous cuff surrounds its margins, this having evolved to improve the stability of the joint. Mobility of the joint is maximized by an extensive synovial-lined joint capsule allowing up to 3 cm of separation of the bones. The majority of shoulder movement occurs at the glenohumeral joint, in particular the first 90° of abduction. The fibrocartilaginous AC joint, between the lateral end of the clavicle and the tip of the acromion, stabilizes the shoulder. The synovial sternoclavicular joint occurring between the superolateral facet of the sternum and the medial end of the clavicle allows increased mobility of the shoulder, particularly abduction.

The subacromial space lies between the superior aspect of the humeral head and the undersurface of the acromion. This virtual joint allows smooth movement of the joint, especially shoulder abduction. The subacromial bursa lies in this area to further facilitate mobility. The scapulothoracic 'joint' occurs between the posterior aspect of the thoracic wall and the undersurface of the scapula. This articulation allows abduction of the shoulder beyond 90°. A number of ligaments lend support to the shoulder including the glenohumeral, coracoacromial, coracohumeral, and transverse humeral ligaments.

The rotator cuff

The musculotendinous complex known as the rotator cuff is made up of the supraspinatus, infraspinatus, subscapularis, and teres minor muscles, and the honorary member, long head of biceps (Figure 151.4). The cuff is the predominant stabilizing structure of the joint as well as playing a role in shoulder movement (Table 151.2). The cuff also contributes up to 50% of the power of the shoulder in abduction and 80% in external rotation.

The supraspinatus muscle originates from the supraspinatus fossa of the scapula and inserts into the greater tuberosity of the humerus. Its main responsibility is to initiate shoulder abduction. The infraspinatus muscle arises from the posterior aspect of the scapula inferior to its spine and inserts into the posterosuperior aspect of the greater tuberosity of the humerus. Its chief action is to externally rotate the shoulder. The teres minor muscle arises from the axillary border of the scapula and inserts into the posterinferior aspect of the greater tuberosity of the humerus. This muscle aids the infraspinatus as a shoulder external rotator. The subscapularis originates from the subscapular fossa and inserts into the lesser tuberosity of the humerus lateral to the glenoid labrum. Subscapularis is separated from the rest of the cuff by the bicipital groove. Its predominant action is to internally rotate the adducted arm. The long head of biceps arises from the superior aspect of the glenoid labrum (the short head arising from the coracoid process) and inserts into the radial tuberosity. It may be considered part of the rotator cuff due to its position and role in shoulder stability. The action of the long head of biceps is to flex the elbow and to supinate the forearm.

A number of bursae are present around the shoulder. The most important of these is the subacromial bursa lying between the joint capsule and deltoid muscle laterally and inferior to the acromion and coracoacromial ligament medially. This bursa allows smooth

movement of the rotator cuff in the subacromial space. Other muscles involved with shoulder movement include the deltoid (flexion, abduction, and extension), pectoralis major (adductor and internal rotator), latissimus dorsi (adductor, internal rotator, and extensor) (Figure 151.4).

Disorders of the shoulder joint

The differential diagnosis of shoulder pain is extensive (Table 151.1). The primary question is whether the pathology is intrinsic to the shoulder itself or due to a cause outside the shoulder. A thorough history and examination is required to help define the abnormality followed by judicious use of imaging. The most commonly encountered intrinsic shoulder disorders are further discussed.

Subacromial impingement syndrome

Although it is strictly not a specific entity, the concept of subacromial impingement syndrome has emerged over the last decade as a system to help classify shoulder disease.[7,8] Subacromial impingement is said to occur when anatomical structures, most commonly the supraspinatus tendon and subacromial bursa, are trapped between the inferior surface of the acromion, AC joint, and coracoacromial ligament, and the superior aspect of the humeral head. Predisposing factors for impingement include a down-sloping or hook-like acromion, AC osteophytes, subacromial spur, muscle imbalance secondary to cuff weakness, joint instability, and manual work carried out overhead.

Fig. 151.4 Muscles of the shoulder girdle and rotator cuff.

Table 151.2 Main actions of the rotator cuff (other than shoulder stabilization)

Muscle	Action
Supraspinatus	Initiation of abduction (first 10°); active throughout range of movement
Infraspinatus	External rotation
Subscapularis	Internal rotation
Teres minor	External rotation (acting with infraspinatus)
Biceps (not strictly rotator cuff muscle but involved with it)	Elbow flexion; forearm supination

Clinical

Impingement is the most common clinical syndrome presenting with shoulder pain.[7] It may occur at any age but is usually found in those over 40 years of age. The onset may be acute or chronic, and pain is felt in the shoulder region and upper arm. Night pain may be prominent, especially following lying on the affected shoulder. Both active and passive movements may be limited and a painful arc is common. A number of tests have been developed to detect subacromial impingement (Table 151.3, Figure 151.5). Persistent impingement may lead to chronic subacromial bursitis and tendinopathy of the rotator cuff.

Imaging

Plain radiographs may show degenerative change of the AC joint, irregularity of the undersurface of the acromion, humeral greater tuberosity degenerative change, and elongation of the anterior process of the acromion. Ultrasound may be normal but frequently reveals degenerative change in the cuff tendons with or without subacromial bursitis. MRI mirrors the plain film findings, often showing a degenerative AC joint indenting the superior surface of

Table 151.3 Impingement tests

Neer's test	Passive forward flexion of arm fixing scapula	Pain develops during this action which is relieved following a subacromial injection of local anaesthetic
Hawkins-Kennedy test	Arm abducted to 90° with 30° flexion. Arm is then passively internally rotated	Pain develops during internal rotation of arm
Painful arc	Arm abducted through full range of movement	Classic painful arc occurs between 60–120° of abduction
Empty can test	(see table 3)	
Fig. 151.5 Tests for subacromial impingement.

Fig. 151.6 Partial thickness tear of the supraspinatus tendon, on a background of severe tendonosis0020 (PT)?.

the supraspinatus tendon. Other features may include an os acromiale, an impingement cyst in the humeral head, rotator cuff tendinopathy and subacromial bursitis.

Management

The majority of patients settle with time following conservative treatment consisting of simple analgesia and non-steroidal anti-inflammatory drugs (NSAIDs), lifestyle modification, physiotherapy, and subacromial corticosteroid injections. The evidence for all of these modalities is limited, however. In a pragmatic randomized controlled trial (RCT) in the treatment of patients with subacromial impingement syndrome, injection plus exercise and exercise only were similarly effective at 12 weeks.[8] In a further study over the short term (3 months), a specific exercise strategy improved outcomes and reduced the subsequent need for surgery.[9] In a meta-analysis therapeutic exercise appeared to be effective for the treatment of painful shoulder conditions.[10] For patients who fail the above, surgical subacromial decompression is an option.

Rotator cuff disease

Although impingement is the most common clinical syndrome presenting with shoulder pain, the most common pathology underlying this is damage to the rotator cuff. The prevalence has been estimated to be 4.5% among men and 6.1% of women of working age; however, these figures vary as a consequence of difficulties with case definition estimates.[3,4,11] The socio-economic impact is substantial, with both direct and indirect costs including

those related to reduced productivity. The precise aetiology of rotator cuff disease has not been determined, but genetic factors, age-related degeneration with reduced blood supply, and inflammation appear to be intimately involved.[12] Not all rotator cuff damage is symptomatic, however, with studies showing full-thickness tears in up to 80% of individuals over 80 years of age without shoulder complaints.[13]

The rotator cuff may be affected by a number of defined lesions. Tendinosis refers to tendon degeneration; partial thickness tears (bursal and/or humeral aspects) refers to tendons which are frayed or torn but overall remain intact (Figure 151.6), full-thickness lesions refer to tears which have passed completely through the tendon substance although some fibres may remain intact (Figure 151.7). Complete tears describe total disruption of the tendon with resultant tendon retraction, and cuff rupture implies large complete tears. The tendon of supraspinatus is the most commonly affected, but combined lesions are common.[3]

Clinical features

Rotator cuff tears usually occur in individuals over 40 years of age and may either have an insidious onset or occur suddenly especially following trauma. Pain is often aching in nature, felt diffusely in

(a)

Painful arc
(active)
Action:	Patient standing. Slow arm abduction (scapular plane).
Positive test:	Pain onset (maximal) at (variable) angular range

(b)

Neer test
(passive)

Action:	Patient sitting/standing. Passive forward flexion. Scapula fixed.
Positive test:	Pain at (variable) angle of flexion.

(c)

Empty can
(active)
Action:	Patient sitting/standing. Active forward flexion to 90° then internal rotation—'can empties'.
Positive test:	Pain with flexion or rotation of arm.

(d)

Kennedy–Hawkins

FIX

Action:	Patient sitting/standing. Passive forward flexion (90°). Fix elbow with hand. Passive internal rotation.
Positive test:	Pain at some stage of elevation or rotation.

Fig. 151.7 Ultrasound showing a supraspinatus full-thickness tear.

the shoulder region, with radiation into the upper arm. Night pain is common and sleep is affected when lying on the affected side. Performing activities above the head and behind the back are problematic. Work involving repetitive movements or lifting heavy loads may lead to the slow development of a tear and may exacerbate the symptoms. Muscle wasting around the shoulder can occur, especially the supraspinatus, and winging of the scapula may be present. A painful arc is frequently present (classically between 60–120° of abduction) as are signs of impingement (Tables 151.3 and 151.4, Figure 151.5). If weakness of the muscles develops, active shoulder movement is reduced but passive mobility is preserved. Complete tears and rupture will lead to total loss of movement, however. A number of tests have been developed to assess the rotator cuff more precisely, including eliciting impingement, although the true validity of all of these is unclear (Tables 151.3 and 151.4, Figure 151.5). Some experts suggest that weakness out of proportion to pain when assessing the rotator cuff implies tendon tear. Impingement testing relies on the ability to force the subacromial structures (e.g. bursa

and rotator cuff) between the inferior surface of the acromion and the humeral head.[14]

Imaging

Further investigation is not required in most cases of uncomplicated shoulder pain, but in persistent or severe cases radiological assessment is necessary. Plain radiographs may show degenerative change in the AC joint and impingement changes in the greater tuberosity with a narrowing of the subacromial space. Both ultrasound and MRI are extremely useful modalities for assessing the rotator cuff, with similar sensitivities and specificities.[15] Ultrasound has the advantage of being dynamic but the disadvantage of being operator dependent. MRI allows assessment of the entire shoulder complex, although cost and access are limiting factors.

Management

In the acute phase pain relief is necessary using simple analgesics and NSAIDs; ice, acupuncture, and laser therapy may be helpful.

Table 151.4 Special tests for rotator cuff tendinopathy

Supraspinatus	'Empty can' test	Arm abducted to 90° with 30° of flexion then internally rotated until thumbs facing ground. Pressure then applied from above by examiner (resisted abduction)
		Pain develops during the 'emptying of the can' (internal rotation). Weakness/pain upon downward pressure on arm (resisted abduction)
Infraspinatus and teres minor	External rotation of arm in neutral position, elbow flexed to 90°	Pain/weakness on resisted external rotation
Subscapularis	Lift-off test. Alternative is 'Napoleon' position with palm of hand placed against abdomen	Hand is placed behind back, palm facing outwards. Patient then lifts off hand away from back
		Alternative method is to then push hand into abdomen
		Pain/weakness upon resisted internal rotation
Biceps brachii	Speed's test	Resisted flexion of the shoulder with the arm in extension
	Yergeson's test	Resisted supination of the arm with the elbow at 90° of flexion

These modalities are utilized essentially to maintain passive joint movement to prevent secondary capsulitis. In latter stages physiotherapists may use a variety of modalities to improve the symptoms, including stretching and cuff-strengthening exercises, as well as muscle balance and re-education programmes especially for those patients with instability.[16] Education regarding avoidance of exacerbating activities is paramount.

The evidence regarding any treatment modality for shoulder pathology is limited: a systematic review of RCTs of physiotherapy for patients with soft tissue disorders concluded that ultrasound therapy was not effective and that the benefit of other interventions (low-level laser therapy, transcutaneous electrical stimulation, pulsed electromagnetic fields, cold therapy, thermotherapy, exercises, mobilizations, and manipulations) was inconclusive.[17] A randomized trial of the effectiveness of corticosteroid injections in comparison with physiotherapy for the treatment of painful stiff shoulder concluded that injections were superior to physiotherapy in the short term.[18] Although corticosteroid injections into the subacromial space are used extensively, the evidence for any long-term benefit is minimal. A Cochrane review concluded that the evidence from RCTs supports the administration of subacromial corticosteroid injections for rotator cuff disease although the effect may be small, short-lived, and no more effective than NSAIDS.[19] Injections should not be given in the acute setting and are generally undertaken if analgesia and physiotherapy fail.

Surgical intervention is appropriate for active patients who suffer from a full-thickness tear or rupture and for those where the above modalities have failed. This may be undertaken in an open fashion or increasingly via the arthroscopic route.[20] Surgery may involve subacromial decompression with or without repair of a torn tendon.

Prognosis

Although it was previously thought to have a favourable prognosis, reports vary as to the long-term outcome in patients with disorders of the rotator cuff. Studies in primary care have shown persist shoulder pain beyond 18 months in more than one-half of patients.[21,22] In another study, after 13 years' follow-up of patients with a rotator cuff tear diagnosed by MRI or arthrography, 90% of patients had no or only slight pain and 70% had no disturbance in activities of daily living.[23]

Biceps tendon lesions

Disorders of the biceps tendon include tendonitis/tenosynovitis, tendinosis, partial tear, full-thickness tear, complete rupture, and instability in the bicipital groove (subluxation or dislocation). Any of these lesions may occur in isolation or associated with damage to the rest of the cuff. Tenosynovitis of the long head of biceps is uncommon and predominantly occurs as a consequence of local friction over bone in the biciptal groove.

Clinical features

Pathology of the biceps tendon may occur at any age although rupture is uncommon in those under 40 years of age. Pain in the anterior shoulder may develop acutely or chronically, but tendon rupture may be painless. A history of trauma to the shoulder may be present. Tenderness is common over the tendon in the bicipital groove and weakness may occur following a tear. The 'Popeye' sign (prominent belly of biceps in the lower third of the arm) is characteristic following rupture of the long head of the biceps. A snapping sound may occur with subluxation and dislocation of the tendon.

Imaging

Ultrasound and MRI are the optimal modalities to evaluate the spectrum of biceps tendon disorders if required.

Management

The mainstay of treatment is analgesia and physiotherapy. Despite the deformity associated with tendon rupture functional limitation is usually minimal and thus patients should be reassured. Corticosteroid injections are not recommended for lesions of the biceps, including tenosynovitis, because of the potential for iatrogenic tendon rupture.

Rotator cuff calcification (calcific tendonitis)

Calcific tendonitis occurs following calcium hydroxyapatite deposition in the rotator cuff (most commonly the tendon of supraspinatus). The aetiology is unclear, although it has been suggested that injury leads to tendon calcification which is followed by variable degrees of resorption of the deposit. Inflammation associated with the resorptive phase (where calcium deposits are extravasated into the subacromial bursa) may be responsible for the severe pain

which characterizes the condition.[24] Asymptomatic calcification within the cuff is not an infrequent finding and thus the association between this and the clinical presentation remains unclear.

Clinical features

Calcific tendonitis affects up to 10% of the population usually between 30 and 60 years of age. It often presents with rapid-onset severe, diffuse shoulder pain in the absence of trauma. The discomfort is constant and night pain is prominent. Systemic symptoms such as fever and anorexia may be present. The shoulder is often tender, and mobility (particularly abduction) is greatly reduced secondary to the pain. Wasting of the supraspinatus may be seen in chronic cases. The arm is usually held in internal rotation and a painful arc is frequent. Signs of impingement are invariable.

Imaging

Plain radiography is the best technique for demonstrating calcific tendonitis as calcium deposition is easily seen. This may be in discrete deposits, or fluffy in appearance, depending upon the stage of disease (Figure 151.8). It is worth noting that calcium deposition may be absent in the early phase. Ultrasound can also detect calcific deposits, but MRI does not as it is reliant on the presence of protons.

Management

The most important aspect of management is adequate pain relief starting with simple analgesics (paracetamol ± codeine) and NSAIDs. Gentle physiotherapy to maintain range of movement is important but is frequently limited by pain. Subacromial injections of corticosteroids and local anaesthetic have been used with variable success. Arthroscopy or ultrasound-guided needling of the calcium deposits has been advocated in severe cases.[25]

Fig. 151.8 Frontal plain film displaying calcium in the subacromial subdeltoid bursa. This has arisen from calcific tendonitis of the supraspinatus tendon which has burst into the bursa.

Adhesive capsulitis (frozen shoulder)

Adhesive capsulitis is one of the most perplexing conditions facing clinicians. It represents a common cause of shoulder pain and disability affecting up to 3% of the population predominantly in the 6th decade.[26] The incidence in diabetics is higher, having been estimated to be up to 38%.[26] The aetiology of adhesive capsulitis is unknown, although chronic inflammatory cell infiltration of the subsynovial capsule with fibrosis, and focal degeneration of collagen, has been described. As a consequence the capsule becomes thickened and contracted, leading to profound loss of movement. A number of conditions are associated with adhesive capsulitis (Box 151.1).

Three overlapping phases have been described for adhesive capsulitis:

- **freezing** phase where the shoulder becomes painful and mobility reduces (10–36 weeks)
- **frozen (adhesive)** phase where the shoulder is immobile and pain subsides (4–12 months)
- **thawing (resolution)** phase where pain resolves and movement returns (12–42 months).

United Kingdom consensus criteria have defined the condition as: symptoms of unilateral pain in the deltoid area with equal restriction of active and passive glenohumeral movement in a capsular pattern (external rotation > abduction > internal rotation).[27]

Clinical features

The onset may be acute, subacute, or chronic and a history of trauma is often described. Pain is felt deep in the shoulder, is poorly localized, and night pain may be severe. Bilateral disease either synchronously or metachronously occurs in up to 17% within 5 years. Following prolonged immobility, wasting of the shoulder muscles ensues. The cardinal feature of adhesive capsulitis is a globally reduced range of movement of the shoulder, especially external rotation and abduction. Assessment of other shoulder structures is generally not possible because of the pain and immobility. The diagnosis should be made on clinical grounds following exclusion of other causes of a painful, 'stiff' shoulder (e.g. glenohumeral osteoarthritis, inflammatory arthritis, crystal disease).

Box 151.1 Conditions associated with adhesive capsulitis

- Rotator cuff tendinopathy
- Diabetes mellitus (types 1 and 2)
- Thyroid disease (hyper- and hypothyroidism)
- Immobility (e.g. post stroke)
- Post myocardial infarction
- Chronic regional pain syndrome type 1
- Thoracotomy
- Dupytren's disease
- Shoulder surgery
- Parkinson's disease
- Pulmonary disease

Imaging

Plain radiographs, ultrasound, and MRI are usually normal. Arthrography is the only radiological way to diagnose adhesive capsulitis. Injection of contrast medium into the shoulder may lead to the following features: less than 5 mL can be injected, irregularity of the capsular attachment to the anatomical neck of the humerus, obliteration of the subscapular and axillary recesses, lymphatic filling, syringe refills once pressure is removed from the plunger, the injection is painful.

Management

The main therapeutic focus of adhesive capsulitis is adequate pain relief (simple analgesics and NSAIDs) in order to maintain and improve shoulder mobility. Physiotherapy is critical to this process and should be introduced early.[28] Oral and intra-articular steroids as well as arthroscopy (including manipulation under anaesthesia) have been advocated; however, the evidence for these is sparse and iatrogenic damage to shoulder structures may occur following surgery.[29,30] Hydrodilatation has been suggested as a useful treatment modality.[31] It is worth noting that no therapeutic intervention has been consistently successful for the condition and therefore an elixir of time coupled with adequate patient education regarding the prolonged course of the condition is the mainstay of management.

Prognosis

The natural history of adhesive capsulitis is of slow resolution which may take 3–4 years. Residual restriction of movement occurs in up to 15% of patients. Diabetics often have a more severe and prolonged course.[26]

Acute dislocation

Acute shoulder dislocation is a frequent presentation to the Emergency Department and usually follows forced abduction, external rotation, and extension of the shoulder. In 98% of cases the dislocation occurs anteriorly and recurrence is common (up to 80%). Posterior dislocation is rare and usually follows trauma, an epileptic seizure, or electrocution.

Clinical features

Shoulder dislocation is a disorder of teenagers and young adults. It is most frequent in females and those with hypermobility or ligamentous laxity. The patient presents with sudden-onset excruciating pain in the shoulder region with anterior bulging of the shoulder (rarely posteriorly). A 'square-shoulder' appearance, with prominence of the acromion, may be present with anterior dislocations. The arm is usually held in slight abduction and external rotation and movement is limited because of pain and anatomical derangement. Middle-aged patients may suffer from an associated rotator cuff tear. Dislocation can lead to humeral head damage, posing an increased risk for further instability and arthritis.

Imaging

Plain radiographs confirm the diagnosis as the head of the humerus is no longer located in the glenoid fossa (Figure 151.9). Two orthogonal views are required if the dislocation is subtle or subluxation has occurred.
Fig. 151.9 Acute anterior dislocation of the right shoulder.

Management

Reduction of the dislocation should occur as soon as possible. Adequate analgesia is required and occasionally a general anaesthetic is necessary. Surgery is reserved for those with recurrent dislocations (to tighten the joint capsule) and for those with associated lesions (see below).[32]

Prognosis

Following dislocation the anteroinferior aspect of the joint capsule and the labrum may be torn off the glenoid, occasionally with a bony fragment (Bankart lesion). This may be accompanied by a compression fracture of the posterior surface of the humeral head (Hills–Sachs lesion) following impaction against the anterior glenoid rim. Recurrence of shoulder dislocation is common, occurring in up to 80%.

Shoulder instability

As the shoulder is the most mobile joint in the body, instability is not uncommon. Instability is defined as an inability to maintain the humeral head within the glenoid fossa and may be classified by the direction of the abnormal movement (anterior, posterior, multidirectional), as well as by its severity and causality.

Clinical features

In general anterior instability first presents in patients under 30 years of age. Pain is intermittent and may develop following specific movements such as throwing. Clicking is a subtle sign, but clunks are a feature of major instability. In a young athlete the development of rotator cuff tendinosis may point to underlying shoulder instability. A pathognomonic sign of shoulder instability/subluxation is 'dead arm syndrome' with transient numbness, tingling, pain, and weakness of the arm or hand followed by a dull

ache occurring following certain activities. Often there is a history of throwing sports, swimming, gymnastics, or ballet. Full active and passive movement is retained and features of hypermobility may be present (see also Chapter 159). The humeral head may be rocked forward and backwards in the glenoid fossa when the patient is relaxed, the 'draw sign' (best appreciated in the supine position). Signs of impingement may also be present. The 'apprehension' test is specific for anterior instability. With the patient in the supine position, pain and anxiety may occur following abduction and external rotation of the arm ('javelin' position). Anterior pressure applied to the humeral head often relieves the discomfort, only to recur when the stabilizing force is removed.

Clinically posterior instability may be identified by noting a concavity below the acromion, anterior deltoid flattening, and a palpable humeral head posteriorly. The arm is usually held in adduction and internal rotation with reduced active and passive external rotation. Applying a downward pressure to the flexed, adducted, and internally rotated arm leads to pain or a feeling of joint dislocation in patients with posterior instability. Posterior instability may be a feature of congenital laxity.

Multidirectional instability is a feature of general laxity of the ligaments or hypermobility syndrome. Dislocation following minimal trauma may point to this predisposition. As with anterior instability, a painful arc may be present. Traction applied to the arm will lead to the shoulder subluxing inferiorly (sulcus sign) and the draw sign may be present. Individuals with multidirectional instability should be assessed for conditions such as Ehlers–Danlos syndrome, osteogenesis imperfect, and Marfan's syndrome.

Imaging

This is usually normal in uncomplicated instability, but plain radiography will show an abnormally placed humeral head if instability has led to dislocation. MR arthrography has 80–90% sensitivity and specificity for labral pathology.

Management

Physiotherapy to improve the strength of the rotator cuff muscles is imperative. Education regarding avoidance of activities leading to pain is mandatory, although difficult in those who pursue sport at a high level. Surgery is reserved for those with disabling symptoms or recurrent dislocations.[33]

Prognosis

The prognosis is good with appropriate management and education. Repeated paroxysms of instability may lead to rotator cuff tendinopathy and signs of impingement. A reverse Hills–Sacks lesion (fracture of the glenoid rim and proximal humerus) may occur following posterior dislocation. A superior labrum in the anterior-posterior (SLAP) lesion may occur in patients with underlying instability of the shoulder (Figure 151.10). Surgery is advocated for labral tears.

Shoulder arthritis

The shoulder is frequently involved in arthritic conditions which may affect the glenohumeral, AC, and/or sternoclavicular joints.
Fig. 151.10 Coronal oblique MR arthrogram showing tear and disruption of the anterior labrum anterosuperiorly (T).

Glenohumeral joint

Up to 90% of patients with rheumatoid arthritis (RA) have involvement of the glenohumeral joint and it is also a common site for gout and pseudogout. Degenerative disease occurs rarely here but may develop secondary to inflammatory arthritides, avascular necrosis or after trauma.

Clinical features

Chronic, deep-seated pain affecting the whole shoulder in patients over 40 years of age characterizes shoulder arthritis. Degenerative disease is aggravated by activity and improved with rest, the opposite being true of inflammatory arthritis. Sleep is often disturbed and early-morning stiffness may be a feature (<30 minutes with degenerative disease, >30 minutes with inflammatory disease). Swelling is a feature of inflammatory and crystal arthritis and crepitus is a sign of bony surfaces grating. Both active and passive movement is significantly limited, especially external rotation and abduction. True glenohumeral movement only occurs up to 90° of abduction (further abduction allowed by the scapulothoracic articulation). Careful assessment is required as patients may 'cheat' and hunch the shoulder giving the impression of glenohumeral movement. If inflammatory arthritis is considered, a full musculoskeletal review of the patient is required.

Imaging

Radiographs may show narrowing of the joint space, irregularity of the joint surfaces, osteophytes, and soft tissue swelling (Figure 151.11). For inflammatory arthritis ultrasound and MRI allow further characterization of the pathology.

Management and prognosis

The treatment and prognosis of degenerative, inflammatory, and crystalline disorders are dealt with in other sections of the book. In
Fig. 151.11 Osteoarthritis of the glenohumeral joint.

Fig. 151.12 Total dislocation of the right acromioclavicular joint.

Fig. 151.13 Moderately severe degenerative change of the acromioclavicular joint (*).

principle analgesia is mandatory and corticosteroid injections may be useful in selected patients. Severe glenohumeral disease often requires hemiarthoplasty or total shoulder replacement. As up to 35% of patients who require arthroplasty have rotator cuff tear, these should be repaired simultaneously.

Acromioclavicular joint trauma

Trauma to the AC joint is common particularly among athletes undertaking contact sports. This may lead to sprain/strain, subluxation, or dislocation of the joint.

Clinical features

The onset of pain is acute following trauma and may occur at any age. Discomfort is worse with movement and activities such as carrying heavy loads and overhead work. The pain is well localized to the shoulder tip, and symptoms at night are common. Weakness is not a feature although shoulder instability may develop. Deformity of the AC joint implies subluxation or dislocation. A high arc of pain may be evident and full active and passive movement is often limited by discomfort.

Imaging

Plain radiographs will delineate AC joint subluxation or dislocation (Figure 151.12). The degree of damage can then be staged.[34]

Management

AC joint subluxation may be managed conservatively. Dislocation generally requires surgical intervention which should be undertaken early.

Acromioclavicular joint arthritis

This joint is commonly affected by osteoarthritic change, especially in older people.

Clinical features as for AC joint trauma. Features of rotator cuff tendinopathy may develop secondary to AC joint degenerative disease. Plain films display degenerative disease of the bones with osteophyte development. MRI may also demonstrate associated rotator cuff damage (Figure 151.13).

Sternoclavicular joint

Degenerative disease occurs rarely in this area. Inflammatory disease occurs more commonly in this joint including RA, spondyloarthropathies, and SAPHO (synovitis, acne, pustulosis, hyperostosis, osteitis). The mainstay of therapy for osteoarthritis of the sternoclavicular joint is analgesia, education, and physiotherapy. Intraarticular corticosteroid injections may help but the effect is usually short lived. Surgery is rarely required.

CHAPTER 152

Elbow

Karen Walker-Bone

Introduction

Elbow pain affects around 12% of adults at any point in time[1,2] and occurs at similar rates in both genders.[3] It may occur as part of a multisystem inflammatory arthropathy such as rheumatoid arthritis (RA) or gout or may be caused by degenerative changes, but it is uncommon for elbow symptoms to be the presenting feature in these conditions. The most common causes of elbow symptoms are soft tissue periarticular conditions such as epicondylitis, olecranon bursitis, and ulnar neuropathy.

Structure and function of the elbow joint

The elbow is a compound synovial joint involving articulation of the greater head of the distal humerus with the ulna, producing flexion/extension. Forearm pronation/supination results from two articulations: one between the lesser head of the humerus and the depression on the radial head and the other between the circumference of the radial head and the proximal ulna. All articular surfaces are covered with cartilage and combine in one capsule and joint cavity. Flexion/extension is stabilized by medial and lateral collateral ligaments. Additional stabilization of the proximal radioulnar joint is ensured by the annular ligament, a complex structure formed of joint capsule fibres and part of the lateral ligament complex and surrounding the radial head.[4]

The healthy elbow is capable of 150° of flexion/extension. In early and late flexion, the shape of the articulation between the distal humerus and the proximal ulna is oblique causing rotation and a valgus angle at full extension and supination (the carrying angle), which is typically greater among women (20–25°) than men (10–15°). Varus deformity of the elbow may result from any elbow joint pathology or from trauma (Figure 152.1). The healthy elbow can extend completely (0°), although healthy young women may achieve additional extension (5°) and patients with hypermobility syndrome or other ligamentous conditions frequently hyperextend further. Rotation of the forearm (typically around 160°) is achieved through pronation/supination at the proximal and distal radioulnar joints accompanied by a twisting movement between the shafts of both bones.

Fig. 152.1 Cubitus varus left elbow caused by trauma.

Differential diagnosis of elbow pain

In any patient with elbow pain, the clinician should consider if the symptom is a manifestation of a more generalized problem such as: a polyarthropathy (degenerative or inflammatory); referred pain from the cervical spine, peripheral nerves, nerve roots, brachial plexus, the shoulder or the wrist; a chronic widespread pain syndrome such as fibromyalgia; or another disease, e.g. metastasis from a primary malignancy.

History

The nature of onset of elbow symptoms is useful diagnostically (Table 152.1). Was there a preceding injury? Exactly what took place, and what were the immediate effects and subsequent progression? Enquire specifically about head/neck and shoulder injuries as well as elbow injury. Pain is the most common symptom: enquire about nature, site (articular, periarticular, regional), radiation (proximal and distal), variation over time, progression, exacerbating and relieving factors, therapies tried and response to those therapies. Has the patient ever had similar symptoms at the elbow or other sites? Enquire specifically about pain in the neck/shoulder and forearm, wrist/hand. Associated symptoms may include stiffness, swelling, heat, redness, dysaesthesiae, muscle weakness, crepitus, or locking. If the patient reports stiffness, enquire about distribution and effects on movements as well as timing and duration. Enquire specifically about functional impairment at home and in the workplace. In taking an occupational history, ask precisely what type and frequency of physical exposures are involved: for example, bending/straightening the elbow; lifting heavy weights; forceful and/or repetitive movements. It is important to establish the arrangements for rotation of tasks and the demands on the patient, e.g. if the patient is paid piecemeal based upon number of tasks completed. Establish which is the dominant arm and which exposures affect only the dominant side and which are bilateral.

Examination

The examiner should keep an open mind during the examination of a patient with elbow symptoms (Table 152.1). To do this, neck and both arms should be fully exposed. The examiner should also consider examining all other joints and a full clinical examination if there is any possibility of multisystem disease. Arms should be compared for wasting, scarring, or asymmetry, bearing in mind, however, that the dominant side may have better-developed musculature. Inspection should focus on the neck, thoracic spine, shoulders, and both hands/wrists as well as the elbows. Inspection of the elbow should include the antecubital fossa, posterior elbow and olecranon bursa and the distal insertion of the triceps, both epicondyles, and the proximal and distal musculature. The joint is continuous, so any inflammatory joint condition will affect all three joints, but swelling is usually best observed posteriorly and/or laterally where it may obliterate the paraolecranon grooves. With an acutely inflamed joint, the patient will often 'guard' the join in flexion but full flexion/extension may be restricted, as may pronation/supination. The bony landmarks should be palpated including the joint line medially and laterally over the distal humerus and the lateral and medial epicondyles. Active and passive range of motion of flexion–extension and pronation and supination should be evaluated and in suspected tendinitis, movement should be examined against resistance. Neurovascular function should also be assessed, including for

Table 152.1 Classification of elbow disorders

Articular	**Arthritis of the elbow joint and proximal** radioulnar joints
	Rheumatoid arthritis
	Psoriatic arthritis
	Gout
	Septic arthritis
	Osteoarthritis
	Traumatic
	Trauma to the joint capsule or ligaments
Periarticular	Lateral epicondylitis (tennis elbow)
	Medial epicondylitis (golfer's elbow)
	Tendinitis affecting the distal insertion of biceps brachii, triceps, or brachialis
Olecranon bursitis	Trauma or friction
	Inflammatory
	Septic
	Olecranon impingement syndrome
Bone disorder	Fracture
	Neoplasm (primary or secondary)
	Osteomyelitis
	Osteochondritis dissecans
Neurological	Cubital tunnel syndrome (ulnar nerve)
	Pronator teres syndrome (median nerve)
	Radial tunnel syndrome (posterior interosseous nerve)
	Spiral groove syndrome (radial nerve)
	Thoracic outlet syndrome (brachial plexus compression)
	Radiculopathy from cervical spine
	Syringomyelia
	Spinal cord tumours
Chronic widespread pain syndrome	Fibromyalgia syndrome
Regional pain syndrome	Complex regional pain syndrome type II (reflex sympathetic dystrophy)
	Somatoform pain syndrome
Vascular	Upper limb claudication
	Systemic vasculitis, e.g. Takayasu's arteritis
	Compartment syndrome

example Tinel's test for cubital tunnel syndrome (performed over the ulnar nerve in the ulnar groove) where appropriate. Comparison of the symmetry of upper limb pulse rate, volume, and character at each of the brachial and radial arteries may be indicated and blood pressure in both upper limbs may need to be compared.

Investigation and imaging of the elbow

Depending upon the working diagnosis, radiography, ultrasonography, diagnostic joint or bursa aspiration with microscopy, culture and sensitivities of the aspirate as well as polarizing light microscopy, CT scan, MRI scan, electromyography (EMG), and nerve conduction studies may be helpful diagnostically.

Elbow symptoms as the presenting feature of inflammatory polyarthritis

Gout, RA, reactive arthritis, psoriatic arthritis, and other types of inflammatory polyarthritis may all involve the elbow joint. It would be uncommon for patients with most of these conditions to present for the first time with symptoms confined to the elbow. Usually, therefore, a history of pain, swelling, and early-morning stiffness affecting other joints can be expected and the pattern and distribution of this will be helpful in diagnosis. Elbow involvement may occur in acute gout, often causing pain and inflammation in the olecranon bursa from where crystals may be aspirated. Most patients with gout (>80%) will have experienced at least one episode of podagra within the first 12 months of their gout, and enquiry should be made specifically about this.

Lateral epicondylitis (tennis elbow)

Lateral epicondylitis, thought to be synonymous with Morris's 1882 description of 'lawn tennis arm',[5] is associated with characteristic pain and sensitivity in the lateral elbow region, at or near the origin of the extensor carpi radialis brevis.

Epidemiology

The annual incidence of lateral epicondylitis was estimated in Sweden as 0.5–1%,[6] and one primary care survey in the United Kingdom found 0.4% of patients presented with a new episode annually.[7] Rates of point prevalence between 0.7–2.5% have been reported.[8,9] Higher rates of occurrence have been suggested among workers performing strenuous manual tasks, e.g. packers and sausage makers.[10] Despite its idiom, the epidemiology of epicondylitis among racket players has been poorly studied. Gruchow[11] reported an incidence rate of 9% among tennis players over a 2 month period but relied on self-reported symptoms rather than objective physical examination for diagnostic criteria. Rates of occurrence seemed

to be higher among men than women and rates peaked in the 45–54 year age group.[9]

Lateral epicondylitis is associated with the use of heavy tools and forceful, repetitive work, particularly when the wrist is in the nonneutral position, e.g. using power tools, saws, or jackhammers.[12] Repeated pronation and supination of the forearm, which may be an integral part of some jobs, aggravates the condition, but whether symptoms can arise ab initio from this action is more contentious. Even allowing for a clustering of the condition in families and a tendency for individuals to have more than one soft tissue lesion at other sites, not necessarily all simultaneously, the balance of probability is that this lesion can be induced in the workplace, particularly if the ergonomic insult corresponds with the use of the forearm muscles. In addition to physical factors, psychosocial risk factors can increase the occurrence of elbow disorders.[13]

Classification and diagnostic criteria

In their multidisciplinary Delphi investigation, Harrington and colleagues reached a consensus case definition of: pain and tenderness over the lateral epicondyle associated with exacerbation of lateral elbow pain on resisted wrist extension (Figure 152.2).[14] These diagnostic criteria have been used in a number of epidemiological studies,[15,16] although some investigators also use 'pain or weakness on gripping'. There is currently no gold standard for investigation of lateral epicondylitis. Radiographs may show evidence of a periostitis, but this is far from a consistent finding and radiographs would rarely be indicated. MRI or ultrasound may have a future role in the diagnosis of this disorder, but both techniques are currently only used as research tools. One clinical study suggested that thermography may have a role in detecting epicondylitis patients from controls.[17]

Aetiopathogenesis

Over 25 mechanisms of lateral epicondylitis have been proposed, but it is unclear how many of these are causes of non-specific lateral elbow pain, rather than 'true' epicondylitis. Few cases come
Fig. 152.2 Provocation test for lateral epicondylitis.

to surgery so that pathological material is rare and really only available in severe and chronic cases, but a number of pathological abnormalities have been described, including periostitis, infection, bursitis, radiohumeral joint disease, fibrillation of the radial head, proximal radioulnar joint disease, radial nerve entrapment, and annular ligament lesions. Despite this, the current consensus is that lateral epicondylitis is probably a tendinopathy of the common extensor-supinator tendon rather than an 'epicondylitis'. Ageing is associated with anatomical alteration at the enthesis, including changes in collagen content and increasing lipids, that may predispose to injury. Degenerative micro-tears can be demonstrated in the common extensor tendon origin and these are hypothesized to be due to cumulative or repetitive mechanical overload.

Clinical features

Patients present with lateral elbow pain and tenderness increased upon gripping, typically resulting in functional restrictions, e.g. in carrying shopping bags. There may be a history of an acute onset such as a wrenching injury, but more commonly the onset is gradual and insidious with no one particular trigger factor but rather longer-term overuse or strain especially with repeated flexion–extension or pronation–supination.

Management

In the acute phase, using ice over the lateral elbow, relative rest of exacerbating activities, analgesia, and use of non-steroidal anti-inflammatory drugs (NSAIDs) topically or orally may be helpful. In more prolonged symptoms, patients seek help from a variety of sources and may be offered local orthotics, local ultrasound, deep friction tissue massage, acupuncture, and extracorporeal shockwave therapy (ESWT). Unfortunately most of these approaches have to date rarely been studied in high-quality randomized controlled trials (RCTs).

Orthotics

In their recent Cochrane review, Striys et al. deduced that no definitive conclusions could be drawn concerning effectiveness of orthotic devices for lateral epicondylitis because there are not enough well-designed and well-conducted RCTs of sufficient power.[18]

Local ultrasound

Ultrasound has been evaluated as part of the treatment of lateral epicondylitis but usually as part of a 'package' of physical therapies including exercise or deep tissue massage, for example. As such, the authors of a Cochrane systematic review found insufficient evidence to conclude whether or not ultrasound alone was effective.[19]

Deep friction massage

One Cochrane review evaluated deep friction massage as a treatment for lateral epicondylitis but only two RCTs were found and the authors concluded that these showed no benefit of deep transverse friction massage combined with concurrent physiotherapy modalities, when compared to either a control group with the same physiotherapy modalities but without the massage, or other active therapies such as phonophoresis or therapeutic ultrasound combined with placebo ointment, for either improved functional performance or increased grip strength.[20] Their conclusions were limited by the lack of RCTs, the use of subjective and non-validated scales for measuring pain, the assessment of a combination of several physiotherapy modalities, and the small sample sizes.

Extracorporeal shockwave therapy

A Cochrane review of ESWT found that it had been evaluated in 1006 patients and that overall, there was 'platinum' evidence that it was of no benefit in reduction of pain or improvement of function from lateral epicondylitis and 'silver' evidence in 93 patients that steroid injection was superior to ESWT.[21] The National Institute for Health and Clinical Excellence (NICE) guidance on ESWT in the treatment of refractory tennis elbow suggested that there were no major safety concerns with this therapy, but found inconsistent evidence for the efficacy of this approach and recommended further research.[22]

Acupuncture

The evidence for acupuncture is conflicting. There have been few studies, including only small numbers of patients. As with evaluating the efficacy of acupuncture in most conditions, blinding of the patient and the assessor is difficult and rarely achieved. It is therefore currently unclear how effective acupuncture is in the treatment of lateral epicondylitis.[23]

Local steroid injections

Given its historically presumed inflammatory origin, local steroid injections have been used for lateral epicondylitis for many years.[24] Remarkably, however, there had been very little formal evaluation of the safety and efficacy of this approach until relatively recently. A 2002 systematic review using a highly sensitive search strategy found only 13 studies making 15 different comparisons (steroids vs placebo, n = 2; steroids vs. local anaesthetic, n = 5; steroids vs. another conservative treatment, n = 5; one type of steroids vs. another type of steroid injection, n = 3) with generally poor internal validity scores.[25] For short–term outcomes (≤6 weeks), including pain, grip strength and function, steroid injections produced better outcomes than placebo, local anaesthetic and conservative treatments. However, for intermediate (>6 weeks and ≤6 months) and longer outcomes (>6 months) there was no evidence for benefit of steroid injections in any 'clinically relevant' outcomes.[25] Another systematic review of corticosteroid injections (in the management of tendinopathy at different sites), again found significant effect sizes in favour of corticosteroid injections for lateral epicondylalgia in the short term (≤6 weeks) but no evidence of efficacy beyond this.[26] It can be generally concluded that although the available evidence is in favour of corticosteroid injections in the short term, it is impossible to draw firm conclusions on effectiveness given the absence of studies of good quality with intermediate and longer-term follow-up.[25]

Autologous blood injection

A small number of studies have been performed using autologous blood injection instead of corticosteroids injected over the lateral epicondyle. In their 2009 review of this procedure, NICE concluded that current evidence for this technique was inadequate in quantity and quality and that the procedure could not currently be recommended.[26]

Surgery

Surgical intervention is usually considered in severe, intractable cases after prolonged conservative therapy. Case series suggest reasonable benefit in some, but not all, study subjects and to date, surgical intervention has not been evaluated by RCTs.

Course and prognosis

Although it is generally described as a condition that is benign and self-limiting,[27] 5% of affected working-aged adults had taken sick

leave because of their lateral epicondylitis, recording a median of 29 days' absence.[13] Up to 20% of those affected have symptoms persistent beyond 1 year, particularly if they have persevered with the activity that caused it.[28] Recurrence may be more common in manual workers where it may be attributable to repeated grasping or lifting activity.

Medial epicondylitis

The underlying disease process is thought to be similar in medial and lateral epicondylitis. Despite its misnomer, medial epicondylitis (golfer's elbow) too is probably a tendinopathy reflecting overuse or strain, affecting the flexor/pronator muscle group that inserts at the medial epicondyle.

Epidemiology

The epidemiology of medial epicondylitis has rarely been studied. Among those presenting with epicondylitis in primary care in the United Kingdom, lateral epicondylar symptoms were six times more common than medial.[7] Among a case series based in a hospital population (likely to represent a skewed sample), the incidence of medial epicondylitis was 1/100 000 person-years (nine times less common than lateral epicondylitis).[29] Using a standardized clinical examination and a predefined case definition,[14] one population survey found a prevalence of 0.6% among men and 1.1% among women with highest rates of occurrence among those aged 45–54 years.[9] The prevalence of medial and lateral epicondylitis was similar among women but lateral epicondylitis was twice as common as medial among men. Risk factors included repetitive bending/straightening the elbow for greater than 1 hour out of the working day (odds ratio 5.1, 95% confidence interval 1.8–14.3).[13] It is currently unclear what proportion of medial epicondylitis occurs among people who play golf.

Diagnostic and classification criteria

Few epidemiological surveys have included criteria for medial epicondylitis. Based upon consensus, Harrington and colleagues published a case definition of tenderness on/around the medial epicondyle associated with pain aggravated by resisted wrist flexion, with the forearm extended.[14] A recent radiographic study showed that diagnostic ultrasound was able to differentiate symptomatic elbows from those without symptoms among a study of 45 elbows, 21 with medial epicondylitis and 25 without elbow pain.[30]

Clinical features

Patients generally present with medial elbow pain radiating proximally or distally and associated with functional restriction. As with lateral epicondylitis, there will sometimes be an acute triggering factor or event but most cases tend to have a gradual and insidious onset. Grip strength may be reduced, predominantly because of the pain.

Management

In general, the same management strategies are applied to medial as to lateral epicondylitis including ice, rest, analgesia, physiotherapy, acupuncture, orthoses, and topical or oral NSAIDs. However, even fewer of these treatment modalities have undergone formal evaluation in medial epicondylitis and their recommendation for use is based mostly on extrapolation from those data available

from lateral epicondylitis. Corticosteroid injections are advocated in most reviews but there are relatively few RCT data available. Stahl and Kaufman performed a double-blind RCT comparing the effect of corticosteroid (40 mg depomedrone) against saline in the treatment of 58 patients with a diagnosis of medial epicondylitis and found that both groups significantly improved at 3 months and 12 months of follow-up.[31] However, the depomedrone demonstrated marginally better results after 6 weeks when compared with the control saline injections (p <0.03). Ulnar nerve injury has been described as a consequence of medial epicondylar injection.[32] Surgical intervention is usually considered only after prolonged conservative treatment. In surgical series, it appears that concomitant ulnar neuritis is frequently identified and that surgical outcomes are less good when it is present.[33] This case series, and that of another surgical group, suggest improvement in pain may be achieved in the majority, but not all, cases of intractable medial epicondylitis.[34]

Course and prognosis

Most of the literature implies that medial epicondylitis is more resistant to treatment than lateral epicondylitis. However, few long-term follow-up studies are available for either condition and there are less data in medial epicondylitis. The results of the available surgical series suggest that 50–70% of patients obtain pain relief and functional improvement after surgery but it is likely that these cases represent a relatively small proportion of the overall numbers.[33–35]

Olecranon bursitis

The elbow is one of the anatomical sites most frequently affected by bursitis. In most cases, it is the superficial olecranon bursa that is affected. Olecranon bursitis can be an inflammatory phenomenon, occurring as part of a crystal arthropathy or RA or may be septic. Aseptic bursitis may also arise as a response to trauma, either a direct injury or chronic repetitive frictional trauma.

Epidemiology

There is very little published epidemiology regarding the occurrence of olecranon bursitis and almost nothing from general population samples. The available data come from hospital-based rates of presentation in Emergency Departments. Here, it has been estimated that olecranon bursitis and prepatellar bursitis together are responsible for 0.1–1.2/1000 Emergency Department visits per year.[36] Different hospital case series provide widely variable estimates of the proportion of cases of acute bursitis that occur at the olecranon (20–80%).[37,38] Predictably, the majority of cases presenting in Emergency Departments are caused by septic bursitis, with a small proportion only found to have acute gout, chondrocalcinosis or bleeding.[36] In acute bursitis presenting to Emergency Departments, risk factors are male gender, mean age 40–50 years, and a history of recent trauma to the affected limb or sustained (occupational) pressure on the elbow. Septic bursitis was also more common amongst those with diabetes mellitus, pre-existing nonseptic bursal disease, alcoholism, immunosuppression, and/or exposure to glucocorticoids.

Classification and diagnostic criteria

For aseptic olecranon bursitis, there are no diagnostic criteria that have been validated for use in general population studies. It has been

proposed however that a suitable definition could include 'localized pain *and* a fluid-filled swelling over the posterior elbow'. Criteria have, however, been published for the differentiation of septic from aseptic acute bursitis based upon retrospective case series.[39]

Aetiopathogenesis

Septic bursitis

This may occur after direct inoculation through local skin lesions (often relatively trivial in nature) and local injections of corticosteroid precede up to 10% of cases. Commonly, more than 80% of cases are associated with *Staphylococcus aureus* and the next most common organism is streptococcus. However, many atypical organisms have been aspirated and reported in the literature.

Aseptic bursitis

Less is known about the aetiopathogenesis of aseptic bursitis. Acute or repetitive trauma appears to predispose to chronic pain and swelling of bursae at other anatomical sites (prominently the prepatellar bursa) and inflammation caused by proinflammatory cytokines has been postulated to occur (for example, RA) and bleeding onto the bursa has also been hypothesized to be responsible but the precise mechanism is yet to be understood.

Clinical features

The onset of symptoms can occur over hours or several days. The patient usually complains of posterior elbow pain associated with localized swelling but the severity at presentation may range from a relatively painless lump to acute, hot, red swelling with severe pain, pyrexia, and cellulitis. There may be features in the history to suggest gout or RA, which can help to differentiate these causes. Patients with septic bursitis usually seek help earlier and about 50% will have pyrexia,[37] but patients with acute gout may also have pyrexia and be systemically unwell. A swollen bursa without pain will almost always be aseptic. Pain, warmth and tenderness are generally worse in septic bursitis but these signs are poorly discriminative in the acute presentation. Erythema is common in septic bursitis (63–100% of cases) but also occurs in up to 25% of aseptic cases. An accompanying effusion of the elbow joint may be present in patients with gout or RA. If in any doubt, diagnosis must be made by aspiration of the bursa and the results of laboratory investigations.

Investigation

Laboratory investigation is mandatory when there is a possibility of septic bursitis. Microscopy can identify urate crystals and Gram stain may demonstrate bacteria in 53–100% of cases of septic bacterial bursitis. Bacterial culture will usually yield the causative organism providing that samples are taken before administration of antibiotics.

Other relevant investigations may include full blood count (total white blood cell count and differential); inflammatory markers (erythrocyte sedimentation rate and/or C-reactive protein); blood cultures; blood glucose; serum urate; rheumatoid factor; anti-cyclic citrullinated peptide antibodies; plain radiography of the elbow and/or ultrasonography or MRI scanning.

Management

Where there remains doubt about diagnosis, treatment with antibiotics may need to be commenced for 'presumed' septic bursitis while awaiting results of cultures. In confirmed septic bursitis, it may be necessary to aspirate the bursa to dryness on one or more occasions. Incision and drainage may be necessary if there is abscess formation or aspiration and antibiotics are failing to control progression. Advice should be sought from local microbiology colleagues as to the policy for treatment of septic bursitis while awaiting culture results, but penicillins and erythromycin penetrate the olecranon bursa effectively.

In established aseptic bursitis, management may be with ice, NSAIDs, and local support with a dressing or bandage. Aspiration may produce lasting benefit without any additional treatment but swelling will remain persistent in up to 10% of patients at 6 months. The results of one RCT showed that intrabursal injection of depomedrone produced more rapid resolution of swelling and reduced risk of recurrence,[40] but follow-up in this trial only took place for 6 months so long-term safety and effectiveness of this approach are not fully evaluated.

Course and prognosis

Where aspiration and antibiotics are commenced promptly for septic bursitis, resolution is usually prompt and long-lasting without the need for surgical treatment. Symptoms of pain and/or swelling may, however, persist for some weeks or even months after presentation. One retrospective case series of septic bursitis (severe enough to require hospital admission) found 343 episodes between 1996–2009 at a surgical unit in Geneva, 85% associated with *Staphylococcus aureus*, and mostly (91%) managed surgically.[41] They showed that total duration of adjuvant antibiotic therapy was not associated with cure and that amongst all other factors; only immunosuppression was a significant predictor of recurrence. Their results showed that neither 8–14 days nor more than 14 days of antibiotics was more effective than ≤7 days.[41]

After treatment in the acute phase, it may be wise to explore underlying risk factors for the original presentation, particularly if the causative organism is atypical or there is no clear history of preceding trauma. Aseptic bursitis may be associated with prolonged swelling (with or without aspiration) but pain will usually settle more rapidly. If pain recurs or fails to settle in an aseptic bursitis, it is important to review the diagnosis, particularly if aspiration or steroid injections have been performed. Rarely, chronic recurrent symptomatic aseptic bursitis may require surgical debridement.

Ulnar neuropathy

At the elbow, the ulnar nerve becomes relatively superficial on its passage through the cubital tunnel behind the medial epicondyle. At this point it becomes vulnerable to trauma, compression, and elbow dislocation. After carpal tunnel syndrome, ulnar neuropathy is the second most common entrapment neuropathy of the upper limb. Although this condition has been described in the literature for more than 100 years, and the ulnar nerve can be compressed at any point in its course, the most common site of compression is within the cubital tunnel and hence, the term 'cubital tunnel syndrome' was coined by Feindel and Stratford in 1958.[42,43]

Epidemiology

Although it is widely agreed to be the second most common nerve entrapment syndrome, there are few epidemiological data on this condition and none derived from general population studies. There

is a growing literature on the occurrence of this condition among throwing athletes, particularly athletes who throw overhead.[44] A recent systematic review of work-related factors and elbow disorders concluded that the occurrence of cubital tunnel syndrome was associated with 'holding a tool in position' (odds ratio 3.53).[45]

Diagnostic and classification criteria

Cubital tunnel syndrome is often overlooked or misdiagnosed.[42] A multiplicity of different clinical tests of motor and sensory function can be utilized in practice,[46] but there is currently no widespread agreement on the gold standard method of diagnosis. In practice, most suspected cases are referred for electrophysiological testing although the sensitivity and specificity of sensory and motor neurophysiology for this condition are currently unknown. Imaging with MRI or ultrasonography is also sometimes used clinically and is thought to demonstrate morphological changes in the nerve in the cubital tunnel, but here also there are limited data as to the validity of the techniques for diagnosis and more research is required.[47]

Clinical features

Patients may complain of deep, aching pain at the medial elbow and proximal forearm which can radiate proximally or distally. Paraesthesiae radiate distally into the hand and/or wrist along the medial border, including the little finger and ulnar aspect of the ring finger. Paraesthesiae may be aggravated by activity (particularly elbow extension) and may be worse at night. Onset may be acute or insidious, depending upon underlying cause, and can progress over time from mild intermittent symptoms to contact anaesthesia. Ultimately, weakness may be detectable in the intrinsic muscles of the hand supplied by the ulnar nerve causing loss of dexterity and clumsiness and eventually wasting of the hand musculature accompanied by weakness and 'clawing' of the ring and little finger.

Management

Conservative management includes rest, splinting, ice, NSAIDs, physiotherapy, and simple analgesics. Unfortunately, few of these approaches have been evaluated formally in RCTs. The recent Cochrane review of the treatment of ulnar neuropathy at the elbow found only limited RCTs providing only moderate quality evidence.[48] The authors concluded that there was insufficient evidence to define the optimal treatment on the basis of clinical, neurophysiological and imaging characteristics,[48] nor whether to treat a patient conservatively or surgically. The results of their meta-analysis did, however, suggest that simple decompression and decompression with transposition were equally effective in the treatment when nerve impairment was severe.

Course and prognosis

Prognosis is likely to be poorer among patients with prolonged symptoms, motor and/or sensory loss, and instability of the elbow joint. In the absence of these adverse features, most patients (90%) are believed to improve with conservative measures only.[49] It is also stated that spontaneous improvement occurs in up to one-half of patients with cubital tunnel syndrome.[50] In severe cases, several surgical techniques are employed and it is difficult to find longer-term follow-up studies of patients treated with these different approaches.

Conclusion

Elbow pain affects around 12% of men and women at any point in time. It may occur as part of a generalized arthropathy, either inflammatory or degenerative and rarely will be the presenting feature of these conditions. Most elbow pain is caused by soft tissue conditions such as epicondylitis and bursitis.

Forearm, hand, and wrist

Karen Walker-Bone and Benjamin Ellis

Structure and function of the forearm, hand, and wrist

Anatomy

The wrist joint is complex, consisting of 19 bones making a total of 17 articulations coordinated by 19 muscles and an array of tendons. The wrist (carpus) has a proximal (scaphoid, lunate, triquetrum, and pisiform) and distal (trapezium, trapezoid, capitate, and hamate) row of bones. The radius and ulna articulate distally with the proximal row of the carpus. The healthy wrist is capable of approximately 130° of total flexion/extension and 40° of radio/ulnar deviation. The ellipsoid shape of the radioulnar joint allows circumduction of approximately 150° (not true rotation) as the distal radius moves about the distal end of the ulna. The wrist is stabilized by ligaments (radial and ulnar collateral and radiocarpal ligaments).

The distal row of the carpus articulates with the proximal carpi at the carpometacarpal (CMC) joints. At the thumb, the first CMC joint allows an extensive range of motion (flexion/extension 40–50°, abduction and adduction 40–70°), facilitated by its saddle shape between the trapezium and base of the first metacarpal. The distal carpi articulate with the proximal phalanges at the metacarpophalangeal (MCP) joints, which are hinge joints but allow radial and ulnar deviation. The MCP joint of the thumb has two sesamoid bones on its palmar surface. The interphalangeal joints are hinge joints, tightly supported by collateral ligaments. Healthy proximal interphalangeal joints (PIPs) allow 100–120° palmar flexion and do not allow hyperextension. The distal interphalangeal joints (DIPs) allow approximately 50–80° palmar flexion and dorsiflex to a small extent (5–10°).

The majority of the hand musculature is on the palmar surface. Releasing grip is effected by the long extensor muscles of the forearm, connected to the hand by long tendons along the back of the hand. Movement of the hand is controlled by two main groups of muscles: one group are in the forearm and attach to bony prominences in the hand (extrinsic muscles) and the other group are the intrinsic muscles of the hand. The extrinsic muscles constitute the long flexor and extensor tendons of the forearm, which attach to the phalanges and metacarpals and some of the carpals and allow strong grip and control of gross motor functions of the hand. The intrinsic muscles include the thenar eminence which produces movement at the thumb, the hypothenar eminence which produces movement at the little finger, the palmar and dorsal interossei, and the lumbricals. The intrinsic muscles facilitate fine movements of the fingers and thumb such as opposition and pinch. The centre of the palm is covered by the thick palmar aponeurosis.

Anatomy of the carpal tunnel

On the palmar surface, the carpus forms a concave arch or tunnel (the carpal tunnel) with the pisiform and hook of the hamate as bony landmarks on the medial side and the tuberosities of the scaphoid and trapezium on the radial side. These four bony prominences are bridged by the flexor retinaculum, producing a natural ceiling over the carpal tunnel which functions to hold the long flexor tendons (flexor digitorum profundus, flexor digitorum superficialis, and flexor pollicis longus) in place during wrist flexion. The median nerve runs through this compartment (Figure 153.1).

Nerve supply to the forearm, hand, and wrist

From the brachial plexus, the important nerves for hand/wrist function are the median (C5–8), ulnar (C8, T1), and radial (C6–8) nerves. Radial nerve compression above the elbow causes wrist drop due to weakness of wrist extension, stiffness in the distal arm and forearm, and inability to extend the little finger. Ulnar nerve lesions in the forearm produce pain and dysaesthesia along the lateral forearm and wrist and into the ring and little fingers. Longer term, the intrinsic muscles of the ring and little fingers may become wasted and contracted into flexion. Median nerve entrapment may occur at the elbow within pronator teres, causing diffuse arm pain, weakness of wrist pronation, and paraesthesia in a median nerve distribution (palmar surface of thumb, index, middle and radial half of ring finger). More commonly, median nerve compression occurs at the carpal tunnel, resulting in the paraesthesia as described and longer term, weakness of thumb opposition, and wasting of the thenar eminence.

Differential diagnosis of hand/wrist pain

Hand and/or wrist pain are common early symptoms of a polyarthropathy, inflammatory or degenerative. Additionally, the physician must consider peripheral nerve lesions, referral from the cervical spine, nerve root lesions, brachial plexus involvement, disease of the shoulder or elbow, or whether the presenting symptoms
Fig. 153.1 Anatomy of the carpal tunnel.

may constitute part of another disease, e.g. metastasis or fibromyalgia syndrome (Table 153.1).

History

The history should enquire about dominant limb, nature of onset, precipitating injury, and involvement of the head/neck, shoulder, or elbow on the same and other sides. The duration and progression of symptoms is useful diagnostically. With pain, enquire about site, nature, variation with time, progression, exacerbating and relieving factors, therapies tried and response. Ask about symptoms of associated inflammation, dysaesthesia, and muscle weakness. A thorough functional assessment is essential to understand completely what home and workplace activities are being performed.

Examination

Examination should be comprehensive including exposure of the neck, shoulders, and upper limbs bilaterally at a minimum. Inspection should focus on the neck and both arms as well as the hand/wrist looking for asymmetry, wasting, or scarring. Specific deformities such as Dupuytren's contracture in the palmar aponeurosis, ganglia, congenital deformities, swelling, or thickening of tendon sheaths should be noted as should visible deformities of the wrist or any small joints of the hand/wrist, including Heberden's and Bouchard's nodes seen in osteoarthritis and the characteristic deformities of swelling of MCPs and PIPs, rheumatoid nodules, subluxation, ulnar deviation, swan neck, or boutonnière deformity seen in rheumatoid arthritis (RA). Signs of skin psoriasis, nail changes, and involvement of the DIPs with/without partial resorption of the phalanges may suggest psoriatic arthritis. Rarer but important abnormalities may be detected: e.g. sclerodactyly, Gottron's papules, calcinosis, telangiectasiae, capillary nailfold abnormalities, digital ulceration, nailfold infarcts, Jaccoud's arthropathy, or signs of an underlying connective tissue disease.

To detect wrist synovitis, place it in slight flexion and use your thumbs to examine carefully for dorsal synovial thickening while

supporting the wrist with your fingers. A large effusion may produce fluctuance. The thickening associated with tenosynovitis is more linear along the line of the tendon and extends beyond the joint margins proximally and/or distally. Palpate the first CMC

Table 153.1 Classification of hand and wrist disorders

Articular	Arthritis of the hand/wrist joints
	Rheumatoid arthritis or other inflammatory arthritis
	Psoriatic arthritis
	Gout
	Septic arthritis
	Osteoarthritis
	Traumatic
	Neoplasm (primary or secondary)
Periarticular	Jaccoud's arthropathy
	Hypermobility syndrome
	Rheumatoid nodules
	Calcinosis
	Tophus (gout)
	Dupuytren's contracture
	Ganglion
	Tenosynovitis (flexor or extensor)
	Trigger finger
	De Quervain's tenosynovitis
	Acute calcific periarthritis (wrist and MCP most commonly)
Bone disorder	Neoplasm (primary or secondary)
	Osteomyelitis
	Fractures
	Osteonecrosis (e.g. keinbock syndrome)
Neurological	**Nerve entrapment syndromes in the upper limb**
	Carpal tunnel syndrome (median nerve)
	Pronator teres syndrome (median nerve)
	Radial tunnel syndrome (posterior interosseous syndrome)
	Spiral groove syndrome (radial nerve)
	Cubital tunnel syndrome (ulnar nerve)
	Thoracic outlet syndrome (brachial plexus lesion)
	Nerve root lesions proximal to the upper limb
	Radiculopathy
	Syringomyelia
	Spinal cord tumours
Chronic widespread pain syndrome	Fibromyalgia syndrome
Regional pain syndrome	Complex regional pain syndrome type II
	Somatoform pain syndrome
Vascular	**Upper limb claudication**
	Systemic vasculitis
	Primary Raynaud's
	Secondary Raynaud's with connective tissue disease
	Compartment syndrome

joint for tenderness, crepitus, and 'squaring' of the joint. Palpate each MCP joint dorsally either side of the extensor tendon using your thumbs while supporting the fingers in your own fingers. Palpate the PIPs and DIPs using your thumb while gently pinching the medial and lateral aspects of the same joint in your other hand so as to detect fluctuance.

Finger joints and thumb joints may be assessed actively and passively and cumulatively or in isolation. For example, extending the fingers, making a fist, testing grip strength, and touching each finger to the thumb are quick 'screening' tests which allow gross assessment of areas of dysfunction. Each small joint of the hand may be isolated and tested actively and passively if appropriate. At the thumb, flexion, extension, abduction, and adduction should all be assessed as well as strength of opposition to the little finger, using your own thumb opposed to test as a comparison.

Investigation of symptoms at the hand and wrist

Radiography, ultrasonography, diagnostic joint aspiration with microscopy, culture and sensitivities of the aspirate, as well as polarizing light microscopy, CT scan, MRI scan, radionuclide scanning, electromyography (EMG), and nerve conduction studies may all be useful for the investigation of hand/wrist symptoms.

Carpal tunnel syndrome

The most common entrapment neuropathy, carpal tunnel syndrome, has an estimated incidence of 99/100 000 per year[1] and prevalence as high as 7–19%, although prevalence estimates vary widely partly depending on case definition.[2] Carpal tunnel syndrome occurs more commonly in women, with an annual incidence of 1.5 per 1000 compared to 0.5 per 1000 for men.[3] Patterns of incidence also differ, such that the incidence among women peaks at age 45–54 years whereas the incidence in men continues to rise with age.

The difference in the pattern of occurrence between the genders may be explained at least partly by hormonal factors: pregnant and breastfeeding women have increased incidence,[4] as well as those taking the oral contraceptive pill and hormone replacement therapy.[5] Oophorectomy appears to reduce the incidence but there is an increased incidence in the first menopausal year.

Obesity is strongly associated with carpal tunnel syndrome, with every 1 unit increase in body mass index (BMI) increasing risk by 8%.[4] A relatively small number of cases are associated with endocrine conditions such as hypothyroidism, acromegaly, and diabetes mellitus. Damage and inflammation of the wrist itself due to wrist fractures and inflammatory rheumatic disorders, such as RA, also increase risk.[5]

There is an extensive body of evidence to suggest that occupational exposure to forceful or repetitive movements, or to hand–arm vibration, increases the risk of carpal tunnel syndrome,[6,7] particularly when these exposures are combined with adverse posture, such as bending or twisting of the wrist/hand.[7] Despite considerable interest, an association with keyboard use has not been convincingly demonstrated.

Classification and diagnostic criteria

Patients typically present with pain and/or dysaesthesia of the fingers (typically the lateral 3½ digits, although it can be diffuse throughout the hand). Symptoms are often worse at night or in the early morning. Pain may be diffuse and extend proximal to the hand. Examination in advanced cases may reveal wasting of the thenar eminence and/or weakness of thumb abduction. Provocation tests such as those of Tinel (tapping the flexor retinaculum) and Phalen (full passive flexion of the wrist for 1 minute) are widely used, but the sensitivity and specificity of these tests is highest in the more advanced cases and sensitivity and specificity are excellent among patients about to undergo carpal tunnel decompression but much reduced among patients with dysaesthesia in the general population.[2] EMG testing has high diagnostic sensitivity (60–84%) and specificity in excess of 95% among patients awaiting decompression, but false positives and negatives may still occur and again its diagnostic utility among the general population is poorer. A negative nerve conduction test in the presence of a positive clinical diagnosis is thus difficult to interpret.

Aetiopathogenesis

Carpal tunnel syndrome arises from any pressure on the median nerve as it traverses the carpal tunnel. It is thought that some families have a congenitally small carpal tunnel. In most individuals, though, compression arises from local pressure caused for example by obesity, wrist inflammation, repetitive occupational use, hormonal factors, or distortions to the median nerve.

Differential diagnosis

Cervical radiculopathies at C6–7 may mimic the sensory symptoms of carpal tunnel syndrome, although in such cases motor involvement will be in the distribution of the radial nerve, affecting wrist flexion and triceps. Pain itself may be difficult to localize and the possibility of an ulnar or small-fibre neuropathy should be considered for patients with neuropathic palmar digit pain, along with other causes of medial neuropathy. Wasting of the thenar muscles may also be caused by a T1 radiculopathy.

Management

Initial management is conservative, including nocturnal splinting to hold the wrist in a neutral position, along with analgesia and addressing any causative risk factors. The evidence does not support specific use of non-steroidal anti-inflammatory drugs (NSAIDs),[8] though oral steroids confer short-term benefit. A single local steroid injection is better than placebo at improving symptoms at 1 month[9] and, combined with splinting, is more effective than splinting alone.[10] Surgery to divide the flexor retinaculum and release the median nerve can be performed as an open procedure or endoscopically, and carries a long-term success rate of over 75%.[11]

De Quervain's tenosynovitis

The extensor retinaculum passes from the lateral radius to the medial carpal bones, and is divided into six compartments by fibrous septa passing to the radius and ulna, with each compartment having its own synovial lining. The tendons of extensor pollicis longus and brevis pass through the lateral or first, dorsal compartment in a single sheath and emerge to form the radial border of the anatomical snuffbox. De Quervain's tenosynovitis is a stenosing tenosynovitis of this first dorsal compartment of the wrist at the radial styloid.

Epidemiology

Few epidemiological studies have explored the occurrence of de Quervain's tenosynovitis in the general population. Where evaluated, it appears more common among women than men with an annual incidence rate of 2.8 cases/1000 women compared to 0.6/1000 men,[12] and point prevalence 1.3% among women and 0.5% among men.[13] Incidence increases with age, so that age over 40 years is a significant risk factor,[14] and there may be an increased rate among black people.[12]

No specific occupational determinants have been demonstrated, although cases have been attributed to repetitive thumb use in piano-playing, sewing, and knitting,[14] as well as text messaging.[15] Hormonal factors may play a role as cases have been described during pregnancy[16] and in the postpartum period.[17,18] Associations have also been reported between de Quervain's tenosynovitis and the inflammatory arthritides and local trauma.

Classification and diagnostic criteria

De Quervain's tenosynovitis typically presents as pain over the radial wrist associated with impaired thumb function. Clinical findings include swelling, crepitus, and tenderness over the first dorsal compartment along with a positive Finkelstein's provocation test (Figure 153.2). Imaging is not routinely required, though ultrasonography and MRI may detect thickening and inflammation of the extensor pollicis longus and brevis tendons. Thumb-base osteoarthritis may cause a similar distribution of pain but typically has different clinical findings on examination.
Fig. 153.2 Finkelstein's test.

Aetiopathogenesis

Repetitive radial and ulnar deviation of the wrist combined with gripping ('washerwoman's wrist') is thought to lead to friction and inflammation of the tendon sheath as it passes through the extensor retinaculum.

Management

Conservative treatment with thumb spica[19] splinting and NSAIDs is usually first-line treatment and this may be most effective for people with relatively mild symptoms.[20] Provoking or exacerbating activities at home or work, e.g. rowing, may need to be avoided. Local injections of glucocorticoid have been shown to be highly effective in the treatment of de Quervain's tenosynovitis, and have been suggested by some as first-line treatment.[21] Using ultrasound to guide injection may reduce side effects,[22] but both intrasynovial and extrafibrous injection appear to convey similar benefit.[23] Where conservative management has failed, there is evidence that surgical decompression to divide the extensor retinaculum can be effective.[24]

Flexor and extensor tenosynovitis of the wrist and fingers

Tenosynovitis occurs at sites where tendons are lined with synovium and occurs most frequently at the wrist (radial, flexor, and extensor compartment) and on the flexor tendons of the digits (trigger digits).

Epidemiology

Tenosynovitis appears more common among women than men, with population prevalence rates estimated at 1.1% among men and 2.2% among women.[13] Tenosynovitis is associated with repetitive hand movements, and some types of factory workers and machinists appear to be at increased risk.[25–27] Imaging of the tendon sheaths amongst patients with early RA shows that tenosynovitis is a frequent finding,[28] and this may predispose to tendon rupture.[29] Diabetics are at increased risk of stenosing flexor tenosynovitis.[30] Urate crystal deposition can also cause tenosynovitis. A rare but important cause of tenosynovitis is infection which may be caused by a penetrating injury, or haematogenous spread with organisms such as neisseria.

Classification and diagnostic criteria

The typical clinical findings of pain, tenderness, and swelling along the length of the tendon or tendon sheath, accompanied by pain increased by resisted movement of that individual tendon, is suggestive of tenosynovitis. Sometimes crepitus may also be demonstrated. Ultrasonography or MRI may confirm the diagnosis when there is uncertainty, but are not routinely required. In patients with RA, tendon rupture may be the first clinical sign of tenosynovitis, and should be suspected if there is painless loss of active movement. In infective flexor tendon tenosynovitis, in addition to pain there may also be a rapid onset of fusiform swelling of the digit, which will be guarded in flexion with pain on passive extension. It is important to remember that these signs may be absent in immunosuppressed patients, or those partially treated with antibiotics. Definitive diagnosis of infection or gouty tenosynovitis requires aspiration.

Aetiopathogenesis

Pathophysiologically, a distinction is made between the true synovial inflammation of tenosynovitis, inflammation of a tendon itself (tendinitis) and the degenerative process of tendinosis, where repetitive mechanical loading leads to collagen degradation with resultant pain and dysfunction. Some tendons are more prone to inflammation than others; for example, flexor carpi ulnaris tenosynovitis is said to be more common than flexor carpi radialis.

Management

Appropriate treatment depends on the cause. First-line therapy for tenosynovitis involves ice, rest, splinting, and NSAIDs. Local injections of glucocorticoid may be administered where needed. Because of the superficiality of the tendon sheath, it is wise to use short-acting steroid preparations such as hydrocortisone acetate and warn the patient of a risk of local steroid atrophy of the skin at the injection site. Where possible, the precipitating activity should be avoided. As with de Quervain's tenosynovitis, surgical release may occasionally be required. In gout or inflammatory arthritis, the management of the tenosynovitis relies upon control of the underlying condition.[31] Where infective tenosynovitis is suspected, empirical intravenous antibiotics should be started for those organisms most commonly involved (staphylococci and streptococci), taking advice from local microbiological colleagues. Although early infective tenosynovitis may respond to antibiotic therapy alone, surgical drainage is frequently recommended to prevent the complications of osteomyelitis, tendon necrosis, and skin loss.

Trigger digit (tenosynovitis of the flexor tendons of the thumb and digits)

At the level of the MCP joint, the superficial and deep finger flexors pass through the first annual (A1) pulley. 'Triggering' occurs as a mechanical catch when there is insufficient space for the tendon to traverse.

Epidemiology

The population prevalence of trigger digit has been estimated to be 2.6%, with women 2–3 times more commonly affected than men.[32] Incidence is greatest in the 40–50 years age group, but rarely can be congenital. The thumb of the dominant hand is the most common digit to be affected, with relative sparing of the index and little fingers.[33]

Chronic repetitive activities are implicated in the development of trigger digit, and there may be increased prevalence among some manual workers.[34,35] Activities such as knitting or sewing[33] may also increase risk. Risk of trigger finger is greatly increased amongst people with all types of diabetes mellitus,[36,37] where trigger digit may be multiple and bilateral. Other associations include hypothyroidism, Dupuytren's contracture, carpal tunnel syndrome, RA, and amyloidosis [33]

Classification and diagnostic criteria

Typically trigger digit presents as a painful catching or clicking/popping feeling when the affected digit is extended, sometimes associated with inability to actively extend the affected digit. There may also be a tender palpable nodule at the level of the metacarpal head. Acute onset of a trigger finger with associated severe pain

and swelling should raise the suspicion of infective tenosynovitis or a gouty tenosynovitis and aspiration should be considered where this is the case.

Aetiopathogenesis

The mechanism is most commonly tenosynovitis, perhaps related to friction or overuse. The result is commonly chronic fibrous nodular enlargement of the flexor digitorum superficialis close to the metacarpal head.

Management

Initial management may consist of rest, ice and oral NSAIDs, and there may be a role for splinting. Local corticosteroid injections may be very effective whether or not they are placed intra-sheath.[38] The injections may be more effective in nodular, rather than diffuse disease.[39] Where symptoms have not resolved, repeat injections can be beneficial resulting in improvements of over 90% at 1 year.[40] A comparison of surgical release with local corticosteroid injection showed that after 1 month, patients with injections achieved greater range of motion than those treated by percutaneous release but that 6-month assessment showed a higher chance of recurrence in those treated with injections.[41] If possible, causative factors should be addressed and underlying inflammatory conditions aggressively treated.

Dupuytren's contracture

Characterized by nodular thickening and contracture of the palmar aponeurosis, Dupuytren's is a relatively common condition. The condition draws the MCP joints into flexion, usually at the ring finger and little finger, but occasionally involves other joints.

Epidemiology

The classical case, with flexion contractures, is easily recognized but more minor forms are more difficult to diagnose reliably so that the epidemiology is difficult to characterize. Dupuytren's contracture becomes more prevalent with increasing age.[42] and is up to sixfold more common among men than women.[43] The incidence of new Dupuytren's nodules in previously unaffected individuals aged over 66 years is around 3%.[44] Typically Dupuytren's is bilateral, but when it is unilateral the dominant hand is more frequently affected. A relationship with local repetitive and/or occupational trauma remains unproven but there is an association between Dupuytren's and vibration-induced white finger.[45]

Dupuytren's contracture is more common in people with elevated fasting blood glucose and diabetes mellitus,[44,46] and may be less common in people with RA.[47] Increased reported prevalence among people with epilepsy may be attributable to medication.[48] Heavy smokers (>25 cigarettes daily) are more likely to be affected,[49–51] but a relationship with excessive alcohol intake has not been clearly established. There appears to be familial clustering of Dupuytren's, with a possible autosomal dominant pattern of inheritance.[52]

Classification and diagnostic criteria

The diagnosis of Dupuytren's is based on the clinical findings of palmar nodularity, overlying skin tethering and puckering, and fixed flexion of the MCP joint distal to the affected area. Ultrasonography can confirm the structural changes, but is not usually required for diagnosis.

Aetiopathogenesis

The pathology is one of fibrous nodule formation within the palmar aponeurosis. Histopathologically, fibroblasts and myofibroblasts proliferate superficially in the palmar fascia and the dermis is infiltrated by fibroblastic cells, resulting in the contracture of the superficial layers which may ultimately be tethered.

Management

In early disease, management may be expectant. Repeated intralesional injections of triamcinolone may reduce nodularity which may in turn prevent contracture formation, but such injections do not reverse a contracture once present. Injectable collagenase clostridium histolyticum, however, has been shown to reduce contractures and improve range of motion in affected joints.[53] Once the affected digit is permanently flexed, surgery is usually offered. This is usually performed under local anaesthetic and consists of either needle aponeurotomy or percutaneous fasciotomy, but following both procedures recurrence rates may be as high as 50%.[54,55] A more extensive fasciectomy can also be performed to dissect away all affected fascia but recurrence rates remain high even with this procedure, with up to 15% of patients requiring repeat surgery.[56]

Raynaud's phenomenon

Raynaud's phenomenon is the name given to intermittent digital vasospasm occurring in response to stress or cold. There is usually a clear line of demarcation, distal to which the skin colour changes caused by vasoconstriction (white), cyanosis (blue), then hyperaemia (red), often accompanied by pain. Primary (benign) Raynaud's phenomenon (Raynaud's disease) occurs commonly with a family history, is usually symmetrical, and begins typically at the age of 15–25 years, in girls more commonly than boys. Secondary Raynaud's reflects endothelial, vascular structural, neural, and intravascular abnormalities; it may occur for the first time at any age and may be asymmetrical.

Epidemiology

The population prevalence varies between 4% and 15%, with higher rates among women.[57] The annualized incidence has been estimated at 2.2% in women and 1.5% in men,[58] with 80–90% of these being primary Raynaud's. The onset of primary Raynaud's is typically in the second or third decades of life, whereas the epidemiology of the secondary Raynaud's reflects that of the underlying disorder.

Primary Raynaud's may more common in people with a family history.[59] Occupational exposure to organic solvents,[60] particularly vinyl chloride,[61] increases the risk of secondary Raynaud's. Prevalence of Raynaud's is doubled among people exposed to hand-transmitted vibration.[62] Raynaud's is associated with a number of autoimmune diseases including systemic sclerosis, mixed connective tissue disease, systemic lupus erythematosus (SLE), vasculitis, RA, and myositis, as well as cryoglobulinaemia and systemic malignancies.

Classification and diagnostic criteria

Raynaud's is diagnosed clinically based upon intermittent painful, frequently bilateral, well-demarcated triphasic colour change of one or more digits (white to blue to red), often precipitated by cold. Primary Raynaud's is diagnosed when there is no history of digital ulceration, no clinical features suggestive of a connective tissue disorder, and negative immunological testing such as erythrocyte sedimentation rate (ESR) and nuclear antibodies. In secondary Raynaud's, capillaroscopy may reveal dilated nailfold capillaries.

Raynaud's should be discriminated from median or ulnar neuropathy or radiculopathy, which cause similar digital pain without colour change. Painful, hot, red fingers, usually in response to a heat stimulus, may be due to erythromelalgia. Acrocyanosis is a painless, persistent, non-paroxysmal bluish-red, symmetrical discoloration to hands and feet, but there is no initial pallor phase. Chilblains occur in response to cold and can cause erythema, pruritus, and ulceration, but lack the clearly demarcated triphasic colour change of Raynaud's.

Aetiopathogenesis

The typical aetiopathogenesis is vasospasm, which may be triggered by cold or stress. Whiteness is caused by restricted blood flow, cyanosis by local ischaemia and deoxygenation, and redness by the typical hyperaemia once blood flow is restored; this latter phase is typically painful.

Management

Initial management is with lifestyle modification, including avoiding triggers such as cold (wearing gloves and lined footwear, avoiding smoking, and addressing any apparent risk factors such as chemical or vibration exposure). Initial pharmacological treatment may include the dihydropyridine calcium channel blockers, including nifedipine,[63] which may be used regularly, or as required. Drugs inhibiting the renin–aldosterone axis, in particular losartan, may reduce the frequency and severity of attacks.[64] Topical nitroglycerin may be effective,[65] though headache is a frequent side effect which may restrict utility. Other treatment options include alpha-blockade[66] and fluoxetine.[67] In secondary Raynaud's, particularly with digital ulceration, treatment with parenteral prostaglandins, such as intravenous iloprost,[68] sildenafil, or bosentan[69] may be indicated.[70] In severe cases, surgical or chemical sympathectomy, including using botulinum toxin,[71] may be required when other treatments have failed.

Non-specific (diffuse) forearm pain

One of the differential diagnoses for hand/wrist tenosynovitis includes non-specific forearm pain. This diagnostic classification has been utilized in the United Kingdom since the publication of a consensus set of case definitions derived from a multidisciplinary workshop, sponsored by the UK Health and Safety Executive, employing a Delphi approach.[72] Prior to this, diagnostic labels such as 'repetitive strain injury', 'occupational cervicobrachial disorder', 'work-related upper limb disorder' had grown in use, with different terms in different countries and different diagnostic criteria, but with the obvious encumbrance of implied causation within their nomenclature which was hindering epidemiological research.

Epidemiology

It is difficult to be certain how commonly diffuse forearm pain occurs, because of the extraordinary diversity of diagnostic criteria that have been applied in epidemiological studies, some of

which are likely to be different but overlapping. Using the UK case definition, a prevalence rate of 0.5% was reported among working-aged adults,[74] but in a prospective cohort study of 782 people from 12 different occupational groups, prevalence of new onset forearm pain over 12 months was 8.3% (7.2% in men and 10% in women).[75] Risk factors for diffuse forearm pain include lifting heavy loads, adverse postural factors (e.g. working with hands above shoulder height), repetitive movements, and psychosocial factors—psychological distress, monotonous work, low job satisfaction, and low levels of control in the workplace. A clear relationship between this condition and workplace keyboard use has not been established.[74]

Diagnostic and classification criteria

Non-specific forearm pain is essentially a diagnosis of exclusion. The published consensus case definition from Harrington et al. was: 'pain in the forearm in the absence of a specific diagnosis or pathology (sometimes includes loss of function, weakness, cramp, muscle tenderness, allodynia, slowing of fine movements).[72] There should be no clinical signs suggestive of specific pathology, and diagnostic testing for specific causes of forearm pain should by definition be negative.

Aetiopathogenesis

The aetiology of non-specific forearm pain may be complex. There is currently no agreement as to underlying cause, though mechanisms involving local tissue damage, peripheral neurological abnormality, referred pain from the neck, sensory cortical change, and pain amplification have all been proposed.[73] There may be overlap with conditions presumed to be predominantly neurological such as focal dystonia and 'writer's cramp'. Tenosynovitis is thought to be a separate entity. It remains to be established whether non-specific arm pain may sometimes constitute the prodromal phase of forearm tenosynovitis.

Clinical features

Patients describe their symptoms as aching, soreness, or tingling which may be diffuse in the forearm. Subjective swelling, dysaesthesia, focal tenderness, and abnormal pain sensitivity may be demonstrated. Sometimes symptoms become more widespread (shoulder–hand syndrome). There may be disturbance of sleep patterns, and generalized fatigue is common. There may be predisposing factors in the workplace, e.g. a change in technique or working practices. Typically, symptoms are relieved initially by a short period of rest, but as symptoms become more chronic not even 2–3 weeks of annual holiday provide relief.

Management

In the absence of consensus on causation, there is currently no specific treatment for this condition. Best practice is to offer an approach that is multimodal and multidisciplinary,[73] including pain management, occupational therapy, and physiotherapy. Occupational health services should be involved early and undertake a workplace ergonomic assessment and psychological support; treatment for anxiety or depression should be initiated where appropriate. The medical approach should be positive and reassuring, emphasizing the absence of local tissue damage, along with encouragement to remain active and if possible in the workplace.

Conclusion

Forearm, hand, and wrist symptoms are common. It should be borne in mind that these are common sites of onset of a polyarthropathy but, once such a condition has been excluded, careful history-taking and examination should facilitate a correct diagnosis and management plan.

Pelvis, groin, and thigh

Cathy Speed

Introduction

Conditions affecting the groin, hip, and thigh can result in significant pain and disability, and can affect those across all age ranges and activity levels. In this chapter, the clinical assessment, diagnosis, and treatment of common conditions in this region are reviewed.

Epidemiology

The overall incidence of problems around the hip, groin, and thigh is not known, but this region is a common source of pain and disability. For example, 4.4% of adults over the age of 55 years have symptomatic osteoarthritis (OA) of the hip.[1] Approximately 2.5% of all sport-related injuries are in the pelvic region. Most of these are soft tissue injuries, but articular complaints are increasingly recognized. Paediatric disorders are also common, and can be serious.

Causes of problems around the hip, groin, and thigh

Most problems of the hip, groin, and thigh cause pain. Complaints can be considered according to the principal site of pain (Table 154.1).

Pain in the anterior hip, groin, and thigh

Articular complaints

Clinical features

Most articular disorders of the hip present with pain that is typically focused in the groin, and aggravated by weightbearing and, in particular, impact-related activity. A mechanism of onset may be identified. As the condition progresses, the pain becomes more intrusive and pain at rest occurs. Posterior hip/buttock pain is variable. Pain may be noted in the thigh and/or knee. Night pain is a feature of more severe complaints.

Examination may reveal gluteal weakness (including a positive Trendelenburg sign), pain, and/or restriction on hip movement and in particular on rotation.

Additional features typical to specific complaints are described below.

Osteoarthritis

The prevalence of moderate to severe radiographic OA adults over the age of 55 years is 1.5% and the prevalence of symptomatic

OA of the hip 4.4% (3.6% female; 5.5% male). The age and sex-standardized incidence rates of symptomatic OA of the hip is 88 per 100 000 person-years. Incidence rates increase with age, and level off around age 80. Women have higher rates than men, especially after age 50; men have a 36% reduced risk of hip OA than women. Fifty to sixty per cent of hip OA may be genetically determined.[1–3]

Established modifiable risk factors include excess body mass (though less than for knee OA), joint injury, excessive loadbearing physical activity,[4] occupation involving excessive mechanical stress, structural malalignment, and muscle weakness. Non-modifiable risk factors are female gender, increasing age until 75 years, race (e.g. lower risk in Asians), and genetics. Other risk factors that have been postulated are oestrogen deficiency, osteoporosis (inversely related to OA), and high C-reactive protein.[5,6]

Risk factors for disease progression in hip OA are patient age, baseline joint space width, femoral head migration, femoral osteophytes, bony sclerosis, a Kellgren Lawrence hip grade of 3, baseline hip pain, and a Lequesne index score (an algofunctional index that measures disease activity in the hip and knee) of at least 10.[7,8]

Diagnostic criteria for osteoarthritis of the hip

The American College of Rheumatology (ACR) criteria for hip OA classification offer several methods for diagnosis. The standard approach requires the presence of hip pain and at least two of the following three criteria: radiographic evidence of femoral or acetabular osteophytes, radiographic evidence of joint space narrowing (superior, axial, or medial), and an erythrocyte sedimentation rate (ESR) less than 20 mm/hour. This approach yields a sensitivity of 89% and a specificity of 91%.[9]

Additional diagnostic criteria that may be helpful for diagnosing OA of the hip include internal hip rotation of 15° or less, morning stiffness in the hip lasting 1 hour or less, and age of 50 years or older.

MRI and MR arthrography allow earlier imaging-based diagnosis of OA than plain radiographs, although further improvements in the technology are still required to accurately image early cartilage changes.[10]

Management

The major clinical guidelines for management of hip OA[11–15] show minor differences. All recommend patient education, weight loss, insoles and a variety of exercise orientated approaches. Paracetamol (acetaminophen) is the analgesic of first choice, moving on to oral

Table 154.1 Causes of pain in the hip, groin, and thigh

Anterior	Posterior	Lateral
Articular		
Osteoarthritis	Advanced hip pathologies	
Inflammatory arthritis	Sacroiliac disease and dysfunctions	
Septic arthritis	Referred facet joint pain	
Osteomyelitis	Sacral bone stress injuries

non-steroidal anti-inflammatory drugs (NSAIDs) at their lowest effective dose if necessary. Choice of a COX-2 inhibitor or standard NSAID + proton pump inhibitor (PPI) is made according to the patient's cardiac and gastroenterological risk factors. Guided intra-articular glucocorticoids are recommended for those who have ongoing pain. While viscosupplement injections are not included in the guidelines for hip OA, studies subsequent to published guidelines indicate benefit.[16,17] Unlike the ACR guidelines, those from the European League Against Rheumatism (EULAR) do not rule out the use of glucosamine sulfate, chondroitin sulfate, or diacerein.[12,13,15] Opioids, with or without paracetamol, may also be used should other oral analgesics fail in those with severe pain.

Total joint arthroplasty provides marked pain relief and functional improvement in the vast majority of patients with OA. Indications from the United States National Institutes of Health (NIH) for total hip replacement include 'radiographic evidence of joint damage and moderate to severe persistent pain or disability, or both, that is not substantially relieved by an extended course of nonsurgical management'.[18] The United Kingdom National Institute for Health and Clinical Excellence (NICE) guidelines[14] adhere to clinical criteria, recommending that referral for joint replacement surgery should be considered for people with OA who experience joint symptoms (pain, stiffness, and reduced function) that have a substantial impact on their quality of life and are refractory to non-surgical treatment. Referral should be made before there is prolonged and established functional limitation and severe pain.

Inflammatory arthritis

Hip disease occurs infrequently in adult-onset RA. However, hip pathology in the form of fracture can occur due to osteoporosis, which has an increased incidence in RA, particularly those with severe disease. With such improvements in medical management of RA, total hip arthroplasties are less commonly needed.

Unlike adult RA, hip disease develops in 30–50% of children with juvenile RA and can result in significant long-term disability, emphasizing the need for aggressive management of such cases.

In ankylosing spondylitis, sacroiliitis typically causes buttock pain, but may refer to the groin. Hip involvement itself occurs in

approximately 10–15% of those with AS after 10 years' disease duration in western Europeans. The incidence is up to 50% in other populations. Hip involvement is related to the degree of spinal involvement, and is considered a bad prognostic sign.[19]

Hip joint architecture and impingement syndromes

Several features of hip joint architecture, such as acetabular dysplasia, pistol grip deformity, wide femoral neck, and altered femoral neck–shaft angle have a strong genetic influence. These features can play an important role in the pathogenesis of osteoarthritis and hip (femoroacetabular) impingement syndromes.[20] The latter can be associated with labral tears and non-specific pain on hip flexion and rotation, typically in young people. Patients present with groin pain and have signs of pain on hip flexion and internal or (less commonly) external rotation. Plain radiography and CT show hip geometry best. In the absence of a labral tear, conservative management through activity modification and physiotherapy should be the first line of approach prior to consideration for surgical interventions.

Bone oedema syndromes of the hip

The hip is a common site of bone marrow oedema syndromes. Bone marrow oedema is an MRI-based diagnosis and is neither a specific MRI finding nor a specific diagnosis. It describes a pattern of signal change of bone on MRI (decreased on T1-weighted and increased on T2-weighted imaging). It may be seen in a number of hip disorders. Bone marrow oedema syndromes of the hip include transient osteoporosis of the hip (TOH), regional migratory osteoporosis (RMO), and complex regional pain syndrome (CRPS type 1). Such conditions are usually benign and self-limiting.

Patients present with non-specific hip/groin pain and a limp. Other symptoms and signs may be present, depending upon the underlying condition. MRI is used to confirm the diagnosis, help to exclude other pathologies, and monitor the condition. Scrutiny for more significant disorders is vital. These include other causes of hip pain, and conditions associated with bone marrow oedema on MRI: stress injury, avascular necrosis/osteonecrosis, osteomyelitis, articular pathologies, myeloproliferative diseases, sickle cell disease. Such conditions can usually be differentiated by their clinical pictures and further investigations as necessary.[21]

In TOH, MRI findings do not show focal changes that are seen in avascular necrosis (AVN); see next section. Plain radiograph shows osteopenia of the femoral head and in some cases into the femoral neck and acetabulum, typically after 4 weeks of symptoms, and in particular transient subchondral cortical thinning that resolves with time. Scintigraphy shows homogenous increased uptake throughout the femoral head, with an epicentre of uptake at the centre of the femoral head.

RMO is a rare condition characterized by a migrating arthralgia involving the weightbearing joints of the lower limb, and typically affecting men aged 40–60 years. There are also more rare intra-articular and spinal forms. The imaging findings on imaging are indistinguishable from TOH. TOH can occur in women in the third trimester of pregnancy. TOH and RMO are likely to be part of the same spectrum of disease. Systemic osteoporosis is seen more commonly in this group of patients.

Avascular necrosis

The reader is directed to a review of AVN elsewhere in this text (Chapter 148). A brief overview relating to the hip is provided here.

AVN of the femoral head is a potentially devastating disorder affecting young people between the third and fifth decades. The femoral head is particularly vulnerable, due to the patterns of its blood supply.

Higher-risk patients include those who have had corticosteroid therapy, particularly long term, alcoholism, myeloproliferative disease, caisson disease, venous outflow occlusion, arterial embolism or thrombosis, autoimmune disease (e.g. systemic lupus erythematosus), and those who have had local radiation therapy or a renal transplant. In those on steroids, reducing the dosage may help to reduce the size of the lesion. Bilateral AVN of the hip in pregnancy has also been described.

On MRI, there are focal subchondral signal changes. Lesions are circumscribed by a rim of low signal intensity on T1-weighted images or a double line consisting of concentric low- and high-signal intensity bands on T2-weighted imaging. Gadolinium fails to enhance areas of early osteonecrosis (ON), while surrounding uninvolved areas do enhance. ON can occasionally appear similar to TOH on initial MR. Plain radiographs may be normal initially but with time usually show collapse of subchondral bone. In 50% of all cases accompanying joint effusion may be found. In later stages calcification as well as new bone formation and microfractures are typically demonstrated and visualized best with plain radiographs and CT.

The prognosis depends on the location, size, stage of the lesion, and underlying risk factors. Those with diffuse involvement of the femoral head or lesions affecting the lateral third of the weightbearing portion of the femoral head have a 90% chance of femoral head collapse.[22]

Fifty per cent of patients develop bilateral disease. Many classification systems have been recommended, but all are associated with observer and/or technical errors.

Non-operative approaches, such as rest and crutches, hyperbaric therapy, statins, bisphosphonate therapy, iloprost infusions, and extracorporeal shock wave therapy (ESWT) have all been proposed. The evidence base for all is limited. Surgical intervention is reported to show superior outcomes to non-surgical. Core decompression is the most common initial surgical procedure, with a reported good outcome in 64% or patients compared to less than 30% of those managed conservatively.[23]

Pubic symphysis instability

Pubic symphysis instability typically occurs in postpartum women and male athletes. Associated symptoms may include local symphysis, groin, adductor, and perineal pain and clicking, all aggravated by activity and lifting. Radiographs may show signs of irregularity and sclerosis of the symphysis, but such changes are frequently seen in asymptomatic active individuals. MRI and bone scan will be more sensitive to active osteitis. Stork radiograph views of the symphysis may reveal instability (>0.2 mm movement).

Management involves lengthy rehabilitation to improve pelvic floor and core muscle strength. In postpartum women a sacroiliac belt and reassurance are particularly useful. Surgery is very rarely indicated.

Osteitis pubis

The term 'osteitis pubis' implies an inflammatory process affecting the pubic symphysis. True osteitis at this site can be related to osteomyelitis, hyperparathyroidism, sarcoidosis, inflammatory arthritis, and haemachromatosis. All such conditions are rare compared to activity-related 'osteitis', when the term is usually used to describe radiological changes at the symphysis, including widening, demineralization, resorption, periosteal reaction, and sclerosis. This is usually due to symphysis instability, and the symptoms are similar.

Scintigraphy will show increased uptake in the joint in active lesions, but MRI scanning has superseded this. MRI shows oedema within the pubic symphysis in patients with chronic groin pain. Nevertheless, the findings must be taken in the clinical context. The recommended treatment of mechanical osteitis pubis includes a long period of relative rest, analgesics, and stability work. Steroid injections should be discouraged, as they are rarely beneficial. In those rare cases with infective or metabolic causes the underlying condition should be managed accordingly.

Soft tissue injuries

In sport, intrinsic risk factors including increased age, female sex, previous injury and inadequate rehabilitation, and extremes of body mass index (BMI) have been reported to have some role in increasing tendency for injury. Extrinsic factors for injury include the athlete's skill level, the competitive nature of the sport, and the type of playing surface.

Acute or chronic adductor injuries may occur along the myotendinous junction, the tendon, or at the enthesis, and may be associated with osteitis pubis or symphysis instability. Adductor longus is most commonly involved. In young, growing athletes, an avulsion injury can occur. There is pain and tenderness of the adductors and pain on resisted adduction. MRI and ultrasound will demonstrate tendinopathies and myotendinous damage, but non-specific intra-tendinous alterations on imaging are common in asymptomatic active patients. Treatment is relative rest, stretching, and progressive strengthening. In chronic tendinopathy, peritendinuos infiltration with steroid may be helpful in achieving pain relief. Rarely, adductor tenotomy may be necessary.

Snapping hip syndrome

A 'snapping hip' may arise as a result of a number of intra- and extra- articular pathologies, including hip subluxation, labral tears, or soft tissue movement. Typically the source is the iliopsoas tendon; the tendon glides over the lesser trochanter or iliopectineal eminence and snaps as it does so. Usually this is due to tightness or a lack of lumbopelvic control. A bursitis may be present. Diagnostic ultrasound confirms the diagnosis and treatment is rehabilitation to strengthen the area and achieve balanced flexibility. Occasionally the iliopsoas tendon sheath or bursa may warrant injection to reduce the pain.

Iliopsoas bursitis

Iliopsoas bursitis can be related to underlying joint pathology or iliopsoas pathology, or may occur in isolation after overuse or trauma. Anterior groin pain with or without a clunk or snap and a deep ache occur. When sufficiently large, a bursitis may also present as a painful or painless inguinal mass, or with symptoms related to a compressive effect, such as femoral nerve irritation or femoral venous engorgement. A large bursa can even cause compression of the large bowel or bladder. An ultrasound scan will confirm the diagnosis. Further evaluation of the hip should be considered. Anti-inflammatories are usually required. If steroid injection is considered then the clinician should be mindful that communication with the joint is possible and the patient must be counselled in the same way as they would for an intra-articular injection.

Calcific tendinitis of the hip

Though rare, calcification of the hip soft tissues including the origins of one or more muscles of the thigh, most commonly the rectus femoris, gluteus maximus, or vastus lateralis, can occur. Acute groin pain and limitation of movement (due to pain), without a history of trauma, are presenting features. Management includes relative rest, analgesics or NSAIDs, ultrasound, ESWT, and if necessary imaging-guided local corticosteroid injection.

Paediatric and adolescent conditions

Regional problems in the paediatric patient are discussed elsewhere in this text (Chapter 158). Table 154.2 provides an overview of conditions specifically affecting the hip.

Lateral hip and thigh pain

Gluteal enthesopathy and trochanteric bursitis

Enthesopathy of the insertion of gluteus medius and minimus at the trochanter is a common condition, particularly in women, and

Table 154.2 Differential diagnosis of hip pain in the young patient

Condition	Age (years)	Clinical features	Frequency	Diagnosis
Apophyseal avulsion fracture	12–25	Pain after sudden forceful movement	Often	History of trauma; radiography
Hip apophysitis	12–25	Activity-related hip pain	Often	History of overuse; radiography to rule out fractures
Transient synovitis	<10	Limping or hip pain	Often	Radiography; laboratory testing; ultrasonography
Fracture	All	Pain after traumatic event	Occasionally	History of trauma; radiography
Slipped capital femoral epiphysis	10–15	Hip, groin, thigh, or knee pain; limping	Occasionally	Bilateral hip radiography (anteroposterior and lateral)
Legg–Calvé–Perthes disease	4–9	Vague hip pain, decreased internal rotation of hip	Infrequently	Hip radiography or MRI
Septic arthritis	All	Fever, limping, hip pain	Infrequently	Radiography; laboratory testing; joint aspiration

Reproduced with permission from Peck.[24]

often inappropriately termed 'trochanteric bursitis'. The enthesopathy arises as a result of a lack of gluteal strength and the patient may also have longstanding back pain and have weak gluteals and pelvic floor and poor core stability. Other factors include muscle imbalances, hip pathology (with limitation of internal rotation and reflex tightening of the external rotators), and leg length differences.

The aetiological and clinical features of trochanteric bursitis overlap with gluteal enthesopathy, but bursitis is much less common. There are four trochanteric bursae, situated deep to the soft tissues at the lateral hip, protecting them from the bony surface of the greater trochanter.

Ultrasound or MRI confirm the diagnosis. Treatment involves correction of underlying cases, strengthening, and in those with bursitis, guided injection of the bursa with corticosteroid.

Posterior hip, buttock, and thigh pain

Hamstring injuries

The hamstrings, and in particular the biceps femoris, are the most commonly injured muscle group in relation to sporting activities. Pain, swelling, and bruising are typical in an acute injury. Injuries to the tendon can also occur. Ultrasound and MRI are useful in confirming the site and extent of the injury. Avulsion injuries can occur, usually in those aged under 18 years. In all cases the principle of management is focused on pain management to allow rehabilitation to proceed. Myotendinous ruptures can be managed conservatively, but can take 18 months, and functional outcome may be poor. For this reason, some recommend early repair, particularly in proximal hamstring rupture in athletes. In avulsion injuries where there is a displacement of more than 3 cm, or in any patient where significant hamstrings weakness seems likely, surgical reattachment should be considered. Early surgery followed by hamstring rehabilitation is also recommended in adult athletes.

Piriformis and hamstring syndromes

Posterior thigh pain in the absence of identifiable hamstring pathology or lumbar nerve root compression is a challenge to any sports medicine team. The sciatic nerve can conceivably be compressed or irritated as it travels beneath the pelvic muscles, particularly the piriformis and hamstrings. The 'hamstring syndrome' is considered to be due to neural dysfunction, either as a result of functional 'compression' beneath semitendinosus and biceps femoris, pelvic rotation, or lumbar dysfunction. There may be a constricting band in the vicinity of the nerve deep to the associated muscles, although usually one is not identified.

Piriformis syndrome is considered to be present when there is sciatic nerve irritation in the absence of any spinal pathology, presumably due to a tight piriformis. Adverse neurodynamics are usually present, with a positive straight-leg raise and slump tests. Treatment is stretching, neurodynamic work, and acupuncture.

Ischial (ischiogluteal) bursitis

Ishcial bursitis is rare. It can occur after direct trauma, resulting in localized pain and tenderness. The diagnosis is confirmed on diagnostic ultrasound or MRI. Relative rest, ice, anti-inflammatories, and cushioning are usually effective but a local guided injection of corticosteroid may be necessary. Surgical excision of the bursa is rarely necessary.

CHAPTER 155

Knee

Roger Wolman

Introduction

Knee pain is a common complaint affecting up to 20% of the adult population. In young adults it is most often caused by injury to the patellofemoral joint, menisci, ligaments, or the soft tissues surrounding the knee. In the older population osteoarthritis (OA) is the most common cause. Knee pain may also be the presenting symptom of disorders referred from elsewhere, in particular the hip and lower back.

Functional anatomy

The knee joint is the largest joint in the body. It is a synovial joint and a common source of symptoms in inflammatory arthritis. It is a hinge joint, predominantly moving in the anterior–posterior plane. There is also a small amount of gliding between the tibia and femur and a small rotatory component which can be a cause of injury. These additional movements are restricted by the two cruciate ligaments in the centre of the knee and the medial and lateral collateral ligaments.

The knee has two different articulations. The tibiofemoral joint consists of the medial and lateral femoral and tibial condyles with the medial and lateral menisci lying in between. The patellofemoral joint forms the articulation between the patella and the trochlear groove between the anterior aspect of the medial and lateral femoral condyles. The patella glides through the trochlear groove as the knee flexes and extends. On knee flexion of 90° or more the patella is in close contact with the groove while on full extension it predominantly sits above the groove. This explains why patellofemoral joint pain is often worse on sitting.

The patellofemoral joint is a common source of knee pain and some of this pain may arise from malalignment. Patella alignment within the groove is controlled by several factors. This includes the direction of pull of the quadriceps on the patella, the force of which follows a line from the centre of the patella to the anterior superior iliac spine. The Q angle is the angle formed by this line and a line drawn from the tibial tubercle to the centre of the patella. The Q angle is increased by having a wide pelvis, by femoral neck anteversion and external tibial torsion. A Q angle of greater than 20° is regarded as abnormal and can lead to maltracking of the patella and even dislocation. The quadriceps is made up of four muscle groups—the rectus femoris and the three vasti (medialis, intermedius, and lateralis). These are attached to the patella through the quadriceps tendon with fibrous expansions onto the medial and lateral borders of the patella (the medial and lateral patellar retinacula). The relative strength of the medialis compared to the lateralis influences the stability of the patella. The patella is connected to the tibial tuberosity through the patellar tendon. This can be a source of pain at either end of its attachments in the adolescent, and an overuse injury of the proximal patellar tendon is common, especially in jumping sports. Additional lateral stability of the knee is provided by the iliotibial band. This is a thick fibrous band that attaches into the lateral tibia and the lateral patellar retinaculum. Proximately it is attached to the tensor fascia lata muscle. This structure helps to stabilize the knee in full extension but can be a source of injury, especially in runners.

The three hamstrings are the main flexors of the knee and originate from the ischial tuberosity. The biceps femoris is inserted posterolaterally into the proximal tibia and fibula; the semimembranosus is inserted posteromedially into the tibia; the semitendinosus tendon combines with those of gracilis and sartorius to form the pes anserinus which inserts into the medial aspect of the proximal tibia.

There are several bursas surrounding the knee which can become the source of pain. These include the prepatellar and infrapatellar bursas which lie anterior to the patella and patellar tendon respectively. They can become inflamed as a result of kneeling or from a direct blow to the front of the knee. There are also bursas at the back of the knee, including one lying deep to the semimembranosus and another deep to the popliteus. On the medial aspect of the knee lies the pes anserinus bursa which separates the tendon of the same name from the medial collateral ligament.

Clinical assessment

The history is very important.[1] Pain is the most common presentation but swelling, giving way, or locking may also occur. It is important to know how the symptoms began—sudden onset or insidious. If the onset was acute then what was the mechanism—e.g. twisting, falling, or a direct blow to the knee. If the symptoms are related to activity then it is important to know what activities provoke it and what types of exercise was the person doing at the time of onset of the symptoms. Many overuse injuries around the knee are due to errors in training or the use of unsuitable equipment.

Swelling may be generalized due to an effusion or more localized due to an enlarged bursa. A joint effusion that develops within an

Table 155.1 Causes of knee pain classified by site of pain

Anterior	Posterior	Medial	Lateral	General
Patellofemoral pain syndrome	Baker's cyst (joint effusion)	OA	OA	OA
Patellar instability	Meniscal tear (posterior horn)	Meniscal tear	Meniscal tear	Referred pain (hip or lumbar spine)
Patellar tendinopathy	Hamstring tendinopathy	Medial ligament injury	Lateral ligament injury	Synovitis
Osgood–Schlatters disease		Chronic pain and fibromyalgia	Iliotibial band friction syndrome	Cruciate ligament tear
Pre- and infrapatellar bursitis				Osteochondritis dissecans
Quadriceps tendinopathy	Postero-lateral corner injury	Pes anserinus bursitis/tendinopathy	Proximal tibiofibular joint pain	PVNS
	Popliteus tendinopathy	Pellegrini–Stieda disease		Osteochondromatosis

OA, osteoarthritis; PVNS, pigmented villonodular synovitis.

hour of an acute injury is usually due to a haemarthrosis whereas one taking much longer to develop is due to synovial fluid. The sensation of 'giving way' is usually due to acute pain (such as a catching of the patellofemoral joint) but may be due to instability (as a result of ligament rupture). 'Locking' may be due to a meniscal tear or a loose body within the joint but can occur as a result of patellofemoral joint irritation (often referred to as pseudo-locking). The anatomical site of the pain can help to make the diagnosis—anterior, medial, posterior, lateral, and generalized (Table 155.1).

Anterior knee pain

Patellofemoral pain syndrome

This is a common disorder, often caused by maltracking of the patella in the trochlear groove leading to irritation on the joint surface.[2] As described above there are several factors which help to control patellar alignment. Additional factors in the upper thigh, such as excessive hip adduction and internal rotation (femoral neck anteversion), and in the lower leg, such as rearfoot eversion and overpronation on walking, will also adversely affect patellar alignment.

The patient presents with pain at the front of the knee which is aggravated by walking (especially on a slope), stairs, and prolonged sitting with the knee bent (described as a positive theatre/cinema sign). Wearing high-heeled shoes, by encouraging knee flexion, can cause further pain. Sporting activities such as running, cycling, and swimming (especially breast stroke) may also aggravate the symptoms. The knee may give way due to pain inhibition of the quadriceps. There may also be a sensation of locking in full extension due to pain (pseudo-locking).

Examination findings include patellofemoral joint tenderness and pain on patella grind. There may be a small effusion and quadriceps muscle wasting, especially affecting the vastus medialis. Examination should also include an assessment of the factors that affect patellofemoral alignment as described above.

Treatment will initially include decreasing or avoiding activities that provoke the symptoms (relative or absolute rest). The patient should be referred for physiotherapy[3] to address the biomechanical problems and provide muscle reconditioning for the quadriceps (vastus medialis especially) and glutei as well as flexibility training for the hamstrings. Techniques to loosen tight lateral knee structures such as the iliotibial band and the lateral retinaculum will

also help. Taping of the patella as well as the use of foot orthotics in patients with overpronated feet should be considered. It is important to treat this condition, as recent evidence suggests that prolonged symptoms related to this condition increase the risk of patellofemoral osteoarthritis (OA).[4]

Patella dislocation and instability

Patella dislocation and instability occurs most commonly in adolescent girls. The biomechanical risk factors, which are similar to those for patellofemoral pain syndrome, also include a shallow trochlear groove and a high-riding patella where the patellar tendon is relatively long (patella alta) and the patella may lie above the groove. Joint hypermobility also increases the risk.

An acute dislocation may be the first sign of the problem. This may occur as a result of trauma but can occur spontaneously. The patella dislocates laterally and will usually reduce spontaneously or with relatively little pressure. Traumatic dislocation will be associated with acute swelling due to a haemarthrosis. The swelling may be less following a spontaneous dislocation. There will be tenderness over the medial retinaculum as a result of the torn fibres. Investigations should include plain radiographs, in particular lateral and skyline views to look for patella alta and a shallow groove, and MRI will help to determine whether an osteochondral fracture has occurred.

Acute dislocation requires immobilization in extension in a leg cylinder for 4–6 weeks followed by physiotherapy. Recurrent dislocation or instability will require more extensive physiotherapy addressing the biomechanical issues that may have contributed to the injury. In cases that do not respond to conservative treatment, surgery should be considered. This includes a release of the lateral retinaculum or patella realignment procedures.[5]

Patellar tendinopathy

As this is seen in athletes doing jumping sports, such as basketball and volleyball, it is often referred as jumper's knee. However, it also occurs in other sports and in the non-sporting population. The abnormality occurs at the proximal end of the patellar tendon with degenerative changes, new vessel formation, and tears evident on histology. The patient will have infrapatellar tenderness and pain aggravated by weightbearing exercise and especially by squats. It may occur with patellofemoral joint pain, as they share similar biomechanical risk factors.

Diagnosis can usually be made clinically and confirmed on ultrasound scanning. This shows changes at the proximal end with enlargement of the tendon, new vessel formation, disruption of the fibres and areas of low echogenicity. Changes can also be seen on MRI (Figure 155.1).

Treatment involves relative rest to help offload the tendon. Biomechanical factors should be addressed. Rehabilitation should include slowly progressive quadriceps strengthening, including eccentric exercises. Image-guided injections of either whole blood or platelet-rich plasma have been advocated although at present there is no strong evidence-base for their use.[6] Resolution of the problem may take up to 6 months. If the problem persists beyond this time despite good conservative treatment then surgery should be considered. There are a range of surgical treatments but the outcomes are unpredictable.

Quadriceps tendinopathy

This occurs at the site of attachment of the quadriceps to the upper border of the patella. There is pain and localized tenderness over this site. It is far less common than patellar tendinopathy. Treatment principles are similar with relative rest, quadriceps reconditioning exercise, and possibly the use of injections.

Enthesial disorders in adolescence

Osgood–Schlatter disease

This occurs at the site of attachment of the patellar tendon to the tibial tuberosity apophysis (Figure 155.2). This is weaker during

Fig. 155.2 Osgood–Schlatters disease: lateral radiograph of the knee showing swelling of the distal patellar tendon (arrow) and new bone formation (arrowhead) at the tendon insertion to the tibial tuberosity.

All the imaging has been provided by Dr A Saifuddin, Consultant Radiologist, Royal National Orthopaedic Hospital.

the adolescent growth spurt and therefore vulnerable to the intense traction that occurs with weightbearing sports. It tends to occur in girls between 11–13 years and in boys between 13–16 years. There will be a localized area of pain and tenderness and the tuberosity may become more prominent.[7] With mild symptoms the adolescent can continue to exercise through it. With more severe symptoms relative rest and physiotherapy may help. The symptoms usually resolve within a year.

Sinding–Larsen–Johansson syndrome

This occurs at the site of attachment of the patellar tendon to lower pole of the patella and occurs in a similar age group as seen in Osgood–Schlatter's, although it is far less common. Management is similar.

Prepatellar and infrapatellar bursitis

These can occur as a result of prolonged kneeling (housemaid's and clergyman's knee respectively). They may also occur as a result of a direct blow. They present with swelling at the front of the knee with relatively little pain. Examination reveals a well-circumscribed fluctuant mass with thickening of the adjacent soft tissues. Diagnosis can be confirmed on ultrasound which will demonstrate the fluid-filled sack and increased Doppler signal on the deep surface due to its good blood supply.

Treatment requires avoidance of kneeling and may require aspiration of the fluid and injection of steroid. This may need to be repeated. Very occasionally a surgical bursectomy is required.

Medial knee pain

The soft tissues on the medial aspect of the knee are a common trigger-spot site. It occurs in fibromyalgia and may be associated with vague pain.

Medial meniscus injury

An acute twisting injury to the knee can result in a tear to the medial meniscus with pain, joint effusion, and possibly locking. A small tear results in mild, more localized symptoms. In middle age, changes in the medial meniscus can result in symptomatic degenerative tears. These can produce pain along the medial joint line on weightbearing with associated joint-line tenderness, a positive McMurray's test, and pain on full flexion of the knee. The diagnosis can be confirmed on MRI. These tears usually respond to conservative management of rest and rehabilitation.[8] Occasionally an arthroscopic meniscectomy is indicated. However, the risk of partial meniscectomy is that it may expose the articular cartilage which, in a middle-aged patient, may itself be degenerate. This can sometimes make the pain worse.

Medial osteoarthritis

Medial tibiofemoral joint osteoarthritis and a degenerative meniscal tear can produce similar symptoms. They often occur together. Patients may have a varus deformity of the knee. Radiographs help to confirm the diagnosis of OA and MRI will help to distinguish between the two conditions.

Medial ligament injury (medial ligament syndrome)

Injury to the medial collateral ligament occurs as a result of valgus stress on the knee. This is more common in women, who are more likely to have a valgus alignment of the knee. It can also occur in breaststroke swimming, where there is a persistent valgus stress on the knee. This can produce a grade I injury (sprain without a tear). Acute knee injuries caused by sudden valgus stress, as in football, can cause more severe injuries including a partial (grade II) or complete tear (grade III) of the ligament. These can be diagnosed clinically by assessing for pain and/or laxity on applying a valgus stress to the knee. Conservative treatment with a combination of rest and immobilization followed by rehabilitation is usually successful.[9]

Pellegrini–Stieda disease

This occurs as a result of a tear to the femoral origin of the medial collateral ligament. Calcification forms at the site which can be seen on the radiograph (Figure 155.3). There will be pain, tenderness, and swelling on the medial aspect of the knee. This usually responds to rest, physical therapy, and non-steroidal anti-inflammatory drugs (NSAIDs). Occasionally a steroid injection can help.

Pes anserinus bursitis/tendinopathy

This tendon, as described above, inserts into the anteromedial upper tibia. The bursa lies between the tendon and the tibial surface (Figure 155.4). This can become symptomatic. It is associated with valgus deformity of the knee,[10] and occurs in runners and breaststroke swimmers. The features include localized swelling and tenderness with pain on activity. Treatment consists of rest and physical therapy. A corticosteroid injection will be helpful if there is a significant bursal swelling.

Fig. 155.4 Pes anserinus bursitis: coronal PDW FSE MRI showing a prominent bursa (arrows) overlying the medial collateral ligament and involving the distal pes anserinus tendons.
All the imaging has been provided by Dr A Saifuddin, Consultant Radiologist, Royal National Orthopaedic Hospital.

Posterior knee pain

The most common cause is a joint effusion which can stretch the posterior joint capsule to cause pain. It can cause a Baker's cyst where the capsule herniates between the two heads of gastrocnemius. It is important to address the cause of the effusion. Tears affecting the posterior aspect of either meniscus may also cause posterior pain.

Posterolateral corner injury

This refers to an injury of the structures that stabilize the posterolateral corner of the knee. It includes the lateral collateral ligament, the popliteus, the iliotibial band, and a series of small ligaments in this area. It is often combined with an injury to the lateral meniscus and posterior cruciate ligament, producing laxity to the lateral knee, a varus deformity, and ultimately medial joint arthritis. The injury occurs when a posterolateral force is directed onto the medial aspect of the tibia leading to varus stress. The patient complains of pain and instability. There are several clinical tests that help to point to the diagnosis which can be confirmed on stress radiographs, MRI (Figure 155.5), or diagnostic arthroscopy. Mild injuries can be treated conservatively but more severe injuries require surgical correction.[11]

Popliteus tendinopathy causes posterior knee pain. It rarely occurs in isolation,[12] usually being part of the above injury.
Hamstring injury

The biceps femoris is the hamstring tendon that is most commonly injured, causing posterolateral knee pain. Diagnosis can be made clinically by tenderness over the tendon and pain on resisted knee flexion and on stretching the tendon. It can be confirmed on ultrasound. It usually responds to rest and rehabilitation over a 3–6 week period.[13]

Lateral knee pain

Injuries to the lateral collateral ligament in isolation are relatively uncommon. They occur as a result of a varus stress applied to the knee and usually occur in association with other structures of the posterolateral corner as described above.

Iliotibial band friction syndrome

This occurs as a result of friction between the deep surface of the iliotibial band and the lateral epicondyle of the femur. It occurs in runners, especially on going downhill. It can occasionally be seen in downhill walkers. Biomechanical factors such as overpronated feet increase the risk. The patient typically complains of lateral knee pain brought on by running. If they continue to run through it the pain will tend to come on earlier in the run and will eventually prevent them from running. Examination reveals tenderness over the lateral femoral condyle and tightness of the iliotibial band on Ober's test, which may also provoke the pain. Diagnosis can be confirmed on ultrasound or MRI (Figure 155.6). Treatment consists of relative rest and the use of ice and NSAIDs to reduce the irritation. Occasionally

Fig. 155.5 Posterolateral corner injury: sagittal fat-suppressed PDW FSE MRI showing oedema (black arrows) at the popliteus musculotendinous junction (black arrowhead).

All the imaging has been provided by Dr A Saifuddin, Consultant Radiologist, Royal National Orthopaedic Hospital.

Fig. 155.6 Iliotibial band friction syndrome: coronal fat-suppressed PDW FSE MRI showing fluid (white arrow) deep to the iliotibial band (white arrowheads) consistent with iliotibial band friction syndrome.

All the imaging has been provided by Dr A Saifuddin, Consultant Radiologist, Royal National Orthopaedic Hospital.

a steroid injection is required. Rehabilitation consists of stretching exercises for the iliotibial band and addressing other biomechanical factors which may be contributing to the symptoms.[14]

Lateral meniscus injury

Tears to the lateral meniscus are less common than the medial meniscus. They also respond less well to surgery. Acute tears can occur in the young athlete, while chronic degenerative tears occur in middle age causing knee pain on weightbearing. Examination will demonstrate positive meniscal signs. Occasionally a lump is seen on the lateral joint due to subluxation of the meniscus or due to a meniscal cyst. Diagnosis can be confirmed on MRI. For chronic degenerative tears the treatment of choice is conservative with rest and rehabilitation. Surgery is reserved for those not responding to conservative treatment.[15]

Proximal tibiofibular joint pain

This joint can become symptomatic as a result of a direct blow or following a rotational injury to the knee. The joint may then become unstable causing lateral knee pain, especially on weightbearing. MRI may be helpful in demonstrating soft tissue damage around the joint. Treatment is usually conservative and may involve immobilization of the joint following an acute injury. Physiotherapy can be helpful. Surgery may be required for a persistently unstable symptomatic joint.[16]

Generalized knee pain

Intra-articular pathology may lead to a more generalized knee pain. Inflammatory arthritis often causes synovitis within the knee with associated pain and swelling.

Cruciate ligament ruptures

These injuries occur in weightbearing twisting sports and more commonly affect the anterior ligament (Figure 155.7). Once this injury has occurred the risk of developing OA in later life is high, even if surgical
reconstruction is performed. In the young adult who wants to get back to a similar level of sport, a reconstruction operation is usually required. In the middle-aged adult, or in an adult who is willing to make lifestyle changes, conservative treatment is usually successful.[17,18]

Osteochondritis dissecans

In this condition a piece of articular cartilage becomes detached from the subchondral bone probably as a result of avascular necrosis (AVN), possibly caused by trauma. It most commonly occurs in teenage males. The main symptoms are pain, swelling, limitation of movement, and possibly locking. Diagnosis can be made on imaging (plain radiograph, CT, and/or MRI; Figure 155.8). Treatment initially consists of rest and physiotherapy. If the fragment is stable this is likely to be successful but if the fragment is loose or has detached then arthroscopic surgery is usually required. This will include removal of the loose fragment or reattachment to the bone. If there is an area of exposed bone then drilling to encourage fibrotic healing or cartilage transplantation are treatment options. There is an increased risk of developing OA.[19]

Pigmented villonodular synovitis

This is a rare proliferative disorder of synovial tissue. The knee is the most common joint to be involved. Although it is locally invasive and has a high recurrence rate, it remains unclear whether this is an inflammatory or neoplastic condition.[20] It most commonly occurs between the ages of 20 and 50 years and presents with pain, swelling, and limitation of movement. Examination findings include a joint effusion and quadriceps wasting. Joint aspiration usually produces bloodstained synovial fluid which should raise the possibility of this diagnosis. MRI gives a very characteristic appearance (Figure 155.9) and is the investigation of choice for making the diagnosis. Aspiration and steroid injection only provides brief pain relief. Surgical synovectomy (either arthroscopic or open) is the treatment of choice although the recurrence rate is 40–60% at 5 years. Radiation (using a yttrium implant or external radiation)

or chemical synovectomy (using osmic acid) offer alternative treatment strategies.[21]

Osteochondromatosis

The aetiology of this condition is poorly understood. It tends to occur between the ages of 30 and 50 years, more commonly in men. The knee is the most common joint to be affected. Synovial cells undergo chondroblastic metaplasia, which then produce deposits of cartilage in the synovial membrane. These grow, calcify, and eventually detach to become loose bodies within the joint. They then become symptomatic causing pain, swelling, and locking. Examination findings are non-specific. Diagnosis can be made on radiograph (Figure 155.10), CT, and/or MRI. Treatment is surgical and should include arthroscopic removal of the loose bodies together with synovectomy to reduce the risk of recurrence.[22] The prognosis is good with a recurrence rate of 5–10%. Malignant transformation is rare.

Lipoma arborescens

This is a very rare disorder of the synovium, of unknown aetiology. It most commonly affects the knee, in particular the suprapatellar pouch. Macroscopically there are numerous papillary villi containing mature adipose tissue with an overlying synovial membrane. The patient presents with pain, swelling, and restricted movement. MRI shows a characteristic appearance of the synovial tissue within the joint. Definitive treatment is with open or arthroscopic synovectomy. Alternative treatments include radiation or chemical synovectomy.[23]

Foot and ankle

Anthony C. Redmond and Philip S. Helliwell

Introduction

Foot problems are common, with approximately 10% of adults reporting significant foot pain at any given time. The prevalence increases with age such that one-half of people over 50 years of age have foot pain.[1,2] Foot problems are five times more common in females than males.[3,4] Foot problems impact significantly, interfering with daily activities,[5,6] and they rarely occur in isolation, usually presenting concomitantly with other musculoskeletal problems such as hip or knee pain.[7] The relevance of musculoskeletal foot pain is relatively well recognized in systemic diseases such as inflammatory arthritis, but the majority of foot pain occurs in otherwise healthy people[6] and foot problems should be considered in a context of local function as well as general health. Although the prevalence of foot symptoms is high in people attending rheumatology clinics, the foot and ankle remains relatively neglected. Possibly this is due to poor training in clinical examination techniques,[8] which is compounded by the inconvenience of accessing feet that may be considered unsightly or smelly. As a consequence foot problems are often ignored or may be referred on unseen to allied services such as podiatry.

Clinical assessment

A basic assessment need take no more than approximately one minute per foot as long as it is performed by an assessor with the requisite knowledge, skill and practice. A basic starting point for a lower limb assessment is the Regional Examination of the Musculoskeletal System (REMS),[8] supplemented by further foot-specific assessments as required (Box 156.1).

For more detailed foot evaluation, we have described extensively a Leeds foot assessment protocol which is a comprehensive assessment of foot problems developing the standard sequential approach of history → observation → examination. A thorough development of this can be found elsewhere.[9,10]

Foot and ankle pathology in rheumatology

The remainder of this chapter focuses on the conditions affecting the foot and ankle, as encountered in rheumatology practice. Much of the best evidence surrounding foot and ankle problems in rheumatology centres on rheumatoid arthritis (RA), and this, and the other systemic conditions, is be covered in detail. The chapter

---

Box 156.1 Regional Examination of the Musculoskeletal System: foot components

- ◆ Examine sole of patient's feet
- ◆ Recognize hallux valgus, claw and hammer toes
- ◆ Assess the patient's feet in standing
- ◆ Assess for flat feet (including patient standing on tiptoe)
- ◆ Recognize hindfoot/heel pathologies
- ◆ Assess plantar- and dorsiflexion of the ankle
- ◆ Assess movements of inversion and eversion of the foot
- ◆ Assess the subtalar joint
- ◆ Perform a lateral squeeze across the metatarsophalangeal joints
- ◆ Assess flexion/extension of the big toe
- ◆ Examine the patient's footwear

After Coady et al.[8]

---

starts, however, with a brief summary of the many foot conditions often encountered that are not the product of systemic disease and can be dealt with purely through their local effects.

Local foot and ankle problems

Flat feet (pes planus) and high-arched feet (pes cavus)

One of the more common non-specific foot complaints is so-called 'flat feet', which may or may not underlie symptoms resulting from 'overuse' type stresses and strains. Although some feet show frank flattening of the medial arch, the structural and functional variations are relatively complex. The presence of a flat foot (or indeed a high-arched foot) does not inherently imply pathology, as the range of normal foot postures is wide. It is unusual to initiate treatment of an asymptomatic flat foot and so therapy is directed at the combination of the symptoms and the underlying mechanics. Mechanical therapies can include footwear modifications, foot orthoses, taping, splints, and braces. Usually the goal is to limit excessive joint mobility and promote stability. Therapy for the cavoid foot is aimed at improving shock absorbency and stretching tight soft tissues. Treatments can include cushioning insoles, change in footwear, and stretching exercises.

Nerve entrapments

Nerve entrapments occur in the feet of rheumatology patients because of the complex anatomy and high prevalence of osteophytes and altered bony structures in this population. The most common nerve entrapment syndrome in the foot is Morton's neuroma, which affects the plantar digital nerve just proximal to the metatarsal heads. It is usually seen in the third and fourth metatarsal space, but can occur between any digits. Tight footwear and high-heeled shoes exacerbate the symptoms and the clinical diagnosis can be aided by squeezing the forefoot across the metatarsals, while exerting a pressure between the metatarsophalangeal (MTP) joints of the affected area to reproduce symptoms. Treatment may include advice to adopt wider-fitting shoes, orthoses, local steroid injection, or oral non-steroidal anti-inflammatory drugs (NSAIDs). Surgery may be required in severe cases. The other significant nerve entrapment found in rheumatology is tarsal tunnel syndrome, which arises when the tibial nerve is compressed as it passes around the medial aspect of the ankle in close association with the tendons under the flexor retinaculum. Tarsal tunnel syndrome may be caused by chronic inflammation of the medial tendons, or secondary to severe valgus position of the ankle, such as can occur in RA. The symptoms are tingling, numbness, and pain in the arch area, which can extend to the plantar surface and medial aspect of the ankle. Clinical diagnosis is made by percussion using Tinel's sign. If the compression arises from local inflammation (e.g. tenosynovitis), local injection of steroid may be helpful. Where heel position is the cause, short-term reduction of symptoms can sometimes be achieved by splinting, taping, or orthoses, although in severe cases referral for surgical assessment is required.

Tendinopathy

The two most common tendonopathies affect the Achilles tendon and the tendon of tibialis posterior. The Achilles tendon can be affected at the myotendinous junction, in the tendon substance, or at the insertion into the calcaneus. Acute, traumatic tears do not usually present in rheumatology outpatient clinics. Chronic lesions are picked up on clinical examination with symptoms of pain and swelling over the tendon exacerbated by weightbearing and dorsiflexion of the foot. Over time the tendon thickens and a fusiform swelling may be palpable and confirmed on MRI or ultrasound imaging (Figure 156.1). There are no definitive treatments,

but Alfredson and Cook[11] have proposed a treatment algorithm based on rest, ice, compression, and rehabilitation, combined with offloading of the Achilles through taping or a heel lift and careful eccentric strengthening.

Tibialis posterior dysfunction is a progressive tendinopathy which leads to an acquired flat foot. Patients (often postmenopausal women) experience pain and swelling on the medial aspect of the ankle and there may be progressive flattening of the arch. Characteristically, the patient is unable to stand on tiptoe on the affected side, unless stabilized by the contralateral limb. Definitive diagnosis is made with ultrasound or MRI[12] and early identification and treatment is important to prevent progression. Non-surgical treatment focuses on symptom relief symptoms and offloading the tendon using orthoses, footwear, ankle taping, or braces. Surgical treatment employs tendon transfer in the early stages with additional rearfoot osteotomy if required. Total reconstruction and arthrodesis of the rearfoot is required in severe cases.

Heel pain

Plantar heel pain affects one in ten of all people at some stage in their lives and is again more common in rheumatology patients.[13] The most common underlying pathology is plantar fasciitis, characterized by thickening of the plantar fascia at the proximal enthesis and sometimes extending along the fascia (Figure 156.2). The typical symptom is pain along the plantar surface of the heel or midfoot during activity or weightbearing. There may be focal tenderness at the origin, particularly first thing in the morning or after period of non-weightbearing. The clinical signs and symptoms are usually sufficient for diagnosis but ultrasound can be useful to confirming thickening. Treatment is change of footwear and weight loss where appropriate as a first option, with physical therapies sometimes helpful. There is some evidence for the efficacy of taping[14] and contoured foot orthoses,[15] and there is also limited evidence for the short-term efficacy of injection therapy with corticosteroid although the injections are painful and the long-term efficacy of injection is doubtful.[16,17]

Posterior to the heel are two sites sometimes affected by bursitis: the retrocalcaneal bursa, an anatomical bursa deep to the Achilles tendon, and the Achilles bursa which, when present, is adventitious and superficial to the tendon. The Achilles bursa is particularly prone to aggravation from footwear. The deeper, retrocalcaneal
Fig. 156.1 Achilles tendonopathy: a fusiform swelling of the tendo Achilles with power Doppler signal indicating severe tendonopathy [a].

bursa is more often associated with systemic inflammatory disease such as RA. MRI or ultrasound imaging is diagnostic.

Treatment of local, mechanical bursitis centres on physical therapies and NSAIDs. Modification to footwear is essential to prevent further irritation. Bursitis associated with inflammatory disease usually responds to corticosteroid injection.

Forefoot pain

In the forefoot, MTP joint mechanical overload can occur because of clawing/subluxation of the toes or loss of fat-pad protection. There may be low-grade discomfort, and associated thickening of the skin, pathological thickening of the skin (callus and corn formation), or bursitis overlying the MTP joints or inflammation of the intermetatarsal bursas. Intermetatarsal bursitis is a common manifestation of inflammatory arthritis and can also be seen in otherwise healthy individuals. Sharp pain will be elicited with a lateral squeeze test across the metatarsal heads. MRI and ultrasound is required for definitive diagnosis. Bursitis will respond well to local injection of corticosteroid.

The foot and ankle in rheumatoid arthritis

The foot has many synovial structures and so the foot is involved in about 80–90% of people with RA.[18–20] Even in early disease, estimates of foot involvement range from 32% to 75%,[21,22] and initial symptoms are reported in the foot almost as frequently as in the hands. The forefoot is the most commonly involved region,[21,23] and the subtalar joint is also involved in two-thirds to three-quarters of all people with longstanding RA. The ankle joint proper is relatively spared, being affected in only 10–20% of people with established RA. As many as one-quarter of patients experience soft tissue problems in the foot, such as plantar fasciitis, peroneal tendonitis, or bursitis.[19,24]

While the articular damage occurs primarily because of synovitis, the inflammatory damage is compounded by the mechanical stresses affecting weightbearing structures. The combination of damage drivers results in irreversible structural changes such as characteristic forefoot changes, flattening of the arch, valgus deformity of the heel, and tibialis posterior dysfunction (Figure 156.3).[24] With better disease-modifying anti-rheumatic

Fig. 156.3 The typical changes occurring in the feet of a person with rheumatoid arthritis.

drug (DMARD) therapy and better early intervention, the presentation of the typical 'rheumatoid foot' appears to be less common, although not all patients do well, even on biologics. Synovitis in the MTP joints leads to stretching and weakening of the joint capsule and failure of the stabilizing structures in the forefoot.[25,26] When the MTP joint dislocates, the plantar fat pad is pulled distally, exposing the metatarsal heads.[27] DMARD therapy helps attenuate this process, although a recent study has indicated that the prevalence and severity of forefoot joint damage continues to accumulate in patients with RA even in the face of clinically effective DMARD treatment.[28]

Soft tissues involved in RA include tendon sheaths, bursas, and entheses.[29] Tenosynovitis of the tibialis posterior or peroneal tendons may be florid. Retrocalcaneal bursitis may present as swelling either side of the Achilles tendon. Nodules may occur, typically at the Achilles tendon, the heel pad, or over bony prominences.

Treatment approaches are set out in the National Institute for Health and Clinical Excellence (NICE) Clinical Guideline CG 79, which recommends that all patients with RA and foot problems should be referred for podiatry assessment,[30] and in the Podiatry Rheumatic Care Association (PRCA) Standards of Care for People with Musculoskeletal Foot Health Problems, which reinforce the need for assessment and management of foot problems in RA, particularly in early RA.[31] Foot health services for rheumatology patients remain highly variable, with large regional variation in the provision of services and a significant unmet need.[32]

There is reasonable evidence that foot orthoses reduce foot pain and improve functional ability in people with RA,[33] although a critical review of foot orthoses in patients with RA demonstrated a lack of consensus on the precise types of foot orthoses likely to do best.[34] Provision of footwear for patients with RA is supported by national guidelines and therapeutic footwear has been shown to provide good symptom relief and improvement in function in patients with RA. Compliance with prescribed footwear can be poor, however, due to dissatisfaction with fit, comfort, and style, particularly in women.

Finally, painful plantar callosities can build up over metatarsal heads and regular scalpel debridement has been the treatment of choice. Callus reduction appears ineffective if used in isolation, however, and should at least be combined with other interventions, such as provision of foot orthoses, to prevent recurrence of symptoms.[35]

Psoriatic arthritis and seronegative diseases

Dactylitis is the classic presenting feature for psoriatic arthritis in the foot, and involvement of the skin and nails completes the picture. Articular involvement varies from involvement of a single mid- or rearfoot joint, to a destructive polyarthritis with extensive bone loss. Bezza et al. reported foot symptoms including plantar heel pain, metatarsal pain, dactylitis, and involvement of the ankle and midfoot as a possible initial manifestation of disease.[36] In established disease, as many as 95% of people with psoriatic arthritis have forefoot involvement including hallux valgus and claw toes; rearfoot deformity in the form of pes planovalgus has been reported in 65%.[37]

Imaging studies have shown inflammation in the midfoot joints in psoriatic arthritis and, given the limitations of clinical examination in this area, appropriate imaging is necessary if midfoot involvement is suspected.

Enthesitis is the striking feature of seronegative disease in the foot, typically at the insertion of the Achilles tendon and origin of the plantar fascia. Even in early psoriatic arthritis, the prevalence of plantar fasciitis and Achilles insertional enthesitis has been reported as 12% and 6%, respectively.[38] On imaging, enthesitis may also be seen at the attachment of the tibialis posterior tendon and the insertion of peroneus brevis as well as other sites.[37] Prior to diagnosis, a presentation of isolated, recurrent, or bilateral Achilles enthesitis should suggest a diagnosis of spondyloarthropathy. There may be osteitis close to the affected entheses, although this is seldom appreciated clinically, and osteitis may also occur in the sesamoid

bones. The management of enthesitis is largely empirical; steroids can be used with good effect at the insertions of the peroneus brevis, tibialis posterior, and plantar fascia. The Achilles insertion poses a particular challenge: the use of depot steroids in this locality is discouraged because of the catastrophic risk of rupture.

Dactylitis as a manifestation of all of the above features is more common in the feet than the hands, with the fourth toes most frequently involved.[39] Dactylitis is an adverse prognostic factor; and the presence of any dactylitis is associated with more severe disease, including arthritis mutilans. Plain radiography may show typical changes such as erosion of the terminal phalangeal tufts, juxta-articular and entheseal new bone formation, periostitis, and severe osteolysis. In dactylitis, determining a precise location for steroid injection can be difficult although it is likely that wherever the steroid is deposited, there will be some diffusion and (beneficial) effect in nearby tissues. There is currently no specific evidence to support the use of interventions such as the provision of footwear and orthoses in psoriatic arthritis, but drawing on the combination of evidence for RA and clinical experience, it is reasonable to conclude that the inflammatory and mechanical factors that affect the feet in psoriatic arthritis should be addressed in much the same way as in RA.

Crystal diseases

Acute gout may occur in any of the joints of the foot although it is most common in the first MTP joint. The presentation is of an acute, hot, swollen joint which is exquisitely tender, with rapid onset. The pain is severe enough to prevent weightbearing but acute episodes typically settle in 10–14 days. Chronic (tophaceous) gout usually occurs insidiously and is often involves large and small joints. The chronic form is likely to be associated with radiological abnormalities such as peri-articular erosions. Tophi may occur in the Achilles tendon and in juxta-articular positions, associated with deformity and swelling. Chronic discharging tophaceous gout is associated with severe pain and disability.

Osteoarthritis

Specific information about foot osteoarthritis (OA) is poor because of lack of consistency in definitions. Radiological definitions generally lead to higher estimates of prevalence, while clinical presentations (symptoms/pain) yield variable rates. Subclinical signs are noted in many older patients, with one cadaveric study reporting moderate or severe degeneration in onehalf of first MTP joints.[40] Beyond the first MTP joint, most cases of foot OA are secondary to mechanical damage, trauma, or systemic disease.[41] Joint pain is common in the feet of older adults and presents most commonly in combination with other joints such as knees, back, hands, and hips.[7]

Clinical signs are stiffness, aching, and/or crepitus in the affected region and degenerative joint disease is often noted during ultrasound examination of foot joints, although the finding is often incidental, reflecting the subclinical nature. The best-known manifestation of OA in the foot is at the first MTP joint where the joint damage presents as limitation, fixation, or deformity of the hallux joint (known as hallux limitus, hallux rigidus, or hallux valgus). Restorative therapies are not well developed for foot OA and so NSAIDs and rest remain the initial treatments of choice, along with advice on exercise, weight loss, and footwear. Insoles and therapeutic footwear may be of benefit and are recommended

by NICE as adjunct therapies. Where conservative treatment fails, surgical intervention can be definitive. Arthrodesis remains the surgical option of choice for most foot OA although at the first MTP joint, where joint-preserving 'bunion' surgeries have become more sophisticated, the prognosis has improved markedly in recent years.

Connective tissue diseases

Vascular features are found in the feet of 90% of people with connective tissue diseases (CTDs) and include Raynaud's phenomenon, telangiectasia, and purpura. Vasculitis and ulceration occur in 10–20% of people with CTDs, in the hands and in the lower extremity.[42] Large-vessel vasculitis and accelerated atherosclerosis compound the effects of local vasculitis, leading to gangrene and increased risk of amputation.[43] Vasculitic ulcers are often intensely painful and the healing process can be lengthy. Patients with CTDs may have coincident inflammatory arthropathy in the feet although it is usually milder than seen in RA.

In systemic sclerosis, Raynaud's phenomenon is often the initial presentation with later oedema and fibrosis of hands or feet (Figure 156.4). Flexion contractures can impair mobility and calcified nodules may manifest on the digits or other areas of mechanical stress. Synovitis may be present, but tends to affect larger joints more than the feet.[44] Similarly, involvement of the foot is generally less common and less severe in the feet than in the hands.[45] Onycholysis and pitting of the nails may also be seen, similar to that occurring in psoriasis. Splinter haemorrhages may also be seen in the nail beds, reflecting the vascular involvement.

The effect of skin and subcutaneous fibrosis, combined with changes in the underlying skeletal structures has been reported to lead to difficulties with shoe fitting,[46] and although not mandated by NICE in the same way as for people with RA, it appears sensible that patients with systemic sclerosis should undergo regular foot checks and should have access to foot health services.

Hypermobility syndromes

In the opening section of this chapter, the local effects of foot posture were discussed and are compounded in the presence of systemic hypermobility. There is some evidence that people with joint hypermobility have greater foot impairment than matched

controls, and that the severity of symptoms correlates with severity of systemic hypermobility.[47] Where there is laxity of foot joints, the midfoot appears more unstable than the hindfoot joints.[48] Treatments are aimed at improving mechanical stability, although there is minimal formal evidence. Building muscle strength may be advantageous, and Pilates-type approaches seem generally helpful. People with hypermobile joints may have pathological tightness of surrounding muscles and tendons, and gentle stretching can also be useful. Footwear choice is important, and a stable shoe combined with cushioning shock-absorbing materials may help to relieve symptoms. Some people with mechanical foot pain will benefit from foot orthoses which control joint function and stabilize specific foot joints.

Conclusion

The foot and ankle are often involved in rheumatic diseases but are often neglected in rheumatology practice. The presentations in the foot can reflect disease manifestations in general but, in addition to treating the systemic disease, particular local circumstances—e.g. the increased mechanical demands on weightbearing structures—dictate a targeted approach local to the foot. If the foot is not considered by the assessing clinician, and there may be a number of barriers to successful assessment of this region, implementation of appropriate therapies will not occur.

CHAPTER 157

Cervical and lumbar spine

David A. Walsh

Introduction

Axial pain is a major source of distress and disability. Mechanisms underlying the pain are often complex, and treatments may not always alter its natural history. Problems of the cervical and lumbar spine therefore place substantial demands on healthcare resources, and pose challenges to practicing clinicians. Chronic spinal pain is so common that it may be considered a normal, albeit undesirable, attribute of life.

Many different theoretical models have been developed in order to explain spinal pain, each supported by research evidence. These models inform diverse treatment strategies among different health care professionals. Some see spinal pain as a result of specific structural or pathological change, leading, for example, to diagnostic and therapeutic injections and surgery. Some see it as an abnormality of neuromuscular control, recommending to specific exercise therapies. Some see it as a result of abnormal processing of sensory signals by the central nervous system, and some see it as a consequence of various adverse psychosocial factors. These models are not mutually exclusive. Many patients are not 'cured' by any single treatment and, as they progress through often complex treatment pathways, they may experience diverse and apparently contradictory explanations and treatment recommendations.

The expert practitioner should provide a coherent explanation that is consistent with management advice, respecting and building upon the patient's prior understanding and experiences. Success in this requires a clear understanding of the mechanisms behind spinal pain, and the congruity between explanatory models. It also requires the ability to convey this understanding unambiguously to the patient.

Epidemiology

Low back pain is one of the commonest causes of pain and disability in Western populations, with a lifetime prevalence of up to 85%.[1] Nearly one-third of a United Kingdom population experienced back or neck pain in any month, nearly one-half of whom reported that their pain was disabling.[2] The problem of mechanical low back pain peaks in the sixth decade, and, although prevalence may remain stable at around 20% in later life, its impact may increase as general health declines.[2–4] Diverse factors may predict spinal pain, including female gender and adverse psychosocial factors.[2,5] Although slightly less common than low back pain, lifetime prevalence of neck pain may be up to 70% with 12 month prevalence up to 50%.[6] Back and neck pain often coincide with each other, and with other chronic musculoskeletal pain problems.[2,5]

Normal anatomy of the cervical and lumbar spine

The spine provides stability, a high degree of mobility, and protection of the spinal cord. To achieve this it has evolved a complex and highly specialized structure. Vertebrae undergo endochondral ossification during development with primary ossification centres in the centre of the vertebral body, one each side of the neural arch at the base of the transverse processes, and ring epiphyses around the outer boarders of each vertebral endplate. Secondary ossification centres are located in the transverse and spinous processes. During childhood and adolescence, coordinated growth around these multiple centres maintains into adulthood the normal resting cervical and lumbar lordoses and dorsal kyphosis, without rotation or lateral angulation (scoliosis).

Vertebrae articulate with each other through the intervertebral discs and facet joints (Figure 157.1). The disc comprises a highly hydrated nucleus pulposus enclosed by the annulus fibrosus that contains little water. These appear bright and dark respectively on T2-weighted MRI. The caudal and rostral disc surfaces interface with hyaline cartilage coating the vertebral endplate. Facet joints, unlike discs, are lined by synovium. The spinal canal is in close proximity to the facet joints and posterior region of the disc, and spinal nerve roots emerge through the spinal foramina whose borders (and therefore size) are determined by the disc, facet joint and ligamentum flavum.

Sources of axial pain are incompletely understood, although several spinal structures contain sensory nerves. Fine, unmyelinated nerves containing neuropeptides such as substance P and calcitonin gene-related peptide (CGRP) are localized to facet joint synovium, muscle, ligaments, tendons, bone, and the annulus fibrosus.[7] Unmyelinated sensory nerves may convey slow, ongoing pain, often described as burning. Faster-conducting, myelinated fibres in muscle, tendons, ligaments, and bone may be responsible for immediate, but again often continuing pain. By contrast, the nucleus pulposus and the hyaline cartilage coating the vertebral endplates and facet joints contain no sensory nerves in healthy adults and therefore cannot of themselves be sources of pain. These structures are

(A)

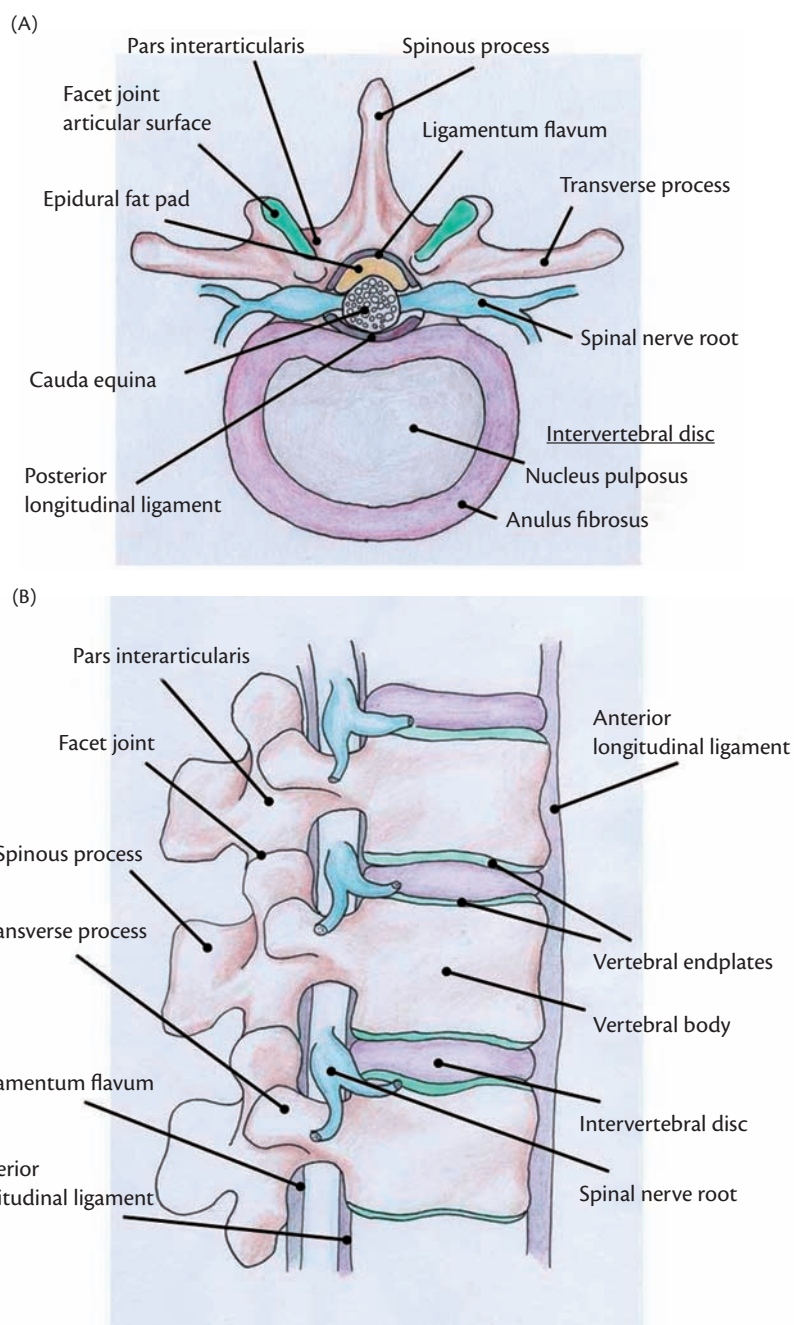
(B)


Fig. 157.1 Schematic diagram of the normal (lumbar) spine indicating close relationships of disc to spinal canal and foraminal contents. (A) Superior aspect. The transected intervertebral disc obscures the underlying vertebral endplate. Below approximately L2, lower motor neurons and sensory nerves of the cauda equina occupy the vertebral canal that at higher levels contains the spinal cord. (B) Lateral aspect.
Graphics by Harriet Walsh.

exposed to high compressive and shearing forces during normal back movements, and their lack of sensory innervation permits normal, pain-free activity. The site at which pain is experienced depends on the central mapping of pain pathways, and need not indicate directly the site of pathology. Radicular pain felt in the arm or leg originates from nerve root irritation in the spine.

Spinal pathology

Facet joint osteoarthritis

Facet joints, are subject to diseases that also affect other synovial joints such as osteoarthritis (OA). Radiological evidence of facet joint OA may be associated with chronic low back pain, and local anaesthetic injection into the facet joint may reduce back pain.[8] Facet joint OA may also contribute to symptoms of nerve root irritation.

Discogenic pain

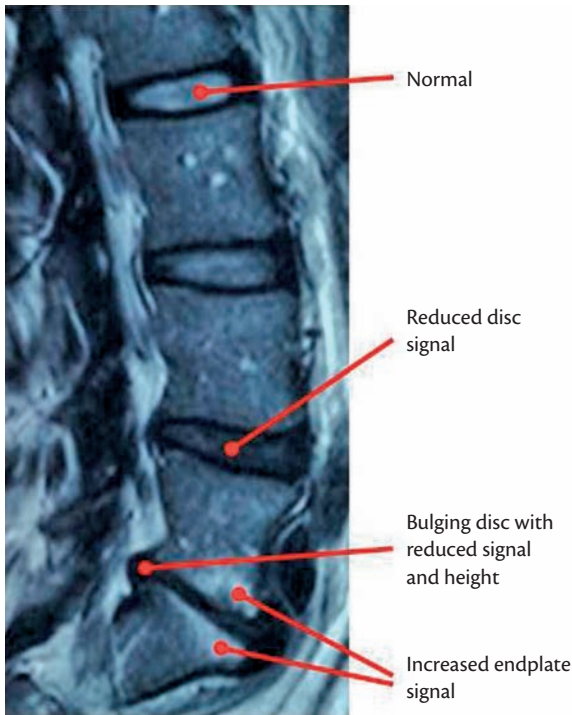
Several lines of evidence indicate the disc as a source of low back pain. Radiological evidence of disc disease (Figure 157.2) is associated with low back pain.[9] Such evidence includes osteophytosis at the margins of the vertebral endplates and disc space narrowing, evident on plain radiographs, and reduced signal from the nucleus pulposus on T2-weighted MRI views, or tears in the annulus fibrosus. Discography, comprising fluid injection into the disc, can reproduce the specific qualities of back pain.[10] Surgery directed at


Fig. 157.2 MRI from a patient experiencing low back pain. T2-weighted sagittal image showing normal appearances at L2/3 and evidence of disc disease at L4/5 and L5/S1. Disc changes are more commonly found in people with pain, but may be noted in pain-free individuals and should not be taken to indicate symptom severity.

Image labels: Normal; Reduced disc signal; Bulging disc with reduced signal and height; Increased endplate signal

reducing stresses on the disc by fusing adjacent vertebrae, or replacing the disc with an artificial implant, may each be successful in reducing pain in appropriately selected patients.[11,12]

The mechanisms by which discs cause pain remain unclear. More nerves were localized deeper within discs in which discography elicited pain, than in discs from non-painful levels, implicating the disc itself as a source of pain.[7] Loss of the mechanical and chemical barrier between disc and subchondral bone, and the altered biomechanical properties of diseased discs, may result in abnormal stimulation of subchondral nerves in the vertebral endplates. Episodes of spinal pain may be associated with annular tears at the edges of discs, or inflammatory activity in the subchondral bone. Genetic factors predispose, through unknown mechanisms, to both pain and radiographic changes.[13]

Spondylosis

Spondylosis indicates the commonly coexisting radiological features of disc space narrowing, osteophytosis, and facet joint OA. The association between radiographic spondylosis and pain and disability, although significant, is weak. The prevalence and extent of radiographic spondylosis, being irreversible, increases with age, whereas the problem of mechanical low back pain peaks in the sixth decade.[4]

Diagnostic terminology can be confusing for patients.[14] Healthcare professionals often use descriptive terms such as 'degenerative disc disease' or 'wear and tear arthritis'. This distinguishes these conditions from medically serious fractures, infection, or malignancy, but may also seem to contradict evidence-based recommendations that activities should be maintained and a graded

approach to increasing exercise should be adopted. Spondylotic change may be regarded as 'normal' or 'normal for age', and ageing and degeneration are closely linked concepts.[14] This may facilitate acceptance, but, alternatively, may seem to negate the patient's experience ('they don't believe I have a problem'), undermine confidence that the cause of their pain has been adequately investigated, and suggest that, as ageing is inevitable, so deteriorating symptoms must also be expected with time. Very few people become wheelchair bound due to low back pain, although many more fear that that is what the future holds for them.

Radiographic changes may alternatively be viewed as consequences of successful repair, rather than wear and tear.[14] Indeed, spondylosis is associated with new bone formation (osteophytes) and increased, rather than decreased, bone densities. Discs undergo fibrovascular repair, which may be likened to scarring of injured skin. Activity is required for the musculoskeletal system to repair most effectively, and fear of activity is a more important predictor of poor prognosis than is the nature of any initiating injury or the appearance of radiographs.[15]

Spondylolysthesis

Displacement between adjacent vertebrae (spondylolysthesis) may be due to defects in the pars articularis (spondylolysis), or to abnormalities of the facet joints. Spondylolysis occurs in up to 11% of the adult population,[16] and may be developmental, 'degenerative', or traumatic.[17] Fracture across the pars interarticularis may be either due to significant trauma, or to repetitive hyperextension, e.g. in athletes such as gymnasts. Developmental or degenerative spondylolysis or spondylolysthesis are not of themselves associated with low back pain,[16,17] and even spondylolystheses with up to 50% loss of contact between adjacent vertebral endplates (grade 2) are typically managed conservatively. Degenerative spondylolysthesis, however, occurs in conjunction with other evidence of spondylosis, either because abnormal stresses necessitate enhanced repair, or because structural repair permits vertebral malalignment. Traumatic spondylolysis will commonly recover with conservative management, although response to surgical stabilization is more successful than for spondylosis-associated spondylolysthesis.

Intravertebral disc herniation

Intervertebral discs may herniate through insufficiencies in the vertebral endplate and produce localized back pain. Acute intravertebral herniation is associated with MRI evidence of inflammation in the adjacent bone marrow. This should not be confused with Schmorl's nodes, which have similar appearance on plain radiographs, but are longstanding, and not associated with local inflammation. Schmorl's nodes may be present in one-fifth of people without back pain.[18] Disc herniation under the ring epiphysis in childhood may be a cause of limbus vertebra. The triangular ossification centre remains visible at the anterosuperior angle of the vertebral body due to failed epiphyseal fusion, but this does not cause pain.

Radicular pain

Pain radiating into the leg or arm, or around the chest or abdomen, may either indicate nerve root pain (radicular), or represent imprecise somatotopic representation of deep structures (pseudoradicular). Sciatica (pain in the sciatic distribution extending below the knee), cruralgia (in the femoral distribution), and brachalgia

(in the arm) classify radicular symptoms without defining underlying pathogenesis. Causes may include foraminal stenosis due to prolapsed intervertebral disc, osteophytosis, or hypetrophy of the ligamentum flavum, local inflammation, spondylolisthesis, or, rarely, space-occupying lesions, either benign (e.g. synovial cysts at the facet joint) or malignant. Rarely radicular pain may be due to other pathology involving the nerve, such as neuroma or infiltrating malignancy. Non-resolving symptoms should lead to further investigation.

Prolapsed ('slipped') intervertebral disc is a common cause of acute radicular pain. Symptoms classically follow a specific mechanical insult, for example during extension from the flexed position while twisting. Radicular pain may not be immediately apparent but evolve over days after injury, and, conversely, radicular pain may occur without significant axial pain. The prolapsed disc represents extrusion of nucleus pulposus through a tear in the annulus fibrosus. Unlike books on a shelf, discs do not slip back into place. Annular tears and extruded disc contents induce local inflammation. Prostaglandins, tumour necrosis factor alpha (TNFα), and nerve growth factor (NGF) facilitate tissue repair, but also activate and sensitize local nerves and adjacent nerve roots.[19] Extruded disc material and oedema can additionally compress the exiting nerve root.

Chronic radicular pain is commonly associated with foraminal stenosis due to facet joint hypertrophy with or without associated disc protrusion or spondylolysthesis. Foraminal stenosis may be associated with continuous pain, or with unilateral, sometimes dermatomal, claudicant symptoms. Sensitization leads to spontaneous or mechanically induced nerve activation that may be experienced as shooting pains and/or paraesthesiae, and neuronal dysfunction may lead to alteration or loss of sensation.

Spinal canal stenosis

Normal variability in spinal canal dimensions is genetically determined. Osteophytosis, hypertrophy of the ligamentum flavum, prolapsed intervertebral discs, spondylolysthesis, and, rarely, posterior longitudinal ligament ossification, epidural fat, or space-occupying lesions can further narrow the canal. Inflammatory arthritis can cause clinically important stenosis due to pannus or subluxation in the cervical spine. Acute cord or cauda equina compression, for example due to central disc prolapse, constitutes a surgical emergency as delay may result in permanent disability. Chronic lumbar spinal stenosis is often identified by imaging in the absence of symptoms or signs and its clinical relevance requires careful evaluation. MRI evidence of cord pathology such as inflammation, demyelination, or syringomyelia secondary to cord compression is of greater clinical significance than reduced canal dimensions alone.

Kyphosis and scoliosis

Abnormal kyphosis (forward curvature) or scoliosis (lateral curvature) may be developmental or acquired. Uncoordinated vertebral growth in childhood may cause scoliosis or exaggerated dorsal kyphosis (Scheuermann's disease), which, if severe, may contribute to restrictive lung impairment and psychosocial problems. Exaggerated dorsal kyphosis may develop in later life, for example following osteoporotic 'wedge' fractures. Scoliosis may also indicate structural deformity, or may represent postural compensation for pelvic asymmetry or leg length disparity. In acute back pain it may be due to paraspinal muscle spasm and therefore disappear as pain improves. Kyphosis or scoliosis do not of themselves predict spinal pain in adults independently of other disc changes.[20] However, onset of back pain may be the factor that leads people to notice spinal asymmetry as a lump or abnormal bend.

Clinical features

Differential diagnosis of spinal symptoms

Spinal pain may be a feature of multisystem disease, referred from other organs, and occasionally indicative of a need for urgent intervention (Table 157.1). Significant pathology such as aortic aneurysm, renal or gynaecological disease can each present with back pain. Most low back pain, however, is not accompanied by treatable medical or surgical pathology, and overinvestigation of people with simple low back pain can cause unnecessary distress and consume limited healthcare resources. The clinician must balance probabilities and potential consequences, while being alert to alternative diagnoses even in people with longstanding symptoms.

Low back pain may also present as the primary focus for a patient with more widespread pain. Chronic widespread pain by definition includes axial as well as bilateral arm and leg pain,[21] and features of fibromyalgia are not uncommon in people with back and/or neck pain.[22] People who have been discharged from secondary care services following treatment for low back pain have a high likelihood of presenting again with pain at another location. Recognizing the interplay between axial and non-axial pain, and associated psychological distress (particularly depression and anxiety) is an important part of diagnosis, as exclusive focus on the presenting site of pain may fail to identify important treatable morbidity and barriers to recovery.

Rheumatoid arthritis (RA) and seronegative spondylarthritides are uncommon causes of spinal pain, and first presentation of RA with isolated spinal symptoms is extremely rare. Although spinal pain is common in people with inflammatory arthritis, it often has mechanical origins.[23] However, attribution of chronic pain to inflammatory rather than mechanical diagnoses may be associated with lower levels of psychological distress.[14]

Radicular pain and neuronal compromise

Radicular pain is classically localized to specific dermatomes, although variations between individuals in dermatomal topography, imprecise perception of sensory boundaries, and nociceptor recruitment from adjacent segments through central sensitization may confound interpretation of pain distribution. This is particularly the case where symptoms are intermittent or historical, as pain memory is thankfully imprecise.

Radicular pain often has characteristics in common with other neuropathic pain, described as burning or lancinating. Shooting pains may be spontaneous or triggered by movement. Dysaesthesiae can include abnormal spontaneous cutaneous or deep sensations. Allodynia, the experience of normally non-noxious stimuli such as the touch of bedclothes as painful, indicates central sensitization. Paraesthesiae (ongoing mechanoceptor afferent activity) or numbness, although not actually painful, may be unpleasant and distressing. Their bothersomeness can reduce with time even if symptoms persist.

Bilateral limb pain or weakness, or upper motor neuron signs in the lower limbs should raise suspicion of spinal cord compromise. Lower motor neuron signs may indicate the level of cervical canal

stenosis, with upper motor neuron signs more caudally. The adult spinal cord terminates around the L1/2 vertebrae, below which the nerve roots of the cauda equina pass through the spinal canal to their exiting foramina. Lumbar canal stenosis produces lower, rather than upper motor neuron features.

Lumbar spinal canal stenosis can cause spinal claudication. Patients describe increasing leg pain during walking, which resolves within minutes of resting, but recurs after walking a similar distance again. Spinal and vascular claudication can be difficult to distinguish. Clinical evidence of cardiovascular risk factors, abdominal bruits, and absent peripheral pulses suggest vascular causation, but can coincide with spinal pathology. Spinal claudication may be indicated by bilateral pain extending into the thighs, associated paraesthesiae or feelings of heaviness or weakness, or lack of symptoms walking upstairs or during forward flexion, positions which increase dimensions of the spinal canal.

Assessment of the patient with spinal pain

Assessment fulfils several purposes; evaluation of the nature and extent of the problem, diagnosis and exclusion of important (treatable) differential diagnoses, identifying comorbidities and factors that may limit response to treatment, and formulation and engagement of the patient in an appropriate treatment plan. Clinical assessment may also be used for other purposes, such as to support or defend litigation, or inform decisions on benefits or future employment. It is important that patients and clinicians share the same understanding of the purpose of an assessment, as this will influence its content.

A full history and examination is essential both to guide further investigations and management, and to create a productive working relationship with the patient. History should address symptom onset; previous episodes and how the current episode may be similar or different; the nature, severity, and functional impact of current symptoms; and evidence of possible underlying conditions that if left untreated may lead to significant harm. The clinician should also enquire about factors that may limit engagement with or response to treatment, such as fear avoidance, depression and anxiety. These are often referred to as psychosocial 'yellow flags', predict poor outcome in low back pain, and may be amenable to specific interventions such as cognitive behavioural therapy (CBT).

Examination is directed to the spine itself, and to evidence of neurological deficit (Figure 157.3, Table 157.2) and systemic disease. Important pathology can exist in the absence of hard examination findings. Spinal canal stenosis may produce no symptoms or signs at rest, despite seriously limiting walking. An L4/5 disc prolapse may cause significant L5 nerve root compression without impairment of tendon reflexes, because knee extensors and ankle flexors are innervated from multiple levels. Furthermore, an absence of signs does not indicate that symptoms are mild, nor should the patient be expected to see their problem as 'not serious'.

The concept of 'red flag' symptoms and signs has proved useful in guiding management of low back pain (Box 157.1). Surgical red flags focus on cauda equina syndrome, and medical red flags may indicate other pathology requiring specific intervention. Red flags have not been comprehensively tested for specificity and sensitivity, although some are more reliable than others. Difficulty in passing urine is common in people with low back pain, particularly during flares. Sleep disturbance is also common, and people are often uncertain as to whether they wake with or because of their pain.[24] Mechanical low back pain is not uncommon in older people, even though osteoporosis and malignancy are more likely with increasing age. However, the onset of bilateral lower motor neuron signs in the legs, loss of anal tone, and perineal sensory loss or incontinence should never be ignored as possible features of cauda equina syndrome. Acute cauda equina compression can rapidly lead to irreversible neuronal compromise and should precipitate immediate
Fig. 157.3 Dermatomes affected by spinal problems. Schematic diagram of human dermatomes highlighting those nerve roots most commonly affected by prolapsed intervertebral discs; in the upper limb C6 (pink) and C7 (blue), and in the lower limb L5 (blue) and S1 (pink). Dermatome maps conceal overlap between dermatomes, and marked interindividual variations lead to diagnostic imprecision.

admission for imaging and surgical decompression, irrespective of back pain. Fever, weight loss, history of malignancy, or an associated acute-phase response should similarly prompt further investigation to exclude treatable infection, malignancy, or inflammatory spinal disease.

Investigations should be instigated where there is a likelihood of underlying pathology that may influence treatment. Urinalysis may provide evidence of renal infection. Full blood count, acute-phase reactants, urea and electrolytes, liver function, and bone profile may reveal a need for further investigation, although abnormalities often prove to be coincidental rather than causes of spinal pain. Plain radiographs are not recommended for the investigation of simple mechanical back pain.[25] Spondylosis is common irrespective of the presence or absence of pain, whereas apparently normal disc spaces on radiographs may contain discs with reduced signal on T2-weighted MRI. Plain radiographs from a single time point have low sensitivity in detecting early inflammatory spinal disease or malignancy, are unable to identify or exclude significant disc prolapse or canal stenosis, and cannot distinguish between recent and longstanding osteoporotic fractures.

MRI is not indicated for all patients, nor for all episodes of spinal pain.[25] Where plain radiographs have already demonstrated multi-level spondylotic changes at multiple levels, further imaging is only indicated if additional treatable pathology is suspected. Undertaking MRI may improve patient satisfaction, but is not necessarily reassuring and may not be a cost-effective means of improving long-term outcomes.[25] MRI is the method of choice for detecting nerve root compression, spinal cord pathology, canal stenosis, or inflammatory and infective spinal disease.

Imaging lacks specificity in determining the source of pain. Discography or local anaesthetic injections may be used to further define the pain's anatomical origin. Discography aims to briefly reproduce symptoms during the injection of contrast medium into the nucleus pulposus. Facet joint injection with local anaesthetic may temporarily reduce pain if appropriately placed. However, there is little robust evidence that such techniques reliably predict response to more permanent nerve ablation or surgical procedures, and back pain rarely originates from a single structure.[26]

Table 157.2 Myotomes affected by spinal problems. Nerve roots most commonly affected by disc prolapse are highlighted in bold. Overlap between myotomes and marked interindividual variations lead to diagnostic imprecision

Disc	Root	Weakness	Reflex

Assessment may differ in emphasis according to age, pain location, and comorbidities. Children not infrequently complain of back pain, but spondylosis and disc prolapse are rare under the age of 18, indicating a need for further investigation. Medical pathologies including osteoporosis are most common over the age of 50. A greater proportion of thoracic pain may be attributable to medical pathology, justifying a lower threshold for investigation. However, disc disease is not uncommon in the thoracic spine, particularly

when also present elsewhere. Osteoporotic fracture should be considered in those at risk, or with increasing spinal deformity or height loss. Recurrent episodes of back pain while on treatment for osteoporosis may indicate a need for further assessment of bone mineral density and consideration of treatment escalation.[27] Acute episodes of pain in patients whose spines are fused due to inflammatory spinal disease should be imaged by MRI or CT, as unstable fractures may not be apparent on plain radiographs. Instability in the cervical spine may have greater clinical significance than in the low back, and MRI is indicated if patients develop shooting pains or other neurological symptoms or upper motor neuron signs in the lower limbs. Cervical spine imaging should be considered in patients with RA to help assess general anaesthetic risk, and in those who go off their feet.[28]

Management

Principles of management

A large number of national guidelines have been produced regarding the treatment of spinal pain, particularly low back pain, and there is a high degree of consistency between countries.[25,29–32] For the majority of patients, spinal and radicular pain improve or resolve during the months after presentation, even when there is MRI evidence of substantial disc herniation and nerve root entrapment.[33] In the absence of evidence of cord or cauda equina compression, initial management is non-surgical. Management aims to reassure, minimize impact, and facilitate recovery, achieved through adequate explanation, analgesia and pain management, treating any specific pathology, and encouraging activity. However, spinal pain is often recurrent, with exacerbations of varying duration, and sometimes incomplete resolution before the onset of another flare. Management of the current episode should always be complemented with advice for the future.

Management should be proportional to severity and risk. The majority of episodes will respond well to non-specific treatments, and inappropriate investigation may delay appropriate management. Investigations, therefore, are not routinely recommended within 3 months of the onset of spinal pain in the absence of red flag symptoms or signs.[34] However, investigations may be justified if symptoms persist and the patient wishes to consider specific treatments such as surgery, or if suspicion is raised of underlying medical pathology.

More intensive non-surgical treatments may lead to better outcomes overall, but may not be cost-effective if offered to all patients. Initial screening determines the likelihood of pathology requiring specific treatment (detection of red flags), and likely prognosis. In general, those with worse prognosis gain most from intensive treatment. Prognosis is traditionally determined by early progress, whereby all patients are offered the same range of treatments in the first instance, and those who respond less well are subsequently offered more intensive therapy (see e.g. Savigny et al.[25]). However, questionnaires may help identify patients for whom intensive therapy should be offered early.[35,36]

Advice and education

Early advice should include an explanation of the likely cause of the pain, consistent both with the patient's own experience and with a recommendation to maintain or return to normal activities as far

and as soon as possible. Advice should be reinforced by consistent written information, such as that provided in *The Back Book*.[37] Explanation alone, provided in a single consultation, has little impact on outcomes in controlled clinical trials. However, the initial consultation sets the context through which other interventions are delivered, and it is important that information provided by all members of the team remains consistent.

Patients bring to the consultation their own understanding of spinal pain, based on their experiences and information obtained from family, friends, media, and other professionals. Such beliefs may be barriers to rehabilitation,[14,15] and care must be taken not to reinforce unhelpful beliefs by a casual use of terminology. Noting coincidental findings such as scoliosis may focus attention away from modifiable factors that make more important contributions to pain.

Pharmacological analgesia

Patients should be advised to use both non-pharmacological and pharmacological therapies to help reduce pain in order to help maintain activity, and to reduce symptoms and distress. Emphasizing how movement and activity facilitate repair can help counter fears that masking symptoms will allow further injury. Pharmacological therapies include paracetamol, non-steroidal anti-inflammatory drugs, and opioids.[25] Tricyclic anti-depressants may reduce pain and improve sleep disturbance in people with chronic low back pain.[25,38] Clinical trials support starting at a low dosage and increasing up to the maximum recommended anti-depressant dosage until therapeutic benefit or unacceptable side effects. For patients with nerve root irritation, treatments effective for neuropathic pain such as tricyclic anti-depressants and/or gabapentin or pregabalin may be helpful.[38] Decisions on continuing analgesic medications should always be based on individual response.

Physical treatments

Physical treatments provide additional benefit to information alone for the management of low back pain.[25] Training in specific exercises aimed at muscle strengthening, postural control, movement instruction and stretching, and aerobic activity, and approaches based on cognitive behavioural principles each have shown similar beneficial effects in randomized controlled trials (RCTs).[25] Physiotherapy may be provided individually or in group settings. Group programmes are generally recommended because of their lower cost, with some evidence of equal efficacy to individual therapy.[25] Such programmes, however, require adequate throughput of patients to be efficient, and group work may not suit all patients. Yoga has also been found helpful for low back pain.[39] Passive physical therapies, such as manipulation or massage, may also provide relief from low back pain, although their clinical effect sizes may be small and short-lived.[40] Interventions that discourage movement and activity, including bed rest, traction, and surgical appliances such as corsets, are not recommended for low back pain. Cervical collars may facilitate temporary pain relief, but have not been associated in prospective trials with sustained benefit.

Fear-avoidance beliefs are associated with high levels of reported pain and disability, and are common barriers to rehabilitation in low back pain.[15] Muscle spasm or inflammation play greater roles in pain exacerbation than does structural damage, and imaging even during severe pain can be unremarkable. Similarly, patients often feel that their back is 'unstable' due to abnormal processing of nociceptive and proprioceptive inputs, but this is rarely associated with biomechanical instability. By contrast, graded, supervised exercise can reduce fear avoidance, and improves low back pain and function.[15] Fear avoidance and catastrophic beliefs should be addressed when they occur. For the back to repair itself fully requires normal activity. Effective rehabilitation aims to reintroduce rather than avoid valued activities.

Complementary therapies

As with other conditions that evade simple cure, a wide range of therapies for spinal pain are commonly accessed outside traditional healthcare. These may complement medical approaches or be offered as alternatives.

Acupuncture needling is commonly recommended for spinal pain due to evidence of efficacy and cost-effectiveness when provided as a course of limited duration.[25,41] Evidence of long-term benefit from ongoing acupuncture is less strong, and increased treatment duration escalates costs. A graded return to normal activity should be advised in conjunction with acupuncture. Transcutaneous electrical nerve stimulation (TENS) has been advocated, although systematic reviews of RCTs are inconclusive.[25]

Mechanisms by which complementary treatments help are incompletely understood, and context may be as important as any specific pathophysiological target. Acupuncture may be more beneficial than waiting list or 'usual care' controls, but similar to sham procedures.[25] Indeed, contextual factors may contribute much of the benefit of prescribing analgesic drugs,[42] and optimizing the context within which treatments are provided has considerable potential for improving patient wellbeing.

Multidisciplinary approaches

The multifaceted nature of spinal pain has led to complex interventions that bring together different and potentially synergistic treatments. Combined physical and psychological (CPP) programmes combine cognitive behavioural approaches and exercise.[25] CPP may be more effective than either component alone, and cost is minimized through group programmes, and selecting patients who continue to have high disability or significant psychological distress despite at least one less intensive treatment. Even programmes involving 100 hours contact over 8 weeks may be cost-effective. Interdisciplinary working, with cognitive behavioural approaches delivered by appropriately trained physiotherapists, may reduce costs and permit wider access to psychological interventions.[43] However, treatment fidelity can be difficult to maintain in routine health service practice, and physiotherapist-led interventions may still leave an important number of people with significant disability and distress from low back pain.

Full multidisciplinary pain management programmes (PMPs) are recommended for people with persistent spinal pain where there is no realistic prospect of cure.[44] PMPs facilitate self-management and reduce the impact of spinal pain on patients' lives. Such programmes combine expertise in clinical psychology and physiotherapy, often including medical and occupational therapy input, to provide a coherent intervention within a group setting. Effectiveness may improve with greater treatment intensity, either through increased contact time or using an inpatient context.[45] Best evidence is for PMPs using traditional CBT-based approaches, challenging unhelpful beliefs and helping patients achieve their goals.[46]

More recently acceptance and commitment therapy (ACT) and mindfulness approaches have focused on acceptance and patients' life values,[47] but RCTs are required.

Back pain disability has great impact on productivity and costs to employers, insurance agencies, and social care. Successful programmes resulting in return to work have typically combined physical therapies, education, and specialist employment advice.[32,48] Return to work is influenced by expectations of both patients and employers. Employment consultants, by helping match patients to opportunities, may facilitate return to work even after several years of disability.

Public health interventions

Social context influences the management and outcome of spinal pain, and different stakeholders—patients, employers, health professionals, insurers, and governments—view outcomes from different perspectives. Benefit thresholds balance costs to the taxpayer against the poverty that can accompany back pain disability. Individualized approaches are effective but costly when delivered for problems as common as spinal pain. Public information campaigns, addressing commonly held but unhelpful beliefs about exercise and activity, have had important benefits, both in the short and long term.[49] Key issues addressed by such campaigns may differ between countries and at different times.

Invasive interventions

Interventional therapies aim to reduce pain either directly (e.g. injection therapies), or by altering spinal structure. Testing such procedures by RCTs raises ethical and methodological difficulties, and trial data often seem inconsistent with cohort studies. This may indicate important contextual or placebo effects, but also the often complex and individualized nature of interventional therapies that is difficult to replicate in controlled trials.

Epidural injections of glucocorticosteroid and local anaesthetic may reduce inflammation around a nerve root, and alter central processing following temporary reduction in afferent barrage. They can reduce the duration or severity of nerve root pain, particularly if nucleus pulposus is extruded/sequestrated outside the annulus fibrosus.[50] The epidural space may be accessed by caudal, interlaminar, or foraminal approaches. Fluoroscopic guidance is recommended to optimize response and reduce adverse events. Although lower lumbar root irritation may be relieved by caudal injection, transforaminal injections may be favoured.[51] Epidural injection has low propensity for systemic adverse effects, and may permit engagement in physical therapy and reduce rates of subsequent surgery. However, pain relief may be temporary and health economic evidence of benefit is incomplete. There is little evidence to suggest that epidural injections provide benefit for symptoms of spinal claudication or back pain.[52] Facet joint injection with glucocorticosteroid and local anaesthetic, and more permanent nerve ablation procedures, have been advocated although evidence of efficacy remains inconclusive.[52]

Surgery aims to decompress, stabilize, and, more recently, replace discs. Surgical decompression of the cauda equina or spinal cord is a matter of immediate urgency if permanent neurological deficit is to be avoided after acute presentation. Decompression is also recommended if progressive muscle weakness follows acute disc prolapse. However, nerve root pain from even large disc protrusions may adequately resolve with conservative management,[53] and surgery does not obviate the need for intensive rehabilitation. Discectomy, either open or with perioperative microscopy (microdiscectomy), may improve outcomes at 1 year for leg pain due to disc prolapse compared with conservative management. However, in cases where natural recovery may occur, there is no long-term disadvantage in initially taking a conservative approach.[54] Decompression is not expected to reduce spinal pain itself, and the balance between axial and referred symptoms should be considered carefully before embarking on surgery.

Surgical decompression may relieve spinal claudication symptoms in people with canal stenosis associated with spondylosis, although the magnitude of benefit compared to conservative treatments remains uncertain.[55] Where canal stenosis is associated with spondylolisthesis, fusion may be combined with decompression.[56] In cases presenting with spinal claudication, imaging often reveals multilevel changes and surgical amelioration may be complex and not without its own risks.

Surgery for severe simple mechanical back pain should only be considered after completion of an optimal package of conservative care, including a CPP treatment programme.[25] Significant psychological distress should be optimally treated prior to surgical referral. Spinal stabilization can reduce back pain, particularly for patients with single-level disease. However, the precise anatomical origin of pain can be difficult to determine, and an immobilized spinal segment may place additional stresses on adjacent levels. This may explain the mixed outcomes observed after fusion surgery.[55] More recently, non-rigid surgical stabilization has been explored for low back pain although controlled trials have not yet consistently demonstrated improved benefit over rigid fusion.[57]

Discs may be replaced with artificial prostheses, which permit continued movement at the operated level and therefore minimize biomechanical stresses to adjacent levels. RCTs comparing cervical disc replacement with fusion suggest improved cervical disability and quality of life up to 12 months, and reduced need for further surgical intervention up to 2 years after disc replacement surgery.[12] RCTs comparing lumbar disc replacement with fusion also suggest improved disability and quality of life following disc replacement surgery, although evidence for maintenance of this benefit beyond 6 months is less strong.[11] Disc replacement surgery may be most suitable for patients with severe pain and disability from localized spinal disease.

Treatments for specific pathologies

Osteoporotic fractures are a common cause of acute spinal pain in older people, although may evade medical diagnosis by resolving with self-management. Differentiation from other forms of pathological fracture (e.g. metastatic or myeloma) requires further investigation and imaging where suspected. Osteoporosis typically results in wedge or endplate compression fractures in the thoracic or lumbar spine. These are inherently stable, and only rarely cause neuronal compression or require surgical fixation. Vertebroplasty, the introduction of cement into the fracture site, has been used to reduce symptoms and subsequent deformity, although clinically important benefit has not been universally found in RCTs.[58,59] Osteoporosis is exacerbated by bed rest, and primary management of osteoporotic fractures should be analgesia and early mobilization.[60] Spinal manipulation is not recommended. Optimizing bone mineral density by treatments such as bisophosphonates together with calcium and vitamin D, and reducing falls

risk, are essential. Bone-strengthening treatments do not, however, reduce current spinal pain, and the distinction between analgesic and preventive therapies should be explained clearly.

Spinal infection is rare, but serious if not treated promptly. Infective discitis and spinal osteomyelitis typically affect a single level, often in the context of previous disease. Diagnosis depends on a combination of MRI, raised acute-phase response, and bacteriological confirmation, either from blood culture or from infected material obtained by aspiration or open surgery. A distant focus of infection may provide material for bacteriology, either as the primary source, or resulting from haematological spread. Bowel or urological foci should particularly be considered as these may influence antibiotic choice, and concurrent bacterial endocarditis requires involvement of the cardiology team. The commonest implicated organisms are staphylococci, especially *Staphylococcus aureus*, although enterobacteria may account for up to 30% of cases. The low levels of vascularization of the intervertebral disc and cartilage on the vertebral endplates compromise access of antibiotics to infected tissues, reducing efficacy and encouraging the development of resistant strains. Prolonged courses of antibiotic combinations are recommended, administered intravenously for at least 2 weeks and continued orally to complete at least 2 months. Paraspinal fluid collections may be present and require surgical drainage. Spinal pain often continues long after resolution of infection, for which management converges with spinal pain from other causes.

Recommendations for the treatment of inflammatory spinal pain are largely congruent with those for mechanical pain, although some aspects of inflammatory spinal pain may dictate specific therapeutic approaches. Discitis at presentation or in established spondylarthropathy may resemble bacterial infection, but can respond to systemic glucocorticosteroids or anti-TNFα therapy. High leverage stresses due to spinal fusion in ankylosing spondylitis combine with associated osteoporosis to increase risk of spinal fracture. Vertebral fractures in ankylosing spondylitis are likely to result in spinal instability and spontaneous or surgical bony repair may be impaired by lack of compensatory movements at adjacent spinal levels. RA commonly affects the cervical spine, although lumbar symptoms are no more common in RA than in matched non-arthritic populations.[23] Cervical (particularly subaxial) instability and pannus each may cause significant cord compression. Pannus may decrease in volume during immunosuppressive therapy.[61] Therapeutic manipulation is not recommended in patients with inflammatory arthritis. Management of inflammatory spinal disease often requires close interaction between specialist rheumatological and surgical units.

Conclusion

Much progress has been made in understanding and treating spinal pain over recent years, but much remains unknown. Many approaches are supported by evidence from RCTs, and even more by cohort or anecdotal evidence. Offering multiple treatments either concurrently or in sequence may enhance benefit, but also increases healthcare costs. Diverse management plans can cause confusion, particularly when based on apparently contradictory explanatory models. Treatment failure can result in disengagement from healthcare services. Further research is required to optimize and definitively determine benefit from existing treatments.

CHAPTER 158

Childhood regional conditions

Kristin Houghton

Introduction

Musculoskeletal (MSK) pain is common in childhood and more frequent in adolescence.[1] The majority of causes are benign and self-limited, but musculoskeletal symptoms may be the presenting feature of infectious, inflammatory, and oncologic conditions, and amplified musculoskeletal pain syndromes. It is important to recognize 'red flags' on history and physical examination that warrant further investigations (Table 158.1). This chapter reviews common non-inflammatory regional pain conditions in childhood (Table 158.2).

Shoulder

Chronic shoulder pain is often due to an overuse injury. Rotator cuff tendinopathy affects skeletally mature adolescents who present with the insidious onset of localized pain coincident with increased activity.

Humeral epiphysitis affects skeletally immature children aged 11–16 years who present with shoulder pain associated with overhead activity. It is commonly referred to as Little League shoulder, as it typically affects baseball pitchers.[2] Tennis players, swimmers, and gymnasts may also be affected. Repetitive microtrauma to the proximal humeral physis causes tenderness over the physis and pain or weakness with internal and external rotation. Radiographs may show widening of the physis or separation of the epiphysis.

Table 158.1 Red flags for pain

Symptom	Differential diagnosis
Fever, weight loss, night sweats, malaise	Systemic disease (malignancy, infection, systemic inflammatory disease)
Night pain, discrete bone pain	Oncological disease
Morning stiffness, joint swelling	Inflammatory disease
Weakness, altered sensation, radiating pain, regression of developmental milestones	Neurological disease

Multidirectional instability (MDI) of the shoulder may be isolated or associated with generalized hypermobility. MDI may cause pain from related subacromial impingement or labral pathology.[3]

Treatment of tendinopathy, humeral epiphysitis, MDI, and secondary impingement includes ice, anti-inflammatory drugs, relative rest, and physiotherapy. Labral pathology requires orthopaedic referral and possible surgical repair.

Elbow

Chronic elbow pain is not common in childhood and causes are fairly specific to skeletal maturity. Skeletally mature adolescents with overuse injury or strain usually present with localized pain and a history of recent increased activity. Injury to the flexor pronator muscle group causes medial elbow pain (medial epicondylitis or 'golfer's elbow') and injury to the extensor supinator muscle group causes lateral elbow pain (lateral epicondylitis or 'tennis elbow'). As with other overuse injuries, pain is present during and after activity, which helps distinguish the pain from inflammatory enthesopathy that is classically present in the morning, at rest, and improves with activity.

Osteochondritis dissecans (OCD) of the capitellum affects skeletally immature children aged 11–16 years who present with progressive lateral elbow pain with activity. Microtrauma from chronic compression (throwing, gymnastics) combined with poor blood supply leads to injury to subchondral bone and its overlying articular cartilage.[4] On examination, there is tenderness over the anterolateral elbow, mild swelling, and lack of full extension. Mechanical symptoms of locking or catching may be present if there is a loose body. Radiographs of early lesions may be normal or show lucency of the capitellum and late radiographs may show sclerosis, joint collapse, or loose bodies. MRI may better evaluate the extent of the lesion.

Medial epicondyle apophysitis (Little League elbow in baseball pitchers) affects skeletally immature children aged 8–15 years who present with medial elbow pain associated with throwing.[5] Repetitive valgus stress on the elbow causes tenderness over the medial epicondyle and pain with valgus stress, and pain or weakness with resisted wrist flexion and forearm pronation. Radiographs are often normal and may show widening of the physis or avulsion fracture.

Table 158.2 Mechanical and developmental conditions presenting with regional pain

Region	Mechanical conditions and overuse injuries	Osteochondroses (eponym: site)	Developmental conditions and anatomical variants
Back	Spondylolysis	Scheuermann: thoracic spine epiphysis	Scoliosis
Shoulder	Tendinopathy Instability Impingement		Humeral epiphysitis
Elbow	Tendinopathy	Panner: capitellum	Pulled elbow Olecranon apophysitis Medial epicondyle apophysitis
Wrist and hand	Tendinopathy TFCC	Kienbock: lunate	
Hip and pelvis	Tendinopathy Apophyseal injuries	Legg–Calvé–Perthes: femoral head	SCFE
Knee	Patellofemoral pain	Osgood–Schlatter: tibial tuberosity	Patellofemoral dysplasia
	Iliotibial band syndrome	Sinding–Larsen–Johansson: inferior pole patella	Synovial plica
	Tendinopathy		Bipartite patella
	OCD—femoral condyles, patella		Discoid meniscus
	Fat pad irritation		
Ankle and foot	Tendinopathy	Frieberg: MT head (2nd, 3rd)	Pes planus
	Chronic lateral ligament instability	Sever: calcaneus	Tarsal coalition
	Plantar fascitis	Iselin: 5th MT tuberosity	Bipartite sesamoid
	Stress fracture		Os trigonum
	OCD—talus		Accessory navicular

MT, metatarsal; OCD, osteochondritis dissecans; SCFE, TFCC, triangular fibrocartilage complex injury.

Panner's disease, an osteochondrosis or idiopathic avascular necrosis of the capitellum, affects children aged 7–12 years who present with dull, aching pain over the lateral elbow, maximal tenderness over the radiocapitellar joint, and loss of extension.[6] Swelling is uncommon. Radiographs show early demineralization and/or fragmentation with eventual consolidation of the capitellum, although persistent flattening may be present. MRI is sensitive in detecting early disease. Panner's disease generally resolves with no long-term sequelae and can be distinguished from OCD by age, pain onset, and radiographic appearance of the lesion.

Treatment of medial and lateral epicondylitis, medial epicondyle apophysitis and Panner's disease includes ice, anti-inflammatory drugs, relative rest, and physiotherapy. OCD requires orthopaedic or sports medicine referral and possible surgical repair.

Wrist and hand

Acute injuries of the wrist and hand are common in childhood. The most common mechanism of injury is a fall on an outstretched hand, often resulting in sprain or fracture. Chronic pain following an acute injury should prompt assessment for physeal injury, distal radioulnar joint instability, non-union or avascular necrosis of scaphoid fracture, scapholunate ligament instability, or triangular fibrocartilage complex injury.

Chronic tendon injury typically occurs in children involved in sports requiring repetitive wrist motion such as rowing, throwing, and racquet sports. DeQuervain's tenosynovitis, extensor carpi ulnaris tendonitis, and intersection syndrome present with the insidious onset of localized pain coincident with increased activity.

Stress injury to the distal radial physis occurs in skeletally immature children involved in weightbearing activity such as gymnastics. Children present with dorsal wrist pain during weight-loading activities (handstands, handsprings) and tenderness over the dorsum of the distal radial physis.[7] Early radiographs may show widening and irregularity of the physis and late radiographs may show distal radius deformity or distal ulna overgrowth.[8] MRI may aid early diagnosis and show oedema on the metaphyseal and epiphyseal sides of the physis before radiographic changes are apparent.[9]

Kienbock's disease, an avascular necrosis of the lunate possibly due to repetitive trauma, affects skeletally mature adolescents and young adults.[10] Adolescents present with dorsal wrist pain, swelling, and loss of grip strength. Radiographs may show sclerosis, collapse, or fragmentation of the lunate. MRI is sensitive in detecting early disease. Some adolescents have progressive disease with eventual degenerative arthritis.

Treatment of chronic sequelae of acute wrist and hand injury requires orthopaedic or sports medicine referral and possible surgical repair. Treatment of chronic wrist and hand injury includes ice,

anti-inflammatory drugs, bracing, relative rest, and physiotherapy. Adolescents with Kienbock's disease may be treated conservatively with immobilization; however, radial shortening may be indicated for persistent pain or advanced disease on imaging.[10]

Back

Back pain is common in childhood, with 1 year prevalence rates varying from 7% to 58%.[11] Paediatric doctrine states that children with back pain may have serious pathology, including malignancy and infection. However, most cases are non-specific and self limiting. A recent prospective study of 73 children under the age of 18 years, with back pain of greater than 3 months duration, found only 21% of the patients had positive findings after diagnostic evaluation or a minimum of 2 years follow-up. Spondylolysis with or without spondylolisthesis was the most common diagnosis.[12]

Spondylolysis is a defect in the pars interarticularis and most commonly affects the fifth and fourth lumbar vertebrae. The majority of cases in childhood represent a stress fracture in the pars interarticularis (Figure 158.1). It is more common in boys and in sports involving repetitive extension, flexion, and rotation (gymnastics, diving, wrestling). Acute and overuse injuries both occur, with overuse injuries being more common. Spondylolithesis occurs with bilateral pars defects and is defined by forward translation of one vertebra on the next caudal segment. Spondylolithesis is graded on the basis of the percentage of slip of one vertebral body on the vertebral body below: grade 1, 0–25% slip; grade 2, 25–50%; grade 3, 50–75%; grade 4, >75%.[13] Posterior element overuse syndrome—also referred to as spondylogenic back pain, hyperlordotic back pain, mechanical low back pain, and lumbar facet syndrome—should be considered if investigations are negative for
Fig. 158.1 Lateral radiograph of the lumbosacral spine in a 12 year old obese girl with bilateral spondylolysis (middle arrow) and grade I spondylolisthesis of L5 on S1 (bottom arrow). There is also evidence of Schmorl's nodes (top arrow) within the thoracic spine.

Radiograph courtesy of the Department of Radiology, British Columbia's Children's Hospital.

spondylolysis.[14] It includes injury to the muscle–tendon units, ligaments, joint capsules, and facet joints. Adolescents with spondylolysis, spondylolisthesis, and posterior element overuse syndrome present with insidious onset of low back pain, worsened by extension, activity, or prolonged standing. Radicular symptoms may be present if there is nerve root irritation. Adolescents may have exaggerated lumbar hyperlordosis, tight hamstrings, limited forward flexion and straight-leg raise, painful spinal extension (especially single leg extension on the affected side, 'stork test'), focal tenderness over the site of a pars lesion, and a step-off at the lumbosacral junction with spondylolisthesis. A neurological deficit affecting the L5 or S1 nerve roots may be present, with nerve root irritation and high-grade spondylolisthesis. Radiographs (standing lateral, anteroposterior) characterize gross bony abnormalities and stage spondylolisthesis and single-photon emission computed tomography (SPECT) bone scan confirms spondylolytic lesions and acuity.[15] Skeletally immature adolescents with bilateral spondylolysis or spondylolisthesis require standing lateral radiographs every 6–12 months until skeletal maturity to assess for slip progression. Treatment includes activity restriction until asymptomatic and physiotherapy focused on core strength and hamstring flexibility. The use of braces is controversial, with studies showing bony healing with the use of a rigid brace, a soft brace, or no brace.[15] Most adolescents return to activities by 6 months after diagnosis. Adolescents with greater than 50% slip (grade 3 or 4) warrant orthopaedic referral and possible surgical treatment.

Scheuermann's disease is the most common cause of kyphotic deformity in adolescence (Table 158.3), with onset just prior to puberty.[16] The thoracic pattern is more common than the thoracolumbar pattern. Adolescents usually present with cosmetic concerns but may have pain with prolonged sitting posture and exercise. The kyphosis is fixed, distinguishing Scheuermann's from postural kyphosis which disappears with forward flexion. Neurological deficits are rare.[17] Standing lateral and anterior-posterior (AP) radiographic features classically show anterior wedging of at least three adjacent vertebral bodies by 5° or more, end plate irregularities, loss of disc space height, Schmorl nodes and Cobb angle of at least 45°.[18] Treatment includes physiotherapy for minor curves and possible bracing for thoracic curves greater than 55° or thoracolumbar curves greater than 40°. Adolescents with curvature of 70° or greater, refractory pain, or neurological deficit may need surgical treatment.[19]

Idiopathic scoliosis affects 1–3% of children and adolescents.[20] Scoliosis is usually painless but one study reported pain in 32% with only 9% having an identifiable cause for pain.[21] Untreated scoliosis may also cause back pain.[20] On examination, forward flexion of the spine accentuates the curve (imbalanced rib cage with one side higher than the other). Standing coronal radiograph with Cobb

Table 158.3 Back pain in adolescence

Clinical presentation	Clinical condition
Pain with extension	Posterior element overuse syndrome, spondylolysis, spondylolisthesis
Pain with flexion ± neurological symptoms	Disc pathology
Kyphotic posture, occasionally pain	Scheuermann's disease

angle of at least 10° confirms the diagnosis.[22] Treatment is dependent on skeletal maturity and degree of curvature and includes observation, physiotherapy, orthoses, and surgery.

Lumbar disc herniation (primarily L4–5 or L5–S1) is uncommon in childhood.[23] Children present with low back, buttock, or hip pain worsened by bending forward, coughing, sneezing, or straining with bowel movements. Children may have limitation of forward flexion and positive straight-leg raise test. Neurological findings are uncommon. Radiographs and MRI help differentiate between spondylolysis with nerve root impingement or disc herniation with nerve root impingement.[24] Treatment includes rest, analgesics, and physical therapy. Adolescents do not fare as well with conservative therapy as do adults. Adolescents who fail to respond to conservative therapy and those with progressive neurological deficit warrant orthopaedic referral for possible surgical treatment.

Hip

Transient synovitis and septic arthritis are the most common diseases among young children with acute hip pain. Causes of chronic hip pain are often related to skeletal maturity and are fairly specific to the age of the child (Table 158.4).

Perthes' disease, an idiopathic avascular necrosis of the femoral epiphysis, affects children aged 4–10 years old (peak 5–7 years), is more common in boys (4:1) and is bilateral in 10%.[25] Children present with a limp or pain in the hip, thigh, or knee; limited and painful rotation and abduction of the hip; and Trendelenburg sign may be positive. Radiographs of early lesions may show decreased size or increased density of the proximal femoral epiphyses and crescent sign (a subchondral fracture that correlates with the extent of necrosis). Late radiographs may show fragmentation, reossification, remodelling, and healing. Perthes' disease generally resolves with no long-term sequelae but early osteoarthritis may occur. Age greater than 6 years is worse prognosis than younger children and femoral head involvement of more than 50% is the strongest predictor of poor outcome.[26] Treatment includes rest and range-of-motion exercises. Older children with greater femoral head involvement may require orthoses or surgery.

Slipped capital femoral epiphyses (SCFE), displacement of the proximal femoral epiphysis off the femoral neck, affects preadolescents (peak 11–14 years) is more common in boys and in obese children, and is bilateral in 20–40%.[27] Children present with a limp; hip, groin, or knee pain; decreased range of motion of the hip (active and passive internal rotation, flexion and abduction); and Trendelenburg sign may be positive. SCFE is classified as stable or unstable based on a child's ability to weightbear on the affected leg.[28] Radiographs of the hip may show widening and irregularity of the physis with posterior inferior displacement of the femoral head. On the AP view, a line drawn from the superior femoral neck (Klein's line) should intersect some portion of the femoral

head (Figure 158.2).[27] Treatment includes non-weightbearing, and surgery with epiphyseal fixation and possible osteotomy. Most children do well after surgical fixation but avascular necrosis and chondrolysis may occur. Unstable slips have worse prognosis. Children require long-term follow-up as SCFE may develop within 12–18 months in the contralateral hip, if prophylactic pinning is not done.[29] Children who do not fit the classic profile for SCFE (under age 10 or over age 16, thin) should undergo evaluation for associated endocrinopathies (thyroid disease, growth hormone abnormalities).[30]

Apophysitis and apophyseal avulsion fractures around the pelvis may occur in skeletally immature adolescents secondary to forceful or repetitive traction of the attached muscle. Apophysitis presents with dull, activity-related pain and avulsion fractures present with localized pain, swelling, and decreased active range of motion. Common sites of injury are the iliac crest (abdominal muscles), anterior superior iliac spine (sartorius), anterior inferior iliac spine (rectus femoris), ischial tuberosity (hamstrings), and lesser trochanter (iliopsoas). Radiographs may show widening of the apophyses in apophysitis and displacement of the apophyseal centre and bony reaction in apophyseal avulsion fracture. MRI is useful if radiographs are normal.[31] Treatment includes activity modification, and physiotherapy with the majority of adolescents recovering within 2 months. Surgical treatment is rarely required.

Idiopathic chondrolysis of the hip affects adolescents and is more common in girls. Adolescents present with pain, limp, and reduced range of motion of the hip. Investigations (haematological, microbiological, immunological, and acute-phase reactants) are normal. Early radiographs may be normal and late radiographs may show regional osteoporosis, premature closure of the femoral capital physis, joint space narrowing, and lateral overgrowth of the femoral head on the neck. MRI shows loss of articular cartilage with minimal synovial enhancement.[31] Many adolescents develop painful osteoarthritis of the hip. Treatment includes protective weightbearing, anti-inflammatories, physiotherapy, and orthopaedic intervention as necessary.

Snapping hip syndrome is a relatively common complaint in childhood. Anterior symptoms are caused by the iliopsoas tendon snapping under the inguinal ligament or over the iliopectineal eminence and lateral symptoms are caused by the iliotibial band snapping over the greater trochanter.[32] Pain may be present if there is an associated bursitis or if snapping is due to an acetabular labral tear. Children can usually reproduce their symptoms during examination. Treatment includes avoidance of aggravating activities and physiotherapy. Recalcitrant cases warrant orthopaedic referral for possible bursal excision and Z-plasty to lengthen the iliotibial band.[33]

Knee

Anterior knee pain is one of the most common musculoskeletal complaints seen in the paediatric population. Most causes involve the patellofemoral joint and the extensor mechanism of the knee.

Patellofemoral pain (PFP), secondary to excessive forces of compression and friction at the patellofemoral joint, affects active and inactive children, is more common in girls, and is most common during the adolescent growth spurt.[34] Children present with dull, achy peripatellar or retropatellar pain during and after weightbearing activity, stair use, and squatting. Stiffness may be present after

Table 158.4 Causes of hip pain during childhood and adolescence

Clinical condition	Age (years)
Toxic synovitis	2–10 (peak 5–6)
Legg–Calvé–Perthes	4–10 (peak 5–7)
Slipped capital femoral epiphyses	11–15
Fig. 158.2 Anterior posterior radiograph of the hips in a teenage boy with slipped capital femoral epiphyses on the right. Klein's line is drawn along the radiographic border of the neck of the femur. This line should intersect the epiphysis.
Radiograph courtesy of the Department of Radiology, British Columbia's Children's Hospital.

prolonged sitting with the knee in flexion ('theatre sign'). Symptoms usually affect both knees with one side more affected. On examination, children may have lower extremity malalignment (genu valgum, genu varum, genu recurvatum, leg length discrepancy, femoral anteversion, external tibial torsion, lateral displacement of the tibial tubercle, excessive pronation of the subtalar joint), vastus medialis wasting, patellar facet tenderness, tightness (hamstrings, quadriceps, iliotibial band, gastrocnemius) and weakness (quadriceps, hip external rotators, abductors, trunk muscles) of the lower extremity muscles. Painful quadriceps setting/grind test (Clarke's test; examiner applies pressure against the superior pole of the patient's patella during an isometric quadriceps contraction with knee in full extension) and patellar compression test (direct compression of the patella in to the trochlea) aid diagnosis.[35] Swelling is unusual. Treatment includes activity modification, ice, short-term anti-inflammatories, and physiotherapy focusing on patellar tracking exercises, strength, and flexibility. Shoe orthoses (subtalar pronation) and patellofemoral orthoses may reduce symptoms. Most children have gradual improvement and resolution of PFP.

Patellofemoral instability is more common in children with hypermobility and anatomic variants (patella alta, unifaceted or bipartite patella, shallow intercondylar groove, lateral attachment of the patellar ligament).[36] Children present with PFP, episodic giving way and locking, recurrent swelling, and positive patellar apprehension test. Treatment is the same as for PFP. Patellofemoral orthoses may prevent recurrent episodes of instability.

Children with recurrent patellar dislocation warrant orthopaedic referral.[36]

Patellar tendinopathy affects skeletally mature individuals who present with infrapatellar pain aggravated by jumping and maximal tenderness at the patellar attachment and proximal tendon. Patellar tendon thickening and nodules may be palpable.

Osgood–Schlatter disease (OSD) and Sinding–Larsen–Johansson disease (SLJD) are osteochondroses/traction apophysitis that affect skeletally immature children and present with pain at the attachments of the patellar tendon. OSD is more common than SLJD, affects 8–12 year old girls and 12–15 year old boys, and occurs at the growth plate of the tibial tuberosity. SLJD affects 10–12 year olds and occurs at the inferior pole of the patella.[37] Children present with localized pain during activity, focal tenderness, and soft tissue swelling. The presentation during growth and the temporal association

of pain during and after activity helps distinguish OSD and SJLD from inflammatory enthesopathy, which is classically present in the morning, at rest, and improves with activity. Radiographs are not required for diagnosis and typically show bony reaction and fragmentation. Treatment includes activity modification, ice, anti-inflammatories, physiotherapy, and infrapatellar strap. Recovery may be expedited by reduction of running and jumping sports, with the natural history being a resolution of symptoms over months to years at skeletal maturity.[38,39]

Osteochondritis dissecans of the knee classically affects the lateral aspect of the medial femoral condyle, but the lateral femoral condyle and patella may also be involved. Repetitive microtrauma combined with poor blood supply leads to injury to subchondral bone and its overlying articular cartilage.[40] Children present with activity-related knee pain and swelling. Mechanical symptoms of locking may be present if there is a loose body. On examination, there is focal bony tenderness and joint effusion, and extension block or palpable loose body may be noted. Radiographs may show a radiolucent lesion, subchondral fracture, separation with subchondral bone and a loose body (Figure 158.3).[40] MRI better evaluates the extent of the lesion. Skeletally immature children with smaller, stable, non-detached lesions have the best prognosis. Treatment includes protective weightbearing and immobilization with surgery reserved for recalcitrant symptoms and detached unstable lesions.[41]

Synovial plica syndrome presents with medial knee pain, and snapping and catching during flexion. There may be tenderness over the medial patellar retinaculum or anteromedial joint line and the plica may be palpable as a thickened band that is tender when pressed against the edge of the condyle. Treatment includes patellar mobilization and massage, anti-inflammatories, and physiotherapy. Recalcitrant cases warrant orthopaedic referral for possible surgical resection.

Fat pad impingement ('Hoffa's syndrome') presents with pain during knee extension, prolonged standing, and kneeling. On examination there is tenderness and swelling over the fat pad and painful knee extension. Treatment includes cryotherapy, anti-inflammatories, activity modification, and physiotherapy.

Discoid lateral meniscus is an anatomic variant that commonly presents in school-aged children and adolescents, with clicking and catching during knee extension. The abnormally shaped meniscus

(A)

(B)
Fig. 158.3 Osteochondritis dissecans in a child with juvenile arthritis: (A) Anterior posterior view shows minimal cystic changes affecting the lateral femoral condyle. (B) Tunnel or notch view shows the lateral femoral condyle cystic changes with surrounding sclerosis more clearly. There is also irregularity of the medial femoral condyle suggesting an osteochondral lesion.
Radiograph courtesy of the Department of Radiology, British Columbia's Children's Hospital.

is easily torn, leading to swelling, instability, catching, and/or locking of the knee. Children may have painful clicking with extension, lateral joint line tenderness, and swelling. MRI confirms the diagnosis. Treatment includes activity modification and physiotherapy for intact discoid meniscus and orthopaedic referral for surgical management of torn discoid meniscus.[42]

Lower leg

'Shin splints'/medial tibial stress syndrome presents as activity-related shin pain and tenderness along the posteromedial border of the tibia due to perisotitis and fascitis caused by repetitive stress. It is more common during the adolescent growth spurt, with subtalar pronation, and often presents after an increase in activity. Radiographs are normal and radionuclide bone scan shows diffuse increased uptake at the junction of the middle and distal thirds of the posteromedial tibia, differentiating it from focal uptake seen in stress fracture.[43] Treatment includes rest, ice, physiotherapy, and change in footwear or orthotic.

Foot and ankle

Foot and ankle pain is common in children and adolescents. Problems are usually related to skeletal maturity and are fairly specific to the age of the child.

Pes planus is common in children up to age 7 and occurs in 10–23% of the general population.[44,45] Flexible flat feet refers to the presence of an arch while toe-standing or sitting. Most children with flexible flat feet are asymptomatic; however, some children may have pain during or after activity. Painful flat feet should be imaged to rule out anatomic variants (tarsal coalition, vertical talus, or accessory navicular). Symptomatic children may benefit from a rigid medial arch support. Orthotics may decrease the risk of ankle or knee injury in young athletes with excessive pronation.

Sever's disease, a traction apophysitis of the os calcis at the insertion of the Achilles tendon, affects children aged 7–14 years, is more common in boys, and is bilateral in 60%.[46] Children present with heel pain during running and jumping activities, tenderness, and possible swelling over the posterior heel at the insertion of the Achilles tendon, pain with medial and lateral squeeze of the calcaneal apophysis, weakness of dorsiflexion, and contracture of the Achilles tendon. Radiographs show a normally irregular apophysis

and soft tissue swelling. The presentation during growth and the temporal association of pain with activity helps distinguish Sever's from inflammatory enthesopathy which is classically present in the morning, at rest, and improves with activity. Treatment includes ice, anti-inflammatories, activity modification, physiotherapy, and insertion of a heel lift or heel cup in footwear.

Iselin's disease, a traction apophysitis of the tuberosity of the fifth metatarsal at the insertion of the peroneus brevis tendon, affects 7–14 year olds, who present with lateral foot pain and point tenderness over the base of the fifth metatarsal. Radiographs differentiate Iselin's disease from avulsion fracture, as the apophysis is parallel to the long axis of the fifth metatarsal and fractures are usually transverse.[47] Treatment includes ice, anti-inflammatories, activity modification, immobilization, and physiotherapy.

Tarsal coalition, failure of complete segmentation between two or more tarsal bones, occurs in 3–5% of the population, affects boys twice as often as girls, and is often bilateral. Onset of symptoms usually occurs at the time of ossification; 8–12 years of age for calcaneonavicular and 12–16 years for talocalcaneal coalitions.[48] Children present with pain, a history of frequent 'ankle sprains' and a rigid flatfoot with restricted and possibly painful subtalar range of motion. Radiographs (oblique and axial views) may show calcaneonavicular coalitions but CT or MRI is needed for fibrous or cartilaginous coalition and other tarsal coalitions.[49] Treatment of symptomatic coalitions includes casting and/or orthoses, physiotherapy, and possible surgical management.

Kohler's disease, an osteochondroses of the tarsal navicular, affects children aged 5–9 years and is bilateral in up to 25% of cases.[50] Children present with midfoot pain with weightbearing activity and localized swelling and tenderness over the navicular. Radiographs show increased sclerosis of the navicular; however, irregular ossification is a normal growth variant and clinical correlation is required for diagnosis. Treatment includes anti-inflammatories, activity modification, and immobilization in a walking boot for severe cases.

Freiberg's disease, an osteonecrosis of the metatarsal head, affects the second and third metatarsals and is more common in athletic adolescent females.[50] Adolescents present with forefoot pain and focal tenderness over the affected metatarsal head. Radiographs show initial joint space widening, followed by collapse and eventual reossification of the metatarsal head.[50] Treatment includes anti-inflammatories, immobilization in a walking boot, and orthotics.

The healing process can take 2–3 years and surgical management may be required for persistent symptoms.

Osteochondral dissecans of the talar dome causes activity-related ankle pain and swelling. Mechanical symptoms of locking and catching may be present if there is a loose body. Radiographs may show a radiolucent lesion, bony defect, or loose body. MRI better characterizes the lesion. Treatment includes rest and immobilization with surgery reserved for recalcitrant symptoms and detached unstable lesions.[51]

Accessory ossification centres in the foot and ankle are normal growth variants and approximately 22% of children have at least one accessory ossicle.[48] Accessory bones are usually asymptomatic but may become painful with activity or may be confused with avulsion fractures. Symptomatic accessory navicular causes medial foot pain and focal tenderness over the bony prominence. Symptomatic os trigonum causes posterolateral ankle pain and focal tenderness over the posterior talus. Radiographs confirm the presence of accessory bones. Treatment includes physiotherapy and orthotics, with surgical excision reserved for recalcitrant cases.

Congenital talipes equinovarus (clubfoot) is a common musculoskeletal congenital anomaly, occurring in 1 in 1000 births.[52] Idiopathic clubfoot is most common, but it may occur in association with neurological disorders such as myelodysplasia and arthrogryposis or with multiple congenital anomalies. Untreated clubfoot leads to gait disturbance (weightbearing on sides and/or tops of the feet), potential pain due to callus formation, potential infection of skin and bone, and limited mobility. Optimal treatment for a pain-free and functional foot includes casting, bracing, and possible soft tissue release surgery.[53]

Growing pains

Growing pains, the most common cause of episodic childhood musculoskeletal pain, classically affect preschool and school-aged children.[54,55] Children present with non-articular leg aches at night that usually respond to massage and over-the-counter analgesics. Children report no pain during the day and are normally active. Increased daily activity may be associated with episodes of growing pains.

The physical examination is normal and there is no associated organic disease. However, growing pains may have a significant impact on a family due to school and work absences, daytime fatigue, and chronic analgesia use.

The cause of growing pains is not known and there are no diagnostic tests. Growing pains are a diagnosis of exclusion and it is important to rule out other causes. Investigations should be considered if there are atypical symptoms including unilateral pain, daytime pain, articular pain, daily pain (not episodic), systemic symptoms, or abnormalities on physical examination. Treatment includes education and reassurance that the pains are self-limited and benign. Over-the-counter analgesics and physiotherapy (flexibility exercises) may also be helpful for symptom management.[56]

Hypermobility syndromes

Alan J. Hakim and Rodney Grahame

Introduction

Hypermobility denotes an increased range in movement as a consequence of ligament and tendon laxity in an otherwise anatomically normal joint. The laxity may arise due to abnormalities of collagen or other connective tissue proteins.

Hypermobility may go unnoticed, confer advantage (e.g. for dancers, musicians, sports persons, and gymnasts), or lead to mechanical injury, tendonitis, dislocations, delayed recovery, and chronic myalgia and arthralgia. Equally, it may be the first clue as to the presence of heritable disorders of connective tissue (HDCT), including joint hypermobility syndrome (JHS), Ehlers–Danlos syndrome (EDS), and Marfan's syndrome (MFS).

Hypermobility can vary considerably between the HDCT and between individuals with the same disorder. In itself it should not make or break a diagnosis. Given the ubiquitous nature of connective tissue proteins, the clinical manifestations of the HDCT are varied. Further enquiry reveals skin abnormalities, vascular fragility, early-onset osteoarthritis and osteoporosis, abnormal stature, and cardiovascular, respiratory, visceral, ocular, auditory and dental pathologies. In addition, there is an association with chronic widespread pain, fatigue, bowel dysfunction, and neuromuscular and cardiovascular dysautonomia.

Osteogenesis imperfecta and Stickler's syndrome are two other discrete HDCT with certain clinical features that overlap with JHS, EDS, and MFS. These are discussed in Chapter 150. There are also many other very rare metabolic disorders associated with joint dysmorphism, joint laxity, and skin hyperextensibility. These usually present at birth or in early childhood and are beyond the scope of this chapter.

Epidemiology

Prevalence

Population studies show a wide variation in the prevalence of generalized joint hypermobility (JHM) with values of 10–30% in males and 20–40% in females in adolescence and adulthood. JHM diminishes with age, and is more common in people of African and Asian descent. Twin studies suggest that it is strongly heritable.[1]

The prevalence of JHS is unknown. Extrapolating from one study of JHM that recorded symptoms consistent with JHS, the prevalence of JHS may be high as 1 in 150 among white female adults.[2] Other evidence to infer JHS is common comes from surveys of general rheumatology clinics where it is identifiable in up to 40% of patients presenting to a rheumatologist with non-inflammatory widespread musculoskeletal pain.[3,4]

The combined prevalence of all types of EDS is approximately 1 in 10 000 worldwide. The hypermobility type (EDSHM) is the most common, but the true prevalence is unknown given that many cases are mild and may not present clinically. The classical type occurs in 1 in 15 000–20 000 of the population, and the vascular type approximately 1 in 200 000. The prevalence of the more rare variants of arthrochalasia, kyphoscoliosis, and dermatosparaxis is unknown.

At approximately 1 in 20 000–30 000, MFS has a similar prevalence to the classical variant of EDS, though, as the reader will learn below, defining true MFS can be challenging as several conditions mimic its features; the true prevalence may therefore be less.

Genetics

EDS arises as a consequence of mutations to genes encoding the assembly of collagens I, III, and V (e.g. *COL1A1*, *COL1A2*, *COL3A1*, *COL3A2*, *COL5A1*, and *COL5A2*), and enzymes (e.g. *ADAMTS2*, *PLOD1*) or extracellular matrix glycoproteins (e.g. *TNXB*) that process or interact with collagen. Mutations in genes encoding collagens I, III, and V, and collagen-modifying enzymes have been identified in most forms of EDS.[5] In many cases a gene defect is not found; the diagnosis is reliant on clinical features. Also, a gene mutation can occur sporadically, the individual presenting with no family history of the condition.

No molecular, biochemical, or ultrastructural defect has been identified in EDSHM other than approximately 5–10% of cases demonstrate diminished levels of tenascin-X, due to heterozygous mutations in the *TNXB* gene.[6] Similarly the genetics of JHS is not understood, anecdotal observation of large family pedigrees suggesting a dominant inheritance.

MFS arises as a result of mutations to the gene *FBN1* on chromosome 15q21. The *FBN1* gene encodes production of fibrillin-1, a key component of microfibrils that add strength and flexibility to connective tissue. In MFS the quality and quantity of fibrillin-1 is reduced, with excessive release of growth factors from the microfibrillar structure. MFS has an autosomal dominant pattern of inheritance; however, a new mutation of the *FBN1* gene may arise in up to 25% of cases.

In a small percentage of cases a Marfan-like disorder (classified by some experts as MFS type II) is caused by mutations of the

TGFBR2 gene that instructs the production of the transforming growth factor (TGF)-β type II receptor. Interference with receptor function results in aberrant intracellular signalling and production of growth factors. Several other conditions share clinical features of MFS. Their genetic markers are described in the next section.

Diagnostic criteria

JHS was originally defined as 'the occurrence of symptoms in otherwise healthy hypermobile individuals'. It is now considered more complex than this, is defined by the Brighton Criteria (see Box 159.1),[7] and shares similar clinical features to EDSHM. Most authorities consider JHS and EDSHM to be synonymous. Similarly, up to one-third of JHS cases have a marfanoid habitus (see Box 159.2) in the absence of MFS and over one-half have blue sclerae in the absence of osteogenesis imperfect (OI). The validation of the criteria for JHS is a subject of current international research amongst experts in the field.

The Villefranche 1997 nosology[8] classifies EDS based on clinical features, biochemical and genetic defect, and the pattern of inheritance (Table 159.1). Six main descriptions substitute for an earlier Roman numeral classification: classic type (EDS I and II), hypermobility type (EDS III), vascular type (EDS IV), kyphoscoliosis type (EDS VI), arthrochalasia type (EDS VIIA and VIIB),

---

Box 159.1 The Beighton diagnostic criteria for the joint hypermobility syndrome[7]

Major criteria

1. A Beighton score of 4/9 or greater (either currently or historically)

2. Arthralgia for longer than 3 months in four or more joints

Minor criteria

1. A Beighton score of 1, 2 or 3/9 (0, 1, 2 or 3 if aged 50+)

2. Arthralgia in 1–3 joints or back pain or spondylosis, spondylolysis/spondylolisthesis

3. Dislocation in more than one joint, or in one joint on more than one occasion

4. Three or more soft tissue lesions (e.g. epicondylitis, tenosynovitis, bursitis)

5. Marfanoid habitus (tall, slim, span > height upper segment:lower segment ratio less than 0.85, arachnodactyly)

6. Skin striae, hyperextensibility, thin skin, or abnormal scarring

7. Eye signs: drooping eyelids or myopia or anti-mongoloid slant

8. Varicose veins or hernia or uterine/rectal prolapse.

◆ JHS is diagnosed in the presence of **two** major criteria, or **one** major and **two** minor criteria, or **four** minor criteria. **Two** minor criteria will suffice where there is an unequivocally affected first-degree relative.

◆ JHS is excluded by presence of EDS (other than the EDS hypermobility type, formerly EDS III) or Marfan's syndrome.

Box 159.2 Features of the marfanoid habitus

◆ High arched palate

◆ Arachnodactyly:

– 'wrist sign' (Walker): positive if able to wrap the thumb and fifth finger of one hand around the opposite wrist such that the nail bed of the digits overlap with each other, *and/or*

– 'thumb sign' (Steinberg): positive if the adducted thumb across the palm projects beyond the ulnar border in the clenched hand

◆ Pectus excavatum or carinatum

◆ Scoliosis >20° is a major criteria in MFS. It is also a sign of EDS kyphoscoliotic type. In other EDSvariants, and in JHS it may be present to a milder degree.

◆ Arm span:height ratio > 1.05 (in adults)

◆ Tall stature with upper body (pubis to crown):lower limb length (floor to pubis) ratio <1 (aged 0–5 years) and <0.85 (aged ≥10 years)

◆ Foot length (heel to first toe):height ratio > 0.15

◆ Hand length (wrist crease to third finger):height ratio > 0.11

---

and dermatosparaxis type (EDS VIIC). Six other forms are listed, including types V, X, and the periodontitis type (EDS VIII), all of which are extremely rare, reported in a handful of cases.

The classification of MFS has been refined from the Ghent 1996 criteria[9] that defined a set of major and minor manifestations in the presence or absence of an associated *FBN1* mutation or family history. Several conditions share certain manifestations with the risk of inadvertent classification as MFS. The 2010 revised Ghent criteria[10] emphasize aortic root disease (dilatation and dissection) and ectopia lentis (EL) (lens dislocation) as cardinal features of MFS, separating it from other conditions on the basis of the following:

◆ Degree of aortic root dissection or dilatation recorded as the Z-score (a measure of the aortic root (sinus of Valsalva) diameter standardized for age and body size). A score of ≥2 is deemed pathological.

◆ Presence of EL.

◆ Presence of a genuine *FBN1* mutation or known linkage to an *FBN1* haplotype.

◆ A weighted score of systemic features described in the 1996 criteria.

Box 159.3 describes the criteria for a diagnosis, and Box 159.4 the weighted score for systemic features in MFS. The differential diagnosis of Marfan-like conditions is more clearly defined as a consequence of the 2010 MFS criteria and includes:

◆ Ectopia lentis syndrome (ELS)—EL associated with mutations of *FBN1* and *ADAMTsL4*, and systemic features of MFS, but not aortic root disease.

◆ A phenotype of mitral valve prolapse, myopia, borderline and non-progressive aortic enlargement, and skin/skeletal systemic

Table 159.1 Classification of Ehlers–Danlos syndromes[7]

Type (Previous number classification)	Clinical manifestations		IP	Protein	Gene and chromosome (Ch)
	Major criteria	**Minor criteria**			
Classic (type I/II)	Skin hyperextensibility Widened atrophic scarring Joint hypermobility	Easy bruising Smooth and velvety skin Molluscoid pseudotumours Subcutaneous spheroids Muscular hypotonia Complications of joint hypermobility Surgical complications Positive family history	AD	Type V procollagen (found in ~50%)	COL5A1 (Ch 9) COL5A2 (Ch 2)
Hypermobility (type III)	Generalized joint hypermobility Mild skin involvement	Recurring joint dislocations Chronic joint pain Positive family history Premature osteoarthritis Pitral valve prolapse	AD	Tenascin-X (found in ~5%)	TNXB
Vascular (type IV)	Excessive bruising Thin, translucent skin Arterial/intestinal/uterine fragility or rupture Characteristic facial appearance	Acrogeria Early-onset varicose veins Hypermobility of small joints Tendon and muscle rupture Arteriovenous or carotid-cavernous sinus fistula Pneumo (haemo)thorax Positive family history, sudden death in close relative(s)	AD	Type III procollagen	COL3A1 (Ch 2)
Kyphoscoliotic (type VI)	Severe muscular hypotonia at birth Generalized joint laxity Kyphoscoliosis at birth Scleral fragility and rupture of the globe	Tissue fragility, including atrophic scars Easy bruising Arterial rupture Marfanoid habitus Microcornea Osteopenia	AR	Type VIA: Lysyl hydroxylase 1 Type VIB: not known	PLOD1 (Ch 1)
Arthrochalasis (type VIIA&B)	Severe generalized joint hypermobility with recurrent subluxations Congenital bilateral hip dislocation	Skin hyperextensibility Tissue fragility, including atrophic scars Easy bruising Muscular hypotonia Kyphoscoliois Mild osteopenia	AD	Type I procollagen	COL1A1 (Ch 17) COL1A2 (Ch 7)
Dermatosparaxis (type VIIC)	Severe skin fragility Sagging, redundant skin Excessive bruising	Soft, doughy skin texture Premature rupture of membranes Large hernias	AR	Procollagen-N-proteinase	ADAMTS2 (Ch 5)

AD, autosomal dominant; AR, autosomal recessive; IP, inheritance pattern.

Box 159.3 The revised Ghent criteria for the diagnosis of Marfan's syndrome (MFS)[10]

In the absence of a family history of MFS a diagnosis is made in the presence of one of four situations:

1. Aortic root Z-score ≥ 2 (or dissection) *and* ectopia lentis (EL), irrespective of systemic features except where these are indicative of other conditions*, *or*

2. Aortic root Z-score ≥ 2 (or dissection) *and* a systemic feature (Box 159.4) score ≥ 7 except where these are indicative of other conditions*. EL is assumed absent otherwise classification reverts to (1) above, and FBN1 status may be unknown or negative, *or*

3. Aortic root Z-score ≥ 2 (or dissection) *and* a recognized *FBN1* mutation (or definite linkage to a predisposing *FBN1* haplotype), *or*

4. Ectopia lentis *and* an *FBN1* mutation unequivocally associated with aortic disease. Aortic root dilatation/dissection may be absent at the time.

With a positive family history (defined by any of the above), a diagnosis of MFS is made in the presence of one of the following three situations:

1. Ectopia lentis

2. A systemic features score ≥ 7 except where these are indicative of other conditions*, *or*

3. Aortic root Z-score ≥ 2 (or dissection) in an individual of 20 years of age and older, *or* aortic root Z-score ≥ 3 (or dissection) if under aged 20 years

* The following conditions should be excluded: vascular EDS (see Table 159.1), Shprintzen–Goldberg syndrome (*FBN1* mutation, craniosynostosis, and mental retardation), and Loeys–Dietz syndrome (*TGFBR1/2* mutations, bifid uvula, cleft palate, craniosynostosis, hypertelorism, cervical spine instability, thin velvety skin, easy bruising, and arterial tortuosity and aneurysms).

Box 159.4 Scores for systemic features of Marfan's syndrome[10]

One point is given for each one of the following eight features:

◆ At least three of the following five facial features: dolichocephaly, enophthalmus, downslanting palpebral fissures, malar hypoplasia, and retrognathia

◆ Reduced elbow extension

◆ Pectus excavatum or chest asymmetry (excluding carinatum which scores 2, as below)

◆ Reduced upper/lower segment and increased arm span/height ratio (see Box 159.2), in the absence of severe scoliosis

◆ Scoliosis or thoracolumbar kyphosis

◆ Skin striae

◆ Mitral valve prolapse

◆ Myopia greater than 3 dioptres

Two points are given for each of the following five features:

◆ Pectus carinatum

◆ Pneumothorax

◆ Dural ectasia

◆ Protrusio acetabulae

◆ Hindfoot deformity (if plain pes planus, only score 1)

Three points are given for:

◆ Wrist *and* thumb sign (see Box 159.2) (if only one of the two signs is present, only score 1).

The maximum score is 20. A score ≥7 is indicative of MFS with the caveats in Box 159.2.

Clinical signs, symptoms, and investigation in heritable disorders of connective tissue

The contents of Table 159.1 and Boxes 159.1–159.4 provide a concise picture of the breadth of clinical features found in EDS, JHS, and MFS respectively. In addition patients often present with chronic widespread pain, fatigue, and neuromuscular, cardiovascular, and bowel autonomic dysfunction. Table 159.2 links the signs and symptoms in HDCT to genetic and radiological testing in pursuit of a diagnosis.

Considerable clinical overlap occurs between the HDCT, particularly in relation to the degree of skin signs, presence of mitral valve prolapse, and the marfanoid habitus (see Box 159.2). It is essential the clinician appreciate the overlap and degree to which signs manifest, in addition to the cardinal features and genetic markers that define a specific condition.

Musculoskeletal

Hypermobility

The extent to which generalized hypermobility (JHM) is present is most often described by applying the Beighton 9-point scoring system (Figure 159.1),[11] a tool that was refined originally for the purposes of epidemiological research.

features (MASS), scoring ≥5 as defined in Box 159.1 with at least one skeletal feature, associated with mutations of *FBN1* but not with EL.

◆ Mitral valve prolapse syndrome—an *FBN1* mutation associated with systemic features of MFS with a score <5 (see Box 159.3), mild aortic root dilatation (Z-score <2), but not with EL.

◆ Congenital contractile arachnodactyly—joint contractures associated with mutation of *FBN2*.

◆ Familial thoracic aortic aneurysm syndrome—vascular pathology associated with mutations of *TGFBR1/2* and *ACTA2* but not with features of the marfanoid habitus.

◆ Homocystinuria—an autosomal recessive defect in methionine metabolism caused by deficiency in cystathionine beta-synthase (CBS), also associated with insufficient vitamin B_{12} synthesis, and a deficiency in methylene-tetrahydrofolate reductase. In relation to MFS characteristic features include arachnodactyly, EL, and myopia. The vascular pathology is thromboembolic, not dilatation/dissection.

Table 159.2 Differentiating the heritable disorders of connective tissue

Clinical evaluation and family history

- skin hyperextensibility
- delayed wound healing
- atrophic scarring
- easy bruising
- congenital dislocation of the hips
- vascular fragility

- history of multiple fractures
- short stature
- blue sclerae
- conductive
- deafness

- marfanoid habitus (tall and slender build, arachnodactyly, ...)
- ectopia lentis
- aortic dilatation/aneurysm
- mitral valve prolapse
- dural ectasia

Evaluation for other specific signs: Early osteoarthritis, ocular pathology... muscular hypotonia, contractures, dysmorphic features, mental retardation.

One point is given for each side of the body for the first four manoeuvres and one for spinal flexion. A value of 4 or more in males, and 5 or more in females, is considered suggestive of JHM. These figures are arbitrary cut-off points and the score ignores a number of joints that are often sites of injury and instability associated with hypermobility. These include the cervical and thoracic spine, shoulders, hips, ankles, midfoot, and first metatarsophalangeal (MTP) joint, and should be examined clinically to support the assertion of generalized JHM and determine sites of risk and pathology.

An alternative tool in screening for JHM is a simple five-part self-report questionnaire (Box 159.5).[12] It is a quick screen while taking the clinical history that may support the need for a detailed physical examination.

The presence and degree of hypermobility can vary considerably between the HDCT and between individuals with the same disorder. It is most pronounced in the variants of EDS and JHS and less common in MFS. Vascular EDS is typically associated with small-joint hypermobility affecting the digits.

Dislocation and subluxation

Joint dislocation or the lesser degree, subluxation, may be a recurrent in EDS and JHS. Sites often affected are the carpometacarpal and glenohumeral joint, and the patella. Congenital hip dislocation is a mark of arthrochalasia EDS, but may also be present in classic and hypermobility EDS. Severe joint hypermobility and multiple congenital joint dislocations of hips, elbows, and knees are the main features of Larsen's syndrome. Other symptoms of this condition include characteristic facial appearance of flat face, prominent forehead, widely spaced eyes, depressed nasal bridge, cleft palate

or uvula, dental abnormalities, short metacarpals and cylindrical fingers, equinovarus deformity of the foot, and cardiovascular lesions.

Tendinopathy and osteoarthritis

Abnormal tension forces and weightbearing at hypermobile joints can induce recurrent tendinosis and acute and chronic inflammation.

Population studies have not shown an association between JHM and local or generalized osteoarthritis. In EDS and JHS studies suggest an increased risk of articular dysfunction and premature osteoarthritis (OA) of the temporomandibular joint and or the knee where association with chondromalacia patellae is also reported and in the small joints of the hand (nodal OA).[13] At other sites such as the hip, premature secondary OA (see Chapter 139) might be accounted for by excessive prolonged weightbearing (e.g. dancers, athletes) or congenital anatomical abnormality including increased risk of recurrent dislocation.

Fractures

Low bone mineral density (BMD) is seen in EDS, MFS, and OI; it is especially common in OI. Osteopenia is a recognized feature of JHS. Aside from OI it is unknown whether the bone quality and low BMD in HDCT represents an independent risk for fragility fracture and there are no specific guidelines for managing osteoporosis associated with the HDCT. Assessment and treatment should be as per guidelines for the primary and secondary prevention of osteoporotic fracture in the general population (see Chapter 143).

Skin, eyes, and dentition

Skin

Like the presence of JHM, skin signs are a valuable clue as to the presence of the HDCT. To varying degrees signs include soft and silky texture, semitransparency, hyperextensibility, easy bruising, abnormal scarring (such as atrophy or keloid), and early-onset stretch marks (striae atrophicae) at atypical sites (Figure 159.2).

Skin hyperextensibility is characteristic for all EDS subtypes, except for the vascular type. It is most prominent in classic EDS,

severe in the rare dermatosparaxis variant, and evident to a lesser degree in EDSHM and JHS. In vascular EDS the skin is not hyperextensible, but thin and transparent, showing the venous pattern over the chest, abdomen, and extremities.

The skin overlying the dorsum of the hand is a convenient site for assessing extensibility. It is measured informally by pinching a fold

between one's thumb and index finger and pulling the skin until resistance is felt (Figure 159.2A). The skin is hyperelastic, which means that it recoils after release. Testing in this way is subjective and requires experience. In MFS skin laxity is also present,[14] but infrequent.

The hyperextensible skin in EDS should be distinguished from that of cutis laxa syndromes, which result from mutations of the elastin gene and loss or fragmentation of the elastic fibre network. In the cutis laxa syndromes, the skin is redundant, hanging in loose folds, is not fragile, and heals normally.

Striae are common in the presence of pregnancy (striae gravidarum), obesity, Cushing's syndrome, or excess exogenous corticosteroids. In the HDCT there is often a different history with early-age onset of atrophic striae at body sites not usually affected by the other causes (e.g. extensor surfaces such as the elbows or knees, inner thigh, and across the chest). Striae are common in JHS and EDS, and to a lesser extent in MFS. Striae gravidarum may be absent or minimal in the HDCTs, including JHS.

Spontaneous easy bruising is also common, especially in EDS. The HDCT have a tendency to manifest prolonged bleeding following simple tasks, e.g. brushing teeth. It can raise suspicion of a haematological disorder, or non-accidental injury (NAI), especially in children. Investigations may require exclusion of platelet dysfunction and abnormal clotting factors.

(b)

(c)

Fig. 159.2 Typical skin features in the heritable disorders of connective tissue.

With permission from Hakim AJ, Malfait F, De Paepe A, Sahota A (2010). The heritable disorders of connective tissue: epidemiology, nosology and clinical features, in Hakim AJ, Keer R, Grahame R (eds) Hypermobility, Fibromyalgia and Chronic Pain, p.14. Churchill Livingstone Elsevier, London.

Poor healing is another feature. Delayed wound healing and atrophic scarring is most prominent in classic, kyphoscoliotic, and arthrochalasia EDS. In JHS the pathology may be less obvious and something the patient may not have recognized as 'abnormal', only coming to light after surgery when the scar becomes atrophic.

Histological examination of the skin may assist in the diagnosis of EDS and OI (see Table 159.2) but may not be necessary where clinical signs are obvious, as in JHS, or when genetic markers are positive.

Eyes

Ocular pathologies in the HDCT range from the relatively benign and non-specific feature of blue sclera seen in OI or in a milder degree in JHS, to retinal detachments, keratoconus, scarring, and visual loss in MFS, Stickler's syndrome, and kyphoscoliotic EDS.

MFS is associated with EL (lens dislocation), early-onset cataract, glaucoma, severe myopia, and hypoplastic iris and ciliary muscles. Myopia is also a feature of JHS.

Formal assessment and treatment by an ophthalmologist is advised.

Dentition

Poor dentition (dentinogenesis imperfecta) is often present in OI. It is not specifically associated with JHS, EDS, or MFS, with the exception of the very rare variant of periodontitis EDS (type VIII). Potentially more problematic is the management of temporomandibular joint pain, sticking, and dislocation during normal dental care.

Visceral disorders

Abdomen and pelvis

Intrinsic weakness of supporting structures in JHS and EDS may lead to complications such as hiatus hernia, abdominal wall herniation, achalasia of the large bowel, and uterine or rectal prolapse.

There is growing recognition of functional gastrointestinal disorders (FGID) in JHS and EDS.[15] The symptoms are typical of irritable bowel syndrome, but may be a consequence of anatomical abnormalities as described above, autonomic dysfunction, or toxicity from analgesics such as non-steroidal anti-inflammatory drugs (NSAIDs) and opiates.

Upper and lower gastrointestinal (GI) endoscopy, tissue biopsy, and dynamic studies are necessary to delineate the nature of the FGID in patients who do not settle with simple remedies for irritable bowel.

The complications of pregnancy (Box 159.6) range from life-threatening (e.g. vascular collapse in MFS or EDS vascular type, or premature rupture of the fetal membranes and antepartum haemorrhage in the classical, vascular, and hypermobility types of EDS) to more benign but problematic. The latter include abdominal herniation, pelvic floor insufficiency, haemorrhoids, joint pain, trauma to the vaginal vault and surrounding soft tissues during labour with poor wound healing, and failure of anaesthetic nerve blocks.[16]

Pulmonary disease

Spontaneous pneumothorax occurs in approximately 5% of cases of MFS. Pneumothorax and asthma are also associated with EDS,[17]

> **Box 159.6** Potential complications of pregnancy and delivery in women with heritable disorders of connective tissue
>
> - Life-threatening vascular rupture in MFS and vascular EDS
> - Joint and spinal pains may increase during the course of pregnancy—typically in JHS and EDSHM
> - Premature rupture of the membranes and thus of premature labour and delivery—typically classic or hypermobility types of EDS
> - There is a tendency to rapid labour
> - There is no absolute indication for caesarean section; the benefits and risks are a clinical judgement
> - Positioning of the mother during labour should be done with caution, avoiding excessive force on overextended joints particularly at the hips and knees.
> - Approximately two-thirds of patients with JHS/EDSHM report resistance to the effects of local anaesthetics.[15] This can complicate epidural anaesthesia or local infiltration for repair of soft tissue (e.g. episiotomy)
> - Healing of wounds may be impaired and/or prolonged and surgical technique may need to be modified accordingly
> - Care of the newborn baby more taxing than usual because of the degree of physical activity
> - Pelvic floor problems (e.g. uterine prolapse) may occur in later life so that the practice of postnatal exercises is important
> - Since many variants of the HDCT including JHS follow a dominant pattern of inheritance there is a high probability that offspring will manifest clinical features that may complicate delivery and the neonatal period, e.g. bruising, bleeding, dislocation, fracture

---

but are not specific to JHS. Investigation and treatment of asthma is the same as for the general population.

Cardiovascular disorders

Structural

Potentially life-threatening complications of MFS (see Box 159.3) include dilatation and dissection of the aortic root and ascending aorta. In vascular EDS there is an increased risk of rupture and/or dilatation/dissection of medium-sized vessels such as renal and splenic arteries. There is otherwise no significant arterial disease in other variants of EDS and JHS.

Mitral valve prolapse (MVP) is a common feature of MFS (and variants such as MASS) and less so of EDS and JHS. It may present with atypical chest pain or symptoms suggestive of extra/dropped beat and palpitations. More often in EDS and JHS it is a chance finding of no particular significance.

Concern over the possible presence of these pathologies should be investigated with echocardiography, Doppler ultrasound of the abdominal vasculature, and—if concerned as to the risk of aortic CT angiography or MRA of the aortic root, arch, and thoracic aorta. Annual echocardiography should be undertaken in the presence of aortic dilatation and MVP in MFS as both are progressive; in MFS

individuals with normal aortic diameter repeat imaging is advisable every 2–3 years. The threshold for detailed imaging with MRA and preparation for surgical intervention is an aortic diameter of 4.5 cm or more, annual increases in aortic diameter in excess of 0.5cm, or a diameter of 5 cm or more at the sinus of Valsalva with or without aortic valve dysfunction.

Easy bruising is considered a consequence weakness of capillary connective tissue support structures. Varicose veins are also associated with EDS and JHS, potentially for the same reasons but also due to laxity of the vessel wall.

Autonomic

Patients with JHS and EDSHM often report fainting or feeling faint, palpitations, chest tightness, or shortness of breath in the absence of asthma or cardiac disease.

Often these symptoms are identifiable as autonomic disturbances of orthostatic hypotension, and postural orthostatic tachycardia syndrome (PoTS) is common in JHS. Hyperresponsiveness to α- and β-adrenoreceptor stimulation has been demonstrated.[18] Other postulated mechanisms for orthostasis include peripheral neuropathy and reduced vascular tone with lower-extremity pooling.

Autonomic dysfunction with orthostatic tachycardia and hypotension has also been documented in children with EDS. Similar atypical cardiac symptoms observed in adults with EDS, historically considered related to the presence of MVP, might also be secondary to cardiac dysautonomia.

These phenomena can be identified in clinic. Table 159.3 describes the typical features of each. More sophisticated testing using the facilities of an autonomic laboratory may be required if simple measures (see 'Management of heritable disorders of connective tissue' below) do not resolve the symptoms.

Pain

Musculoskeletal pain can occur in any of the HDCT. It can be severely disabling, as is often typical in JHS/EDSHM. It may be localized and acute, secondary to tendon or soft tissue inflammation or rupture, or to joint degeneration.

More often pain is widespread in the absence of significant mechanical damage to account for the symptoms. Axial, core and limb imbalance, poor proprioception, and poor recruitment within muscle groups, may account for the widespread nature of these symptoms. Neural tension related to peripheral nerve stretch in the presence of hypermobility may account for the neuropathic nature of the pain.

Often there is also an association with fatigue and disturbances of mood and psychosocial dysfunction similar to that of fibromyalgia and chronic fatigue syndrome.

Depending on the nature of the presentation, further investigation may require exclusion of a systemic inflammatory disorder, myopathy, nerve entrapment, or other causes of fatigue.

Management of the heritable disorders of connective tissue

There is no cure for HDCT. Management is multidisciplinary in the majority of cases, with a combination of symptom control and regression of deterioration through education, physical therapies, pharmacological interventions, and behavioural therapies (Figure 159.3).

Surgery

Surgical correction of structural problems such as intervertebral disc herniation, prolapse and, at its extreme, prevention of vascular rupture may be required. Surgery may be complicated by tissue fragility, bleeding, and scarring. These risks are of particular concern in classical and vascular EDS, and aortic involvement in MFS. To a lesser degree in JHS is associated with scarring and slow healing. Pregnancy and peripartum concerns are described in Box 159.6.

The surgical threshold for vascular intervention at the aorta is described above in the section on investigation. Beta-blockers remain the treatment of choice in preventing aortic complications.

Table 159.3 Definitions and associations with common cardiovascular autonomic disorders

Condition	Definition	Associations
Orthostatic hypotension (OH)	Rapid drop in blood pressure ≥20/10 mmHg in 3 min and up to 30 min (delayed reaction)	Dehydration Anaemia Extreme vasodilation, e.g. heat Congestive cardiac failure Drugs and substances associated with OH: diuretics, ACE inhibitors, alpha- and beta-blockers, tricyclic anti-depressants, nitrates, calcium channel blockers, opiates, sildenafil, phenothiazine, hydralazine, MAO inhibitors, bromocriptine, alcohol, illicit agents
Orthostatic intolerance	Delayed signs of OH	Deficiency of the renin–angiotensin–aldosterone system
Postural orthostatic tachycardia (PoTS)	>30 bpm rise in pulse, plus symptoms of OH, or >120 bpm within 10 min of head-up tilt or standing and usually without OH	Physical deconditioning

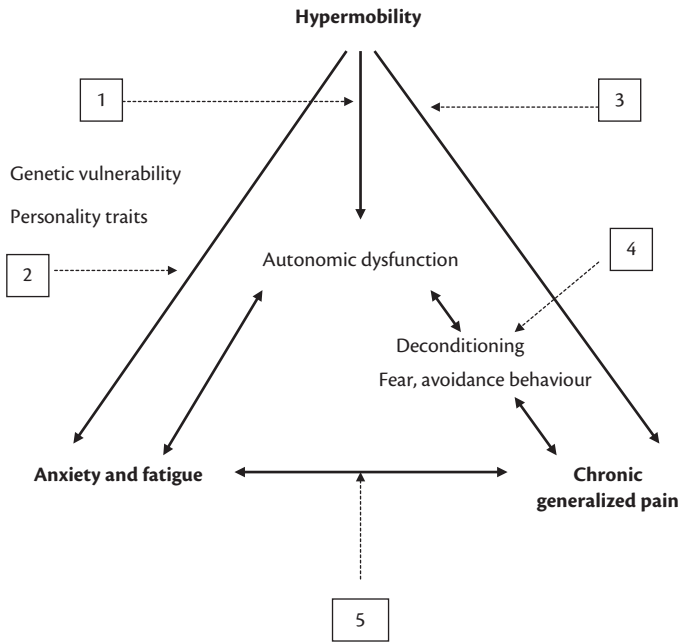
Adapted from Bravo J, Sanhueza G, Hakim AJ. Cardiovascular autonomic dysfunction and chronic fatigue in fibromyalgia and joint hypermobility syndrome. In: Hakim AJ, Keer R, Grahame R (eds) *Hypermobility, fibromyalgia and chronic pain*, Elsevier Churchill Livingstone, London, 2010:72.


Fig. 159.3 The association between hypermobility, autonomic disorders, anxiety syndromes, pain, physical pathologies and deconditioning, and the interplay of therapies.

Reproduced from Hakim AJ, Malfait F, De Paepe A, Sahota AThe heritable disorders of connective tissue: epidemiology, nosology and clinical features. In: Hakim AJ, Keer R, Grahame R (eds) Hypermobility, fibromyalgia and chronic pain, p.14. Churchill Livingstone Elsevier, London, 2010, with permission.

When they are not tolerated or are contraindicated, ACE inhibitors, calcium channel blockers, or angiotensin receptor blockers should be considered.

Intervention in aortic or mitral valve disease should be based on severity and speed of deterioration of valve and ventricular dysfunction. Acute dissection is a surgical emergency. Chronic dissection also warrants annual imaging. Indications for intervention include:

◆ sinus of Valsalva dilated more than 5 cm or the aorta at the site of dissection wider thanthan 5.5 cm

◆ annual increase in dilatation of the aorta in excess of 0.5 cm, or a strong family history of early dissection and rupture

◆ severe aortic regurgitation, or exacerbating ventricular dysfunction in the presence of severe mitral valve regurgitation

◆ intractable pain

◆ progressive limb and organ ischaemia

◆ planning pregnancy in high-risk individuals.

Orthopaedic intervention for recurrent dislocation and unstable joints is often unsuccessful in the long term and a last resort for severe cases when conservative measures have failed. Surgery for degenerative joint disorders is the same for hypermobile as non-hypermobile individuals, though rehabilitation needs to take account

of the individuals' general physical and cardiovascular well-being, as well as slow healing.

Pain relief

Analgesics are often helpful in acute and acute-on-chronic pain of soft tissue inflammation and joint degeneration. Widespread chronic pain tends not to respond to even the most potent analgesics. There are no randomized controlled trials of analgesics, neuropathic agents such as gabapentin and amitriptyline, or anti-depressants in the HDCT. Management is similar to that of fibromyalgia (see Chapter 160) and may incorporate the use of serotonergic and norepinephric agents that influence central pain processing as well as mood.[19] These agents may also assist in the symptom control of FGID.

The hormonal environment can also influence pain. Female patients report deterioration in their symptoms, including pain, clumsiness and reduced coordination, in the few days prior to menstruation when progesterone is at its highest. Progesterone-only contraceptive agents are more likely to exacerbate symptoms; this does not imply that oestrogen is specifically protective.

Cognitive behavioural therapies have also been shown to be of value in managing widespread pain, fatigue, and low mood in JHS.[20] This approach aims to:

◆ improve understanding of pain and communication with others over symptoms

◆ reduce pain related psychological distress

◆ improve sleep and reduce fatigue

◆ reduce dependency on opioid analgesics and other medication

◆ improve physical functioning with return to valued and enjoyable activities.

Interventions of autonomic dysfunction

The symptoms of cardiovascular autonomic dysfunction (CAD) can be reduced by ensuring good fluid balance and salt intake, physical conditioning to improve vascular return to the heart, intermittent use of elastic support stockings, and avoidance of very rapid changes in posture and environments that might cause rapid vasodilatation.[21] Pharmacological interventions should be used under the guidance of an autonomics specialist and usually after more detailed investigation including tilt-table testing. The aim is to either increase blood volume (fludrocortisone, clonidine, erythropoetin), increase vasoconstriction (midodrine, (pseudo)-ephedrine, etilefrine, selective serotonin re-uptake inhibitors, methylphenidate), or block the effect of (nor)epinephrine (adrenaline) (beta-blockers, disopyramide, ACE inhibitors).

Rehabilitation of patients with heritable disorders of connective tissue

In general rehabilitation/physiotherapy aims to improve function and enable individuals to self-manage their condition more effectively. A comprehensive assessment identifies postural abnormalities, movement faults, muscle imbalances, and weakness and balance deficits. A specific, individualized exercise programme is developed with the patient on the basis of the examination findings. The programme is usually focused on functional restoration through improvement of movement control, joint stability, stretching, muscle strength, and general fitness.[22]

Physiotherapy and occupational therapy methods need to be adapted to account of lax tissues with low tensile strength, a deconditioned musculature, poor proprioceptive acuity,[23] and age, with attention to specific needs (e.g. schooling, fitness) in childhood and adolescence.[24–26] Physical interventions aim to:

◆ build up muscles responsible for joint and core stability

◆ improve diminished proprioception

◆ mobilize to restore natural hypermobile range while avoiding harmful postures, weightbearing, or resting at the extremes of the hypermobile range

◆ improve general fitness by encouraging muscle-strengthening exercises

◆ educate in self-management

◆ support clinical psychology by enabling pacing, relaxation etc.

Occupational therapy (OT) and podiatry interventions include splints to protect unstable joints (e.g. small joints of the hands, wrist, elbow, knee, and ankle) and orthotics to correct midfoot pronation and hindfoot deformities that often induce discomfort when walking and encourage instability due to malalignment of the lower limbs. Hand therapy is invaluable in improving handwriting and other manual activities in hypermobile children and adults by means of improving hand strength and stamina.

Conclusion

The clinical manifestations of the HDCT are varied and as such individuals may present first to one of a number of clinicians. The challenge is to recognize each syndrome early and direct further investigation in the pursuit of cardinal signs and genetic markers accordingly. This requires a strong clinical acumen. While it is essential to exclude cardiovascular and ocular pathologies, even the more benign and non-life-threatening conditions can have a high morbidity. Interventions should be multidisciplinary, addressing the breadth of complications in a coordinated and holistic manner.

CHAPTER 160

Fibromyalgia and chronic widespread pain syndromes—adult onset

Anoop Kuttikat and Nicholas Shenker

Introduction

Pain and fatigue are the two most common symptoms of many musculoskeletal conditions. Chronic widespread pain and excessive fatigue have been reported in the Western medical literature since the 19th century. Sir William Gowers introduced the term 'fibrositis' in 1904 to describe this clinical constellation of symptoms believed to be caused by inflammation of fibrous tissue overlying muscles.[1] This term has been discarded since the understanding that there is no real inflammation in the tissues. Fibromyalgia syndrome (FMS) was adopted as the preferred name for this condition in the1970s and has gained international acceptance since the publication of American College of Rheumatology (ACR) classification criteria in 1990. The focus of this chapter is on FMS as the prototype disease manifesting with chronic widespread pain and fatigue.

Epidemiology

Chronic widespread pain is very common in the general population, with an estimated point prevalence of 11% in the United Kingdom.[2] The prevalence of FMS is 2–4% and increases with age, reaching a peak between 60 and 79 years. It is about six times more common in women.[3] Lower income, being disabled, divorced or separated, and having a lower educational status, are associated with FMS. Epidemiological studies in China have reported that FMS has rarely been seen there.[4] Genetic differences in pain processing and sociocultural attitudes to reporting chronic pain may explain this low prevalence. Investigation of FMS prevalence in migrant Chinese communities will help to delineate various factors underlying this phenomenon. FMS has a significant economic impact on society, in terms of both direct medical care costs and indirect costs related to work productivity loss. A study in the United States estimated that the annual costs per patient were $10 199 in 2005, nearly double that of matched controls.[5]

Classification and preliminary diagnostic criteria

The ACR classification criteria for FMS, published in 1990, are widely used in clinical trials (Box 160.1) These criteria have a sensitivity of 88.4% and a specificity of 81.1% in a population of patients with rheumatic disorders.[6]

Box 160.1 American College of Rheumatology 1990 classification criteria for fibromyalgia syndrome[a]

A. History of widespread pain for at least 3 months. Pain is considered widespread when it is present at all of the following sites:[b]

- the left side of the body
- the right side of the body
- above the waist
- below the waist
- in the axial skeletal (cervical spine *or* anterior chest *or* thoracic spine *or* low back)

B. Pain on digital palpation in at least 11 of the 18 tender point sites shown in Figure 160.1; all sites bilateral:[c]

[a]For purposes of classification, patients will be said to have FMS if both criteria A and B are satisfied. The presence of a second clinical disorder does not exclude the classification of FMS.

[b]Pain in a patient in for instance the left shoulder, right buttock, and cervical spine is generalized, according to these criteria.

[c]Digital palpation should be performed with an approximate force of 4 kg. For a tender point to be considered positive, the palpation has to be painful. 'Tender points' that are only tender are not tender points.
Fig. 160.1 Tender points in fibromyalgia syndrome: 1, occiput; 2, low cervical; 3, trapezius; 4, second rib; 5, supraspinatus; 6, lateral epicondyle; 7, gluteal; 8, greater trochanter; 9, knee. "Spinal irritation" and fibromyalgia: a Surgeon General and The Three Graces. Weissmann G. FASEB J. 2008 Feb;22(2):327–31.

The ACR has subsequently published preliminary diagnostic criteria in 2010 (Box 160.2), taking into account the importance of somatic symptoms such as fatigue and cognitive difficulties associated with FMS. These practical criteria developed for clinical use have a symptoms severity scale, making them useful for longitudinal use. They do not require a tender point count.[7]

Aetiopathogenesis

The precise aetiopathogenesis of FMS remains unclear. The current understanding is that the primary abnormality is in pain processing within the central nervous system. This dysfunctional pain processing results from the interplay between different factors including central sensitization, blunting of inhibitory pain pathways, altered neurotransmitters, and psychosocial stressors (Figure 160.2).[8]

FMS patients have augmented pain perception and decreased threshold to sensory stimuli such as heat, cold, electrical stimuli, and auditory tones.[9,10] Functional MRI studies have demonstrated that the insula is the part of the brain consistently hyperactive in FMS patients. The insula is critical in sensory integration and emotional processing of pain.[11] Decreased central μ-opioid receptor availability has been reported in FMS.[12] Substance P, an important neurotransmitter in pain, has been found to be increased three-fold in the cerebrospinal fluid (CSF) of FMS patients compared to controls.[13] Excess levels of glutamate have been found in the posterior insula.[14] MRI studies have demonstrated significant loss of grey matter and accelerated age-related grey matter changes in FMS patients compared to controls.[15]

Box 160.2 American College of Rheumatology 2010 preliminary diagnostic criteria for fibromyalgia syndrome

Criteria

A patient satisfies diagnostic criteria for FMS if the following three conditions are met:

1. Widespread pain index (WPI) ≥7 and symptom severity (SS) scale score ≥5 or WPI 3–6 and SS scale score ≥9.

2. Symptoms have been present at a similar level for at least 3 months.

3. The patient does not have a disorder that would otherwise explain the pain.

Ascertainment

1. WPI

◆ Note the number of areas in which the patient has had pain over the last week. In how many areas has the patient had pain?

Shoulder girdle (left, right)	Hip (left, right)	Jaw (left, right)	Upper back
Upper arm (left, right)	Upper leg (left, right)	Chest	Lower back
Lower arm (left, right)	Lower leg (left, right)	Abdomen	Neck

◆ Score will be between 0 and 19.

2. **SS scale score**: fatigue, waking unrefreshed, cognitive symptoms

◆ For the each of the three symptoms above, indicate the level of severity over the past week using the following scale: 0 = no problem, 1 = slight or mild problems, generally mild or intermittent, 2 = moderate, considerable problems, often present and/or at a moderate level, 3 = severe: pervasive, continuous, life-disturbing problems

◆ Considering somatic symptoms in general*, indicate whether the patient has: 0 = no symptoms,1 = few symptoms, 2 = a moderate number of symptoms, 3 = a great deal of symptoms

◆ The SS scale score is the sum of the severity of the three symptoms (fatigue, waking unrefreshed, cognitive symptoms) plus the extent (severity) of somatic symptoms in general.

◆ The final score is between 0 and 12.

* Somatic symptoms that might be considered
Muscle pain, irritable bowel syndrome, fatigue/tiredness, thinking or remembering problem, muscle weakness, headache, pain/cramps in the abdomen, numbness/tingling, dizziness, insomnia, depression, constipation, pain in the upper abdomen, nausea, nervousness, chest pain, blurred vision, fever, diarrhoea, dry mouth, itching, wheezing, Raynaud's phenomenon, hives/welts, ringing in ears, vomiting, heartburn, oral ulcers, loss of/change in taste, seizures, dry eyes, shortness of breath, loss of appetite, rash, sun sensitivity, hearing difficulties, easy bruising, hair loss, frequent urination, painful urination, and bladder spasms.

Sleep abnormalities

Disrupting slow wave sleep in healthy volunteers for three consecutive nights was found to be associated with decreased pain threshold and fatigue.[16] An increased cyclic alternating pattern, an
Fig. 160.2 Pathways of pain processing implicated in fibromyalgia syndrome: (a) Central nervous system neurotransmitters that either facilitate or inhibit pain transmission. (b) Low levels of inhibitory neurotransmitters lead to an attenuated anti-nociceptive system. Serotonin–noradrenaline (norepinephrine) reuptake inhibitors increase anti-nociceptive activity. Levels of neurotransmitters that augment pain transmission, such as substance P, glutamate/EAA and nerve growth factor, are increased in fibromyalgia, and probably contribute to increased activity in ascending pain transmission pathways. $\alpha_2\delta$ ligands might be working to decrease the release of excitatory neurotransmitters. 5-HT, 5-hydroxytryptamine (serotonin); CCK, cholecystokinin; CNS, central nervous system; DNIC, diffuse noxious inhibitory control; EAA, excitatory amino acids; GABA, γ-aminobutyric acid.

(Adapted from Schmidt-Wilcke T, Clauw DJ. Fibromyalgia: from pathophysiology to therapy. Nat Rev Rheumatol 2011, with permission.)

electroencephalographic marker of unstable sleep, was noted to be correlated to the severity of symptoms in FMS.[17] However, these changes are neither specific nor sensitive for FMS.

Hypothalamic–pituitary–adrenal axis dysfunction

Hyperactive stress response linked to altered hypothalamic–pituitary–adrenal (HPA) axis activity has been demonstrated in some patients. Corticotropin-releasing factor (CRF) is the principal central nervous system (CNS) mediator of the stress response. CRF concentration in the CSF was found to be associated with pain but not fatigue symptoms in FMS.[18]

Autonomic dysfunction

Dysautonomia has been documented in some patients using heart rate variability analysis and the tilt table test. Dysfunctional autonomic system is characterized as a sympathetic nervous system that is persistently hyperactive but is hyporeactive to stress. This could potentially explain many FMS symptoms including orthostatic hypotension causing dizziness, excessive arousal/awakening episodes, sicca symptoms, and pseudo-Raynaud's phenomenon.[19]

Genetics

Observational studies have shown familial aggregation of chronic pain disorders. A proband study showed that first-degree relatives

of FMS patients are 8.5 times more likely to have FMS than relatives of rheumatoid arthritis patients.[20] Family members of FMS patients are also much more likely to have irritable bowel syndrome, temporomandibular disorder, headaches, and other regional pain syndromes.[21] A Swedish twin registry study of 15 950 pairs of twins estimated that approximately 50% of the risk of developing chronic widespread pain is genetic or shared environmental influences.[22] A large candidate gene association study revealed that four genes—*TAAR1* (trace amine associated receptor 1), *CNRI* (cannabinoid receptor 1), *RGS4* (regulator of G protein signalling 4), and *GRIA4* (glutamate receptor, ionotrophic, AMPA 4)—were associated with FMS. These genes may contribute to the pathophysiology of FMS and represent potential therapeutic targets.[23]

Infection

Several infectious agents including hepatitis C, Epstein–Barr virus, borrelia, mycoplasma, and HIV have been postulated as potential triggers although none has conclusively been proven to be associated with FMS.[24]

Clinical features

FMS patients complain of generalized aches and pains affecting all four quadrants of the body. The pain is usually reported in

the muscles and joints. They describe a feeling of joint swelling or 'puffiness', although this is not clinically evident. Poor spatiotemporal awareness is reported by many chronic pain patients including FMS patients and may reflect disturbances in the somatosensory system.[25] Fatigue, exacerbated by minor activity and disproportionate to the level of activity, is reported by most patients. There is considerable overlap with chronic fatigue syndrome and 55% of chronic fatigue syndrome patients fulfil the diagnostic criteria for FMS.[26] Paraesthesiae in arms and legs are reported in more than 80% of patients, although formal neurological testing is usually normal in the absence of a coexistent disorder such as carpal tunnel syndrome or cervical radiculopathy.[27]

Cognitive disturbances including short-term memory impairment and difficulties in concentrating are more common in fibromyalgia patients compared to patients with other rheumatic diseases.[28] Depression and/or anxiety have been reported in 30–50% of FMS patients.[29] Chronic headaches were reported in 76% of patients in one study, of which 63% were of the migraine type and 8% related to analgesic overuse.[30]

FMS patients may also have other symptoms such as chest pain, abdominal pain, bloating, alternating diarrhoea/constipation, pelvic pain, or urinary frequency and urgency. They have often been previously investigated by different specialists and having had unremarkable tests been given a diagnosis of 'non-cardiac chest pain', 'irritable bowel syndrome' or 'painful bladder syndrome/interstitial cystitis'. Hypersensitivity to light, noise, and temperature has also been reported.[31]

Differential diagnosis and investigations

FMS can coexist with other systemic diseases. Many systemic diseases can present with some of the fibromyalgia symptoms. FMS was found in 22% of systemic lupus erythematosus (SLE) and 17% of inflammatory arthritides patients in a cohort study of over 23 000

patients.[32] Careful history and physical examination combined with limited but targeted investigations are necessary to diagnose other mimics or coexisting conditions. However, it is important to remember that FMS is a clinical diagnosis based on pattern recognition and extensive testing is not needed unless there are specific pointers to other diagnosis. In Table 160.1, the differential diagnosis and key features to differentiate each condition from FMS are listed.

Management

FMS is a complex and heterogeneous condition and effective management should adopt a multidisciplinary approach. Careful assessment of pain, function, and psychosocial context is essential. Patient education, physical therapies, psychological therapies, and pharmacotherapy are the four pillars of management. The interventions must be tailored to the individual needs of the patient.

Patient education

Patient education plays a key part in management. Physicians should provide reassurance about the validity of the diagnosis. Minimizing symptoms and restoring function should be the treatment goal. Self-management programmes are important to improve function and promote self-efficacy. A randomized controlled trial (RCT) of 216 patients found that a 2 month psychoeducational intervention improved functional status of FMS patients to a greater extent than usual care.[33]

Physical therapies

Physical therapies have been investigated in over 90 clinical trials with more than 5000 patients with FMS in the last three decades. However, many of these trials have suffered from lack of quality and high attrition rates.[34] Balneotherapy or heated pool therapy was found to be effective in a small number of fairly high-quality studies.

Table 160.1 Differential diagnosis of fibromyalgia syndrome

Condition	Key differentiating features	Investigations
Rheumatoid arthritis	Symmetrical synovitis	ESR, CRP, RF, anti-CCP, radiography
SLE/Sjögren's	Systemic features (eye, skin, kidney involvement)	ANA, anti-dsDNA, ENA, ESR, Schirmer's test
Polymyalgia rheumatica	Age > 50, stiffness > pain, rapid response to prednisolone (dose < 15 mg/;day)	ESR,CRP
Polymyositis/;dermatomyositis	Muscle weakness, rash	CK, ANA
Hypothyroidism	Puffy facies, delayed relaxation of deep tendon reflexes	TFTs
Hyperparathyroidism	Renal stones, bone disease	Calcium, phosphate, 25(OH) D, PTH, AP
Vitamin D deficiency/osteomalacia	Presence of risk factors: lack of sunlight exposure, malabsorption, intestinal bypass surgery, coeliac disease, chronic liver or kidney disease	25(OH) D
Disseminated malignancy/;myeloma	Significant weight loss; rapidly progressive symptoms	CRP, ESR, radiography, isotope bone scan, serum and urine protein electrophoresis
Glucocorticoid withdrawal	Medication history	SST

25(OH) D, 25-hydroxy vitamin D; ANA, anti-nuclear antibodies; anti-CCP, anti-cyclic citrullinated peptide; anti-dsDNA, anti-double-stranded DNA; AP, alkaline phosphatase; CK, creatine kinase; CRP, C-reactive protein; ENA, extractable nuclear antigens; ESR, erythrocyte sedimentation rate; PTH, parathyroid hormone; RF, rheumatoid factor; SLE, systemic lupus erythematosis; SST, short synacthen test; TFTs, thyroid function tests.

Three out of the five studies also included exercise. Improvement in both pain and function was reported.[35,36]

Moderate to high-intensity aerobic exercise by means of Nordic walking twice a week for 15 weeks was found to improve functional capacity in an RCT of 67 patients. Pain severity, however, did not change over time during the exercise period.[37] Individually tailored exercise programmes are recommended, given their safety and benefit to general health.[38] T'ai chi, a Chinese mind–body practice, was found to produce significant improvement in pain and function in a randomized trial lasting 12 weeks when compared to a control group who had wellness education and stretching exercises. Longer and larger studies are needed to confirm the usefulness of t'ai chi.[39]

Psychological therapies

Psychological therapies including cognitive behavioural therapy (CBT), mindfulness-based treatments, relaxation, and biofeedback are used to treat FMS. CBT offers short-term, goal-orientated psychotherapy emphasizing changes in thought patterns and behaviours. CBT is incorporated into pain management programmes based on the physiological link between chronic pain and mood disorders. A meta-analysis of 23 trials involving nearly 1400 patients found a significant but small size effect for CBT and relaxation/biofeedback in reducing pain, improving sleep, and decreasing depression.[40]

Pharmacotherapy

Pregabalin, milnacipran, and duloxetine are approved by the United States Food and Drug Authority (FDA) for FMS. The European Medicines Agency, to date, has not authorized any drugs specifically for FMS. Milnacipran is currently not available in the United Kingdom. Several agents are recommended by the European League Against Rheumatism (EULAR) for treating FMS (Table 160.2). EULAR and the American Pain Society recommend the use of low-dose tricyclic anti-depressants, particularly amitriptyline, as initial

pharmacological management of patients with FMS.[41,42] Selective serotonin reuptake inhibitors (e.g. fluoxetine) were found to be less efficacious than the tricyclics or serotonin–norepinephrine (noradrenaline) reuptake inhibitors (e.g. duloxetine, milnacipran), suggesting a critical role for norepinephrine in the analgesic effect in FMS.[43]

A large meta-analysis that compared the efficacy and acceptability of amitriptyline, duloxetine, and milnacipran found that all three were superior to placebo except duloxetine for fatigue, milnacipran for sleep disturbance, and amitriptyline for health-related quality of life. The significant effects of amitriptyline and duloxetine were small and those of milnacipran not substantial. There were no significant differences in acceptability of these drugs.[44] Pregabalin and gabapentin were found to be safe and efficacious in large meta-analyses of RCTs. Dizziness, somnolence, and weight gain were the most frequently reported dose-related adverse effects.[45–47]

Expert opinion does not recommend corticosteroids or strong opiates for the treatment of FMS, as they have significant long-term side effects and there are no clinical trials data to support their use. Simple analgesics such as paracetamol (acetaminophen) and weak opiates may be considered as adjuncts for pain relief. Tramadol, alone and in combination with paracetamol, was found to be effective and well tolerated.[48] Combination of drugs with different mechanisms of action are useful in many patients. A randomized trial found that combining fluoxetine 20 mg in the morning with amitryptiline 25 mg in the evening was more effective than either medication alone.[49]

Table 160.2 Pharmacotherapy in fibromyalgia syndrome

Drug	Mechanism	Dose (mg/day)	Approval/ recommendation	NNT
Amitryptiline	Serotonin and/or norepinephrine reuptake inhibitor anti-cholinergic and anti-histaminergic	10–75	EULAR	3.54
Tramadol	Weak μ-opioid receptor agonist Norepinephrine reuptake inhibitor	50–400	EULAR	5.5
Milnacipran	SNRI	100–200	EULAR, FDA	10.96
Duloxetine	SNRI	30–120	EULAR, FDA	8.21
Pregabalin	$\alpha_2\delta$ ligand	75–450	EULAR, FDA	6.6
Gabapentin	$\alpha_2\delta$ ligand	900–2700	EULAR	5.8

$\alpha_2\delta$ ligand, blocks $\alpha_2\delta$ subunit of voltage-gated calcium channels; EULAR, European League Against Rheumatism; FDA, United States Food and Drug Authority; NNT, number needed to treat to improve pain by ≥30%; SNRI, serotonin norepinephrine (noradrenaline) reuptake inhibitor.

Case history

A 40 year old woman presented with a 1 year history of widespread pain, excessive fatigue, and unrefreshing sleep. She has noted 'puffiness' of her hands and paraesthesiae in her hands and legs. She reports alternating diarrhoea and constipation associated with abdominal cramps. She denies any bloody stools or weight loss. Past medical history includes irritable bowel syndrome and anxiety.

Physical examination reveals no signs of active synovitis or dactylitis. No skin rash or nail changes. Tinel's and Phalen's test are negative. No objective muscle weakness or sensory changes. There are multiple tender points in all four quadrants and along her spine.

This patient has a typical presentation of FMS. Initial tests include a full blood count, urea, electrolytes, CRP, ESR, thyroid function tests, liver function tests, bone profile, B_{12}, and folate to rule out coexisting conditions. Given her abdominal symptoms, screening for coeliac disease may be considered.

All laboratory tests were completely normal and she was given a diagnosis of FMS. She was relieved to know that all her symptoms can be explained by the diagnosis. She was given a patient information leaflet on FMS. She was started on amitriptiline 10 mg daily to be taken 2 hours before sleep and was advised that the dose can be gradually titrated up to 50 mg daily. She was also prescribed tramadol for breakthrough pain. She was enrolled in a holistic multidisciplinary programme incorporating physical and psychological therapies.

Prognosis and monitoring

A longitudinal study of 1500 FMS patients over 11 years found that 25% had at least moderate improvement of pain and 35% had worsening of symptoms.[50] In a 2007 cross-sectional study of an internet questionnaire in the United States, 51% of 1700 FMS patients in the working age group were working, with 70% of this group working more than 30 hours/week. Employment, higher income, and education were strongly associated with fewer symptoms.[51]

There is an increased risk of suicide and death from suicide among FMS patients.[52] An increased incidence of cancer and cardiovascular deaths in patients with chronic widespread pain has also been reported.[53] A British birth cohort study found that such individuals had unhealthy diet, increased rates of smoking, and higher body mass index compared to those without pain.[54] Physicians should emphasize the importance of improving lifestyle factors such as diet, smoking status, and body weight as part of the overall management plan.

The revised Fibromyalgia Impact Questionnaire (FIQR) is a validated tool useful for monitoring symptoms. It has good psychometric properties, can be completed in less than 2 minutes, and is easy to score.[55]

Conclusion

FMS is a common condition characterized by chronic widespread pain, unrefreshing sleep, excessive fatigue, and other somatic symptoms. There is altered pain processing in the CNS. Functional MRI studies have shown changes in neuronal circuitry responsible for sensory integration and emotional processing of pain. FMS can coexist with other systemic diseases. Careful history, detailed physical examination, and targeted investigations are needed to diagnose coexisting conditions. A multidisciplinary approach incorporating patient education, physical therapies, psychological therapies, and pharmacological agents can improve the quality of life of FMS patients. Improving lifestyle factors such as smoking status, diet, and weight can significantly extend their life expectancy.

CHAPTER 161

Chronic musculoskeletal pain in children and adolescents

Jacqui Clinch

Introduction

Paediatricians review a large number of children who have a wide variety of musculoskeletal pains.[1,2] The most common chronic pain conditions reviewed in paediatric rheumatology settings include diffuse idiopathic musculoskeletal pain (DIPs, also called juvenile fibromyalgia or chronic widespread pain), chronic pain related to childhood hypermobility, complex regional pain syndromes (CRPS), chronic back pain and persistent joint pain following previous or controlled inflammation, e.g. juvenile idiopathic arthritis (JIA). For most young people presenting to clinic the chronic experience of pain has often had a large and wholly negative impact on the physical and psychological well-being of the young person and their family.[1] Data has shown that chronic pain also has a serious negative impact on financial well-being, not only for each family but also for the economy as a whole. It is conservatively calculated that the annual financial burden of adolescent chronic pain on the United Kingdom economy is £3840 million.[3] Children who suffer persistent musculoskeletal pain and associated symptoms have a significant chance of developing chronic widespread pain and continuing to have pain and pain-associated disability in adult life.[4]

In this chapter, there is a review of the epidemiology of musculoskeletal pain in childhood; discussion of current theories of the aetiology of pain; evaluation of the impact of chronic pain, the clinical features of common pain presentations and their relevance to diagnosis and treatment planning and finally rehabilitation interventions aimed at the management of chronic pain.

Epidemiology

In a recent study up to 83% of the school-aged children had experienced an episode of pain during the preceding 3 months.[5] Pain is a normal sensation but becomes disabling when it persists and is associated with suffering. In this same study sample, 30.8% of the children and adolescents stated that the pains had been present for over 6 months. Musculoskeletal pains accounted for 64% of all the pains that were reported.[3] Other studies support this finding.[6,7]

Whether there is more chronic pain, or whether children with chronic pain are presenting more frequently, is not known.

The epidemiology of diffuse idiopathic pain (DIPs, also referred to as juvenile fibromyalgia or chronic widespread pain) is difficult to accurately assess.[8] The HUNT study[9] showed that 8.5% of a population of 7373 adolescents fulfilled the criteria for DIPs, whereas a United Kingdom study showed the prevalence of chronic widespread pain in over 6000 17 year old schoolchildren to be 4.3%.[10] Hypermobility, as currently defined, is present in 19.8% of the normal United Kingdom adolescent population.[11] We do not know the percentage of children who suffer pain as a direct consequence of their joint laxity. Undoubtedly some young people do have mechanical pain; whether this is directly due to a hypermobility syndrome is not currently evidenced in large studies.

Low back pain is common in adolescence; the HUNT study showed this to be 16.7% for girls and 11% for boys (one day a week for at least 3 months).[9]

The prevalence of CRPS in adults is 26 per 100 000 person-years.[12] In children the epidemiology has not been robustly evaluated but recent studies have demonstrated that, unlike the adult population, about 90% of the cases reported are females aged 8–16 years.[19–21] There tends to be delay in recognizing the diagnosis.[13] A complicating factor is the lack of clear diagnostic criteria for children; currently the adult International Association for the Study of Pain (IASP) criteria are used.

In JIA it is clear that persistent pain is a significant problem for many children.[14] Approximately 40% describe pain 5 years after diagnosis.[15] A significant minority progress to develop localized or diffuse musculoskeletal pain that is not directly related to the control of their inflammatory condition.[16]

There is a robust finding that girls experience more pain than boys[9,17] (although it should be noted that the incidence in boys may be increasing[5]). Children living in low-educated, low-income families have a 1.4-fold increase in the odds of having pain.[19] The incidence of chronic widespread musculoskeletal pain peaks in older adolescence.[17] Significantly, a large cohort study showed that multiple common symptoms in childhood are associated

with a moderately increased risk of chronic widespread pain in adulthood.[4]

Clinical features of chronic musculoskeletal pain

General features

It is not unusual for pain to start in a localized area of the body and lead to a reluctance to mobilize. Discomfort and pain intensity increase and become constant and the young person may avoid contact with, or use of, an area of the body affected, which can lead to muscular spasms, abnormal posture and gait, and—with chronic avoidance—greatly reduced fitness. This can lead to fear of pain and movement, and a resultant amplification of the pain. In some circumstances pain has a direct effect on other systems, leading to symptoms that can be as disabling as the pain itself. Symptoms and signs frequently associated are listed in Box 161.1.

Box 161.1 Symptoms and signs frequently associated in chronic musculoskeletal pain

- **Hypervigilance and hypersensitivity**. Children often report a heightened awareness of pain and pain-associated cues.[2] It is unclear whether this is caused by fear of pain, or hypersensitivity of pain receptors in allodynic and hyperalgesic ranges. Clinically this presents as young people describing unbearable pain on minimal skin contact, and heightened fear of being touched, for example, on examination.

- **Perceived thermodysregulation**. This is more common in adolescent girls. Limbs are particularly cool and mottled. Occasionally there will be areas that are very red and hot to touch on a background of the mottled skin. There may also be an abnormal perception of temperature with an increase in thermal pain sensitivity.[18]

- **Autonomic dysfunction**. Pain is a powerful stressor. Continuous pain signals, immobility, and fatigue act directly on the autonomic system.[20] In an environment of physical and emotional anxiety, the sympathetic system is more active. This leads to tachycardia, hyperventilation (compounded with panic attacks), cold sweats, blurred vision, abdominal pain, and extreme pallor. Girls particularly complain of nausea, dizziness, and episodes of feeling faint. Children look unwell during these episodes of increased pain. It is not unusual for attending paediatricians to investigate cardiovascular, neurological, and gastrointestinal systems in an attempt to elicit pathology.

- **Musculoskeletal disequilibrium**. These young people are still growing, often in their peripubertal growth spurt, and this can have lasting effects on the final positioning. Proprioceptive signals from the joints are reduced and the limb held in a rigid, fixed position. Legs may 'give way'. Knees and hips are held flexed, feet are inverted, and hands are clenched with flexed wrists. These positions are often described as the most comfortable. Muscles and tendons quickly tighten and this complicates the pain and disability. The adaptive positioning of a young person with leg or abdominal pains particularly affects the gait and resting positions and thus alters the loads on the spine and pelvis.

Specific childhood musculoskeletal pain conditions commonly seen in a rheumatology setting

Diffuse idiopathic pain syndromes (juvenile fibromyalgia/chronic widespread pain)

This describes widespread pain, often located over muscles and joints, where there is significant pain-associated disability.[20,21] There are no current agreed criteria, although some authors have suggested the term juvenile fibromyalgia can be used and have recently proposed diagnostic criteria akin to the adult fibromyalgia criteria.[8]

The onset of pain in DIPs/juvenile fibromyalgia.[2,20] is often gradual. There may have been an initial insult or trauma but often there is no obvious trigger and only vague recollections of the time of onset. The pain is generalized. There may be areas of allodynia (profound hypersensitivity to light touch) and hyperalgesia, but there is often an absence of the autonomic changes that we see in more localized pain conditions.[1] What is striking in young people with diffuse pain is fatigue, poor sleep pattern, and extremely low mood. It is widely believed, however, that the low moods in adolescents are reactive (to the pain-associated disability) rather than a primary depression.[22] This is in contrast to adults with fibromyalgia where primary depression is frequently seen.[23]

Complex regional pain syndrome

The diagnosis of CRPS remains a clinical one.[24,25] There may be precipitating trauma. In children, the lower limb is much more commonly involved than the upper limb. The pain is usually out of proportion to the inciting event and accompanied by allodynia. The children most often describe the pain as burning and describe sensations akin to dysaethesia. Autonomic changes are present; these include swelling, reduced cutaneous perfusion, and thermodynamic instability. As this is present on the background of a developing musculoskeletal system, limbs can become distorted and feet or hands held in seemingly fixed and often flexed positions. Cutaneous blood flow often reduces; the affected limb develops a purplish hue with other colour changes that can cause concern to the child and family (Figure 161.1). The skin takes on a shiny, stretched appearance, with coarse hairs developing in patches. In rare severe cases, trophic changes develop with ulceration and marked wasting. Figure 161.2 shows the marked changes on thermography (reduction in cutaneous blood flow represented by lack of heat detected) of the wasted, flexed, ulcerated foot that is shown in Figure 161.3. Although the pathophysiology is poorly understood, many features, particularly the neurological abnormalities, suggest both peripheral and central nervous system (CNS) involvement. Peripheral small-fibre neuropathy as an aetiology and inflammation involving small nerve fibres (neurogenic inflammatory pain) has been suggested. A tissue inflammatory aetiology has been investigated over the past 25 years. However, these inflammatory aspects differ from those seen in other conditions involving tissue inflammation. The suggestion that CRPS in children is a different clinical entity than that seen in the adult is probably incorrect, as recent evidence would suggest that the pathophysiology is most likely identical involving endocrine, behavioural, developmental, and environmental factors that distinguish clinical presentation in children from the adult.[13]

Fig. 161.1 Early changes in chronic regional pain syndrome; left leg.
Fig. 161.2 Loss of cutaneous capillary blood flow in left foot on thermography. FASEB J. 2008 Feb;22(2):327–31.

Fig. 161.3 Wasted, ulcerated left leg in advanced chronic regional pain syndrome.

The IASP has diagnostic criteria for adults with CRPS. Although these diagnostic criteria hold true for children and adolescents, it is widely believed that the dystrophic changes and long-term disability are less common than they are in adults.

Back pain

Adolescents commonly present with lower lumbar pain. Often this is thought to be related to lifestyle influences on a developing spine such as postural habit (slouching), load bearing on the back (e.g. schoolbags), or engagement in sedentary activity (e.g. computer use). There are insufficient data to bring clarity to these arguments although it is fair to say that there is no conclusive evidence for any one of these factors being significantly related to the increase in back pain.[26] Recent cross-sectional and prospective studies clearly indicate a role of psychological factors in the manifestation of chronic low back pain.[26] Red flags for pathology include nocturnal pain, presentation in young child, or long tract symptoms. These must be fully investigated to exclude inflammation, compression, and malignancy.

In some cases young people describe the back 'locking' or 'going in to spasm'. This causes a markedly altered gait and can lead to other generalized joint pains. For girls, menstruation can lead to an escalation in pain. A recent systematic review showed that idiopathic adolescent spinal pain is a risk factor for adult spinal pain.[27] A robust study from Denmark looked at 10 000 Danish twins and showed low back pain in adolescence to be a significant risk factor for low back pain in adulthood, with odds ratios as high as 4.[28]

Juvenile idiopathic arthritis and pain

The relationship between juvenile arthritis and chronic pain is well recognized.[14] Despite significant advances in medical treatments for children with JIA, persistent pain is a common complaint. Pain has been shown to be a primary determinant of the physical, emotional, and social functioning in these children.[14] As with other diseases, the degree of disabling pain does not always mirror inflammatory joint activity. A growing body of research in rheumatic diseases, such as JIA, highlights the importance of environmental and cognitive-behavioural influences in the pain experience of children, in addition to the contribution of disease activity.[29,30]

Idiopathic chronic limb pains

Many idiopathic pains are seen in paediatric settings that do not meet the criteria for DIPs/juvenile fibromyalgia or CRPS. These include the poorly understood 'growing pains'. These are described as recurrent bilateral non-articular pain in lower extremities that occur late in the evening or at night. They have been observed to coexist with vascular pain problems, including migraines; this has led to speculation that there may be a vascular component to the

bone pain experienced. A recent small study challenged this theory.[31] Other describe growing pains as a form of overuse injury.[32] The jury remains out.

Juvenile hypermobility and pain

The association between joint hypermobility in children and diffuse pain[33] is poorly understood. A recent cross-sectional study of schoolchildren showed no association between joint laxity and pain.[34] Other authors of smaller studies suggested prevalence of pain among those children with generalized joint laxity ranging at around 30%.[35] A large cohort study has shown a positive association between generalized joint laxity and habitual levels of physical activity, body mass index (BMI), and maternal education in girls.[11] A proportion of children noted to be hypermobile can present with recurrent lower limb arthralgia, anterior knee pain syndromes, and back pain.[36] What seems clear is that the majority of hypermobile individuals will be not have pain or have any risk for specific musculoskeletal disorders in later life. Screening tools such as the Beighton score are likely to be inadequate in children, as they are generally more mobile than adults.[11] The challenge remains to interpret symptoms correctly as being related to the hypermobility and to predict why such children become symptomatic. The answer is likely to involve mechanical and psychosocial factors.

Possible aetiological factors

Over the past 10 years there has been significant advance in the understanding of pain processing in the developing brain. In adolescents there is a relationship, either singularly or in combination, to illness, injury, psychological distress, and environmental factors (Figure 161.4).[1] The neuroplasticity of the brain is key to understanding the possible effects of these factors on potential amplification or dampening of pain signals and the degree of pain-associated disability. The main topical aetiological factors are discussed below.

Psychological influences

There is no evidence for purely psychologically generated pain conditions in children. There are a few case reports of conversion neuroses manifesting as widespread pain complaints, but this is highly unusual. There is strong evidence for psychosocial influences as complicating factors and as being implicated in the maintenance of pain complaints,[4] but not their aetiology.[37]

Procedural pain

Although there is some evidence that early repeated exposure to invasive medical procedures that typically involve tissue cutting or puncture is a risk factor for lowered threshold to pain,[38] there is, to date, no evidence to suggest that any of the common childhood procedural pains, such as on immunization, is a risk factor for adult chronic pain. Recent research has shown a relationship between procedural pain in neonatal/early infancy and the potential centralization effect on pain pathways as the child gets older.[39] It is difficult to know whether a primary infectious or inflammatory condition (such as JIA) has an effect on the evolution of chronic pain or whether the pain is a consequence of the immobility, medical therapies, and environmental changes that are associated with these conditions, or a combination.

Injury

It is not unusual for a child with a localized chronic pain to recall a sporting injury, operation, or other trauma around the onset of chronic pain.[40] Hypermobility has also been associated with falls and subsequent pain problems. Altered proprioception that can accompany joint laxity, dyspraxia, and other musculoskeletal conditions frequently leads to falls and further pain escalation. There may be a period of enforced immobilization that can be an additional factor in the development of a localized chronic pain problem.

Genetic influences

There is emerging evidence that patients with CRPS may have a genetic predisposition[41] in Caucasian women, but the underlying genomics are far from clear. There have also been reports of chronic idiopathic musculoskeletal pains in siblings and parent–child pairs.[42]

Environmental influences

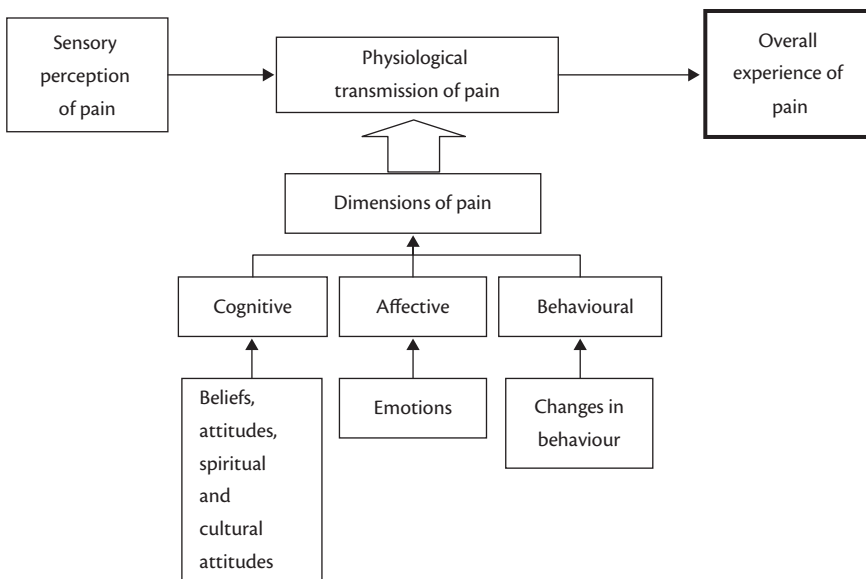
Although there is no strong evidence for the intergenerational transmission of pain and pain-related behaviour,[43] there is a lack


Fig. 161.4 Biopsychosocial model of complex pain. Irrespective of aetiology, pain is a multidimensional phenomenon with sensory, physiological, cognitive, affective, spiritual, and behavioural components. Konijnenberg, A.Y., C.S Uiterwaal et al. (2005) "Children with Unexplained Chronic Pain" Arch Dis Child 90(7) 680–6

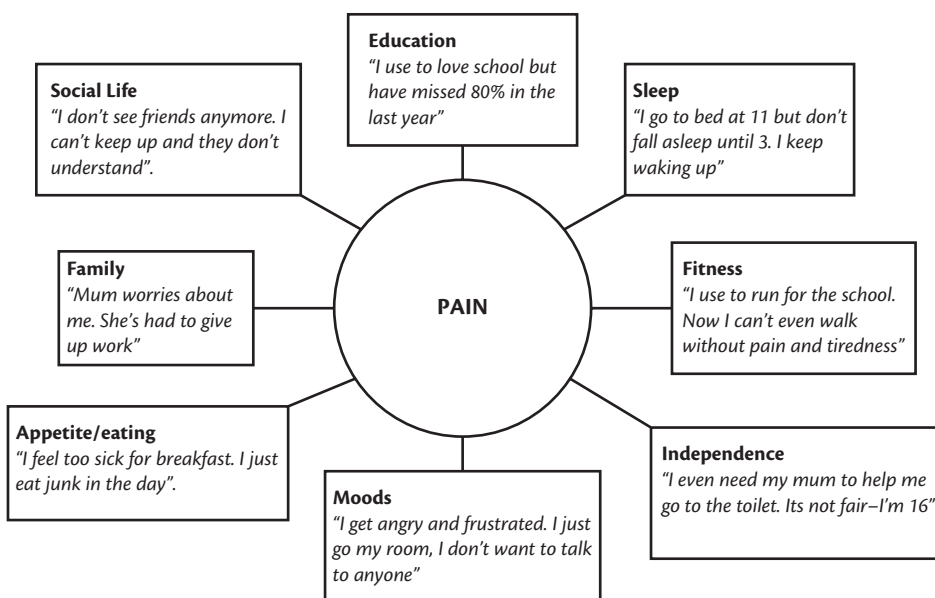
of study of common environmental risk factors other than social learning. Social history may show a recent life event (moving house/school, illness, or death in the family) that has relevance to the presentation.

Developmental influences

There is current interest in the neuropathic mechanisms of paediatric pain. Considerable postnatal development occurs within nociceptic pathways over the first few postnatal weeks.[39] Interruption of this development may have a direct role in the later susceptibility of a child to suffer neuropathic pain. Neonatal pain experience may also have a role in long-term alterations in pain processing and development, with a greater tendency to amplified pain behaviour as a child. There has been interest in the preliminary findings that pain sensitivity may be altered in adolescents who were born prematurely[44] and those exposed to early neonatal insult.

With functional MRI it has recently been shown that considerable CNS circuitry changes take place in young people with a diagnosis of CRPS.[45] Although a pathophysiological mechanism for CRPS remains unknown, a number of aetiologies have been proposed: a peripheral small-fibre neuropathy, an autonomic dysfunction, and an exaggerated regional inflammation.[15]

The impact of chronic pain on the child and family

Persistent or recurrent chronic pain, irrespective of the trigger(s), can bring persistent and recurrent distress, disability, adult attention, and widespread family disruption. Most families have relatively successful mechanisms for dealing with short-lived demands or disruption. However, a young person with chronic pain typically demands sustained physical, emotional, and financial resource.[3] Young people with chronic pain report sleep disturbance, disordered mood, appetite disruption, low feelings (depression is often masked in this population), social isolation, and unwelcome dependency on parents. It can be useful to graphically represent this with patients and others, as shown in Figure 161.5.


Children with chronic pain are commonly outside the formal education system, absent from normal schooling.[5] The routines of normal school, rigidly applied, are often unmanageable for children who experience severe pain when sitting, concentration and memory difficulties, interpersonal problems in explaining confusing problems to peers, frequent anxiety-provoking 'emergency events' associated with pain, and time away for hospital visits. Adolescence is by definition a time of change and experimentation. Adolescents with chronic pain report that they are less socially developed on virtually every metric than their peers.[46]

Levels of parental stress are clinically significant and parents experience severe distress and conflict in parenting their child. Typically they report struggling with the desire to cure their child's pain and comfort their child, while recognizing that the desire to protect may be counterproductive.

Managing chronic childhood musculoskeletal pain

Assessment

It is important to exclude significant disease. With serious medical causes excluded, one can then work to move on to de-medicalize and rehabilitate safely. In practice this is more difficult in paediatrics, as there can be a tendency to catastrophize about persistent pain by the family, and sometimes by the physician. The need to find a cause for the pain can be overwhelming and, in this way, the child may be overmedicalized.[47]

History

Table 161.1 summarizes the important areas that should be covered when taking a history from a child and their carers. For the physician, the goal of the history-taking is often to exclude serious possible causes, identify key problems, build a trusting relationship with the patient (and family), and identify a treatment plan. The child often has chronic experience of medical settings, feelings of being doubted, having the validity of their pain contested, and often

Social Life
"I don't see friends anymore. I can't keep up and they don't understand".

Education
"I use to love school but have missed 80% in the last year"

Sleep
"I go to bed at 11 but don't fall asleep until 3. I keep waking up"

Family
"Mum worries about me. She's had to give up work"

PAIN

Fitness
"I use to run for the school. Now I can't even walk without pain and tiredness"

Appetite/eating
"I feel too sick for breakfast. I just eat junk in the day".

Moods
"I get angry and frustrated. I just go my room, I don't want to talk to anyone"

Independence
"I even need my mum to help me go to the toilet. Its not fair–I'm 16"

Fig. 161.5 Model illustrating pain associated disability in children.

Table 161.1 Outline of key areas to be addressed while taking a history

Questions	Reasons
Onset of pain	
When did the pain start?	Identify any nerve injury, muscular trauma or intercurrent infection that may have triggered pain
Where did it start?	
Was there a preceding infection, trauma or operation?	Therapeutic interventions that include long periods of immobilization, accelerated physical rehabilitation and repeat operative investigations may all be factors in pain amplification
How was it treated initially	
What was happening around the time the pain started	Environmental events (school, home, other medical episodes) may be factors in the onset of pain
Characteristics of the pain	
Has the pain spread from original place?	It is important to establish the nature of the pain episodes as this may direct management
How would you describe the pain?	
How severe is the pain on a good day and on a bad day?	
Is the pain constant?	
Has the pain got any better or worse?	
Do you suffer pins and needles?	Neuropathic pains are often described as burning, shooting, deep, electric and occasionally episodic. There may be pins and needles and areas of numbness
Is there variation in the pain during the day?	Erythromelalgia is usually worse at night, with painful burning sensations in hands and/or feet
Does the pain alter at night? Does it wake you up?	
What makes it worse?	Movement usually leads to an escalation of pain. Many young people avoid weightbearing or transferring for fear of a pain flare
What makes it better?	
Is it painful to lightly touch the area that is painful?	CRPS has neuropathic features and also extreme hypersensitivity (allodynia) over affected regions—'I cannot have a duvet on my leg at night'
Does that area look unusual?	The affected area may appear swollen and shiny. Young people often feel the limb is more swollen than it actually is
Other symptoms	
Is there a fever, rash or weight loss?	It is important to ensure there are no red flags indicating missed pathology. Nocturnal pain, extreme weight loss, hard neurological features are examples of symptoms and signs that need further paediatric work-up.
Has menstruation altered?	
Is there altered bowel habit?	Common pain-associated symptoms are included in this list on the left. On occasion these become as disabling as the pain and need to be included in the rehabilitation plan.
Do you have nausea?	
Do you suffer abdominal pain?	
Is there any muscle weakness?	
Do you have any areas that are numb?	
Do you suffer dizziness?	
Have you passed out or suddenly fallen to the floor?	
Is fatigue a problem?	
Do you suffer headaches/migraines?	
Do you feel colder/warmer than previously?	
Do you suffer from blurred vision?	
Has your mood been affected?	
Effect of pain on daily living	
Do you find it hard to get to sleep / stay asleep?	Pain can have a significant effect on sleep, mood, independence and general functioning. It is important to know how well a young person is sleeping (and where – it is not unusual for a previously independent teenager to go back into the parents' bed)
Do you 'catnap' in the day?	

(Continued)

Table 161. 1 (Continued)

Questions	Reasons
What can you do on a 'bad'/good day?	Establishing how catastrophic the effect on lifestyle has been is also key; children may have a history of lying on the sofa reading all day or they may have been competing for their country in hockey—by understanding expectations of quality of life you can tailor the rehabilitation process
How much school have you managed over the past 6 months?	
How is your concentration/memory?	
On 'bad/good days' how is your mood?	
How has the pain affected your fitness/hobbies?	
Do you need help in areas where you were previously independent?	
How has this affected your family?	
What do you think is causing this? Do you have fears about a particular illness?	
Do the parents have fears concerning the pain that they feel has not been addressed?	
Past and family history of illness	
Have you suffered painful conditions previously?	There is much recent research into past painful events on the developing nociceptive system. This is particularly relevant to children who have been premature and received intensive care
Have you suffered fatigue, sleeplessness or anxiety previously?	
Any operations or illnesses as a younger child?	
Any neonatal problems?	
Have any family members suffered illness?	Other family illness experience is relevant; there may be a direct genetic link with pain experienced and/or environmental aspects that are factors in the child developing a pain condition
Is there a family history of painful conditions?	
Family, emotional, and social circumstances	
Who currently lives at home?	Having an idea of the family environment is important. Parents often adapt their home life to care for the child and employment patterns change. Siblings' relationships and friendships may alter
What are the occupations of the main carers?	
Have one or both carers changed/stopped their job since the pain condition started?	
Can you identify any stressors in school, family or peer groups?	School often becomes challenging both physically and emotionally (previously able children may not know how to communicate their conditions to peers and have differing degrees of help from school staff)

a history of failed and pain-exacerbating interventions. Three key psychological features of this setting are worth keeping in mind:

◆ Both child and family are likely to be fearful, hoping for a cure, desperate to be helpful, but often 'on their best behaviour', so may not immediately appear to be distressed, and may have flat or neutral affect.

◆ Because of their history, any attempt to shift the treatment goal from one of cure to management or symptom control may be heard as blaming of patient and carer(s), and so should be done only after building trust.

◆ What matters is not necessarily what information has been given to the patient and carers, but what they believe to be true. Typically both patient and family will have heard a variety of stories about what may be happening to them.[47]

Physical examination

Time spent fully on examining at the beginning may prevent repetition and unnecessary, distressing investigations at a later date.[14] If there is concern regarding the diagnosis then this is the time to order all investigations and ensure that these are followed up. Undue delay leads to fear and often a worsening of pain symptoms and associated disability.

Psychometric instruments

There are some well-validated and commonly used tools, most notably the Varni/Thompson Paediatric Pain Questionnaire[48] focusing on pain, and the Functional Disability Index[49] focusing on disability. Pain intensity in children has long been measured using simple severity measurement tools, such as the visual analogue scale (VAS).[50] These give a subjective measure of the pain intensity according to the adolescent and/or that pain perceived by their carer. While these are useful measures, prospectively they give no indication of the impact of pain on the young person's life. For example, one adolescent with a pain score of 7 on the VAS may still get to school where another adolescent with the same score may not be getting out of bed.

Two multidisciplinary tools have recently been developed, one specifically for use in measuring the impact of pain on adolescents with chronic pain (Bath Adolescent Pain Questionnaire)[51] and one specifically for use in measuring the impact of adolescent chronic pain on parents (Bath Adolescent Pain Questionnaire for Parents).[52]

Physiological measures of pain-related indexes.

There are few data on the role or utility of measuring physiological processes in the context of childhood chronic pain. Functional

MRI has recently been shown to be a useful tool in evaluating the role of the CNS in childhood CRPS.[45] Quantitative Sensory Testing (QST) is a valuable tool for assessing sensory perception (including pain) in children.

Rehabilitation and self-management

A dedicated team that works consistently with the adolescent and family will facilitate communication, ensure effective delivery of therapy, reduce iatrogenic influences, and enable goals to be reached earlier.[20] Most approaches to rehabilitation share common features including education, symptom control, behavioural science, and physical therapy.

Education

Although the evidence for education alone as a treatment for behaviour change is wanting, the provision of a rationale for what are often counter-intuitive instructions in self-management is essential. Additionally, one should never underestimate that the average lay person's understanding of anatomy and physiology is at best partial, and more typically fantastic. A critical first step in all rehabilitation is to offer, re-offer, and reinforce an understanding of how one's body may be working to maintain pain. Children and their parents often have inflexible or rigid ideas not only about the cause of pain, but also of pain as an important signal of damage or disease. Rhetorical devices (metaphors, stories, examples, pictures) that counter this rigid thinking can be helpful. Back pain is extremely common but rarely related to malignancy or arthritis. Explaining the fascinating case of phantom limb experiences can also be helpful, to introduce flexibility to the idea that brain signals must signify peripheral damage.

Pharmacotherapy

The number of analgesics and interventions used is a sign that there are no well-controlled therapeutic trials in childhood chronic pain. It is becoming widely accepted, however, that any analgesic intervention should be used alongside multidisciplinary therapy.[53,54] Oral treatments that can be used, with variable success, include tricyclic anti-depressants, non-steroidal anti-inflammatory drugs (NSAIDs), opioids, anti-convulsants, and glucocorticoids.[55,56] Sympathetic blockade and botulinum toxin injections have been used in localized muscular pain.[55] Gabapentin and pregabalin may have a role in addressing neuropathic pain in CRPS. A Cochrane review in 2005 showed that tricyclic anti-depressants have a role in modifying aspects of neuropathic pain in some patients.[57]

The evidence supporting the efficacy of any of these therapies in children is lacking. In CRPS and neuropathic pain gabapentin and pregabalin have shown a small degree of promise but these have not been robustly studied in children. Some authors have shown effect of spinal cord stimulation, regional blocks, and epidural infusions in the small number of children with intractable CRPS[58]; it is widely accepted, however, that these more interventional techniques are only effective alongside active physical and psychological rehabilitation.

Medicine review is often an essential task in this population. Polypharmacy, risk of dosing and combination errors, and confusion over the utility of previously and currently prescribed medication is common. Drug withdrawal, detoxification, and replacement should be carefully managed.

Psychological therapies

A Cochrane systematic review of psychological therapy reported on the effectiveness of psychological treatments for pain control in common chronic pain problems.[59] Small studies using cognitive-behavioural therapy (CBT) in juvenile fibromyalgia show significant improvement in the child's confidence with managing the pain (but disappointing effect on functional disability and depressive symptoms).[8] For the complexly disabled patient there is evidence that an interdisciplinary programme for adolescents complexly disabled with chronic pain has a positive significant impact.[60] The role of the physician is often as an educator, to oversee analgesic withdrawal and to support the overall message that it is safe to increase activity despite pain and reduce reliance on medical support.[47]

Physical therapies

In conditions such as CRPS, early intensive physiotherapy (including desensitization) with behavioural support can provide dramatic reversal of the presenting signs and symptoms.[61] The aim of this is accelerated mobilization. This is complicated if the diagnosis is delayed and access to appropriate physical and psychological rehabilitation difficult. Many cases of diffuse pain will require a gentle, paced approach. Along with musculoskeletal pains, the more active the musculoskeletal system becomes the more likely the muscle spasms and tightening are to reduce. Proprioception improves and autonomic changes subside. Where possible, young people should work to devise their own 'fitness plan'. Using a local gym rather than a hospital physiotherapy gym allows them to start to return to a more normal environment.[60] Working in this consistent and paced manner can be extremely hard for the young person and their parents. The pain often continues at the beginning (if not throughout) and motivation is poor. Parental anxiety is high and there is a fear that damage will be done. Psychological support during this time is important. The young person will need help setting goals, learning how to communicate pain to peers and family, maintaining motivation on 'bad days', managing low mood, dealing with anger and frustration, and overcoming fears. Often they have not been at school for a long period of time and need help in preparing again for this difficult environment. In some cases, there may be other mental health needs that can be identified and appropriately treated.

There are ongoing studies that show promise, specifically with CRPS patients and visual counter-stimulation. Mirror therapy focusing on the hypothesis that incongruence between motor output and sensory input produces CRPS is under way with adults,[62] but there is no data for children.

Complementary therapies are commonly utilized by patients with chronic pain. The evidence supporting many of these therapies in children and adolescents is poor.[63]

Natural history and long-term outcomes

The natural history of chronic musculoskeletal pain in children shows that, in many cases, outcome is improved compared with that in adults.[64] Early, multidisciplinary input (including CBT) has favourable outcome.[60] CRPS in children generally has a favourable prognosis if early physiotherapy is initiated (with psychological support).[64] This is improved if the parents are involved in the rehabilitation process. However, a prolonged time to treatment and the presence of marked autonomic changes are not good prognostic indicators in this condition.

Practice points

1. Ensure an early, thorough history and physical musculoskeletal examination to rule out new or suboptimally treated pathology.

2. Evaluate the impact of the pain on the child and family (not just the level of pain) so that rehabilitation can be tailored.

3. Involve multidisciplinary team early (ideally in early clinics) to facilitate cohesive working and the introduction of psychological and physical therapies.

Sports and exercise injuries

Nicola Maffulli and Angelo Del Buono

Introduction

Regular aerobic exercise has beneficial effects on the cardiovascular system, reduces the incidence of osteoporosis, increases the metabolic rate, and induces a general sense of well-being. However, injuries commonly occur in athletes: if not recognized or treated adequately, they may become recurrent or chronic. Different rates and patterns of injury are observed depending on the type of sport activity. Muscle, tendon, and ligaments are frequently injured acutely, and repeated sporting insults may result in strain, overuse, and fatigue. We describe the current evidence of clinical features and therapeutic aspects of muscle, ligament and tendon disorders.

Muscle injuries

Acute muscle strain injuries account for 10–55% of all acute sports injuries.[1,2] The hamstrings, rectus femoris, and medial head of the gastrocnemius are the most commonly injured muscles.[2] Most commonly occurring at the musculotendinous junction (MTJ), acute muscle injuries are classified as strains (grade i), partial tears (grade II), and complete tears (grade III),[3–5] can be intramuscular, proximal, or distal to the proximal and distal MTJ, and may extend to the osteotendinous junction.[6] Acute strains result from active contractions of muscles, or after indirect trauma and excessive tensile forces which disrupt the myofibres of the MTJ, as commonly happens in sprinting and jumping activities.[2,7] Indirect injuries may be active, usually resulting from eccentric overload, or passive, in response to tensile overstretching of the muscle, with no contraction.[8]

In grade I acute muscle injury (strain), changes are limited, less than 5% of fibres are disrupted, there is some swelling and discomfort, and strength and range of motion are not impaired. Ultrasonography (US) may show normal appearance, or focal or general increased echogenicity, but, given the difficulty of depicting the normal hyperechoic intramuscular portion of the tendon after injury, MRI is more accurate.[9]

Grade II injuries (partial tear) are partial thickness tears, with continuity of fibres at the injury site, involving from less than one-third (low-grade injuries) to more than two-thirds (high-grade) of the muscle fibres.[10] Strength may be reduced. Using US, muscle fibres appear discontinuous; the disruption site is hypervascular and altered in echogenicity in and around the lesion.[9] The appearance at MRI depends on the acuity and severity of the tear, characterized by oedema and haemorrhage of the muscle or MTJ extending along the fascial planes between muscle groups, fibre disorganization, surrounding haematoma, and perifascial fluid.[11]

On US and MRI, grade III (complete tear) injuries show complete discontinuity of muscle fibres, associated hematoma, and retraction of the muscle ends.[9] If the tears are not treated, the ends of the muscle can become rounded and may tether to adjacent muscles or fascia.[12] However, both strains and complete tears occur most often at the MTJ, the weakest link within the muscle tendon unit, independently of the rate or direction of strain and differences in muscle architecture.[13] The pathophysiology of muscular strain is poorly understood, but any condition that diminishes the ability of a muscle to contract (e.g. fatigue, weakness) impairs the muscle's ability to absorb force, and exposes the muscle further risk of injury. Therefore, a weaker muscle is more predisposed to more deleterious injuries.

Management

Despite the high rate of muscle injuries, there is no consensus on their management, with a large number of different interventions being used. In acute injury, treatment includes ice and rest, followed by stretching, agility, and stability exercises. Even though non-steroidal anti-inflammatory drugs (NSAIDs) or manipulation have been commonly used, the evidence in support of their use is limited. Although platelet-rich plasma (PRP) injections are increasingly used, the evidence supporting their use is still scanty (see 'Regenerative therapies, below). Surgery is indicated in chronic tears unresponsive to conservative measures or in high-demand patients complaining of residual inability which impairs performance and requiring return to preinjury level of sport activity. Muscle reattachment is advocated as first line but when this is not possible, muscle release and removal of surrounding scar tissue and adhesions are recommended. Interestingly, from the analysis of risk and protective factors for recurrent hamstring injuries, it has emerged that athletes who follow agility/stabilization exercises rather than strength/stretching exercises have a lower risk of reinjury, whereas there is conflicting evidence that larger extent of initial trauma, a grade 1 hamstring injury, or a previous ipsilateral anterior cruciate ligament (ACL) reconstruction could predispose to recurrence.

Ligaments

Injuries to ligaments occur frequently in exercise. They can be graded from 1 to 3 (strain, partial tear, complete rupture). The most

common injury sites are the lateral ligament complex in the ankle and the four main ligaments around the knee: the medial and lateral collateral, and the anterior and posterior cruciate (see also Chapter 155).

Anterior cruciate ligament

The management of an ACL tear continues to be the most studied area in sports medicine, and a recent debate concerns reconstruction using double-bundle or single-bundle techniques. Recent randomized clinical studies have demonstrated that the double-bundle technique is superior for pain scores and anterior knee laxity, with no significant differences in terms of rotational control and patient-reported pain and function scores.[14] However, the evidence is not convincing, and it appears that anatomical reconstruction of the ACL using a single-bundle technique is at least as good as a double-bundle technique, and less technically demanding.

From the comparison of ACL reconstructions with hamstring and patellar tendon autografts, no significant differences emerge in terms of patient-reported outcomes, osteoarthritis outcome scores, and laxity at 2, 8, and 10 years of follow-up;[15–17] however, patients undergoing patellar tendon reconstruction experience greater anterior knee pain. The best methods of fixation of the graft are still being investigated. Compared with other forms of fixation, biodegradable screws produce greater tunnel enlargement, but this is not clinically relevant.

New emerging areas are trying to elucidate the causes of development of osteoarthritis following ACL surgery, and evaluate the role of PRP in ACL primary repair and reconstruction.[18]

Posterior cruciate ligament

In posterior cruciate ligament (PCL) reconstruction, double- and single-bundle reconstruction, tibial inlay, and transtibial graft placement are increasingly compared. The comparison of transtibial single-bundle arthroscopic tibial inlay procedures and double-bundle arthroscopic tibial inlay procedures[19] has shown that the double-bundle arthroscopic tibial inlay procedure provides better posterior stability with no difference in terms of knee motion or Lysholm scores. The analysis of kinematics of single-bundle reconstruction has demonstrated that this procedure restores anteroposterior translation of the tibia, patellar flexion, and shift, with no effects on mediolateral translation, patellar rotation, and tilt.[20]

Posterolateral corner, posteromedial corner, and multiligamentous injury

The management of posterolateral corner injuries aims to restore normal knee kinematics. Anatomically based posterolateral corner reconstructions improve stability and clinical outcomes at intermediate follow-up,[21] and reconstruction is more reliable than repair.[22] Anatomical reconstruction of the medial collateral ligament and posteromedial corner injuries, including reconstruction of the posterior oblique ligament, is recommended.[21] A recent study on elite athletes with post-traumatic multiligamentous injury involving both cruciate ligaments and at least one collateral ligament suggests that early, single-stage procedures provide the best outcomes, but only one-third of patients return to preinjury activity levels.[23]

Patellofemoral joint

Stability of the patellofemoral articulation is complex and requires a thorough understanding of lower extremity alignment and soft tissue restraints. The medial patellofemoral ligament is the primary restraint to lateral patellar translation, but patella alta, trochlear dysplasia, systemic hyperlaxity, and malalignment also contribute to patellofemoral instability. There is still debate over the appropriate surgical intervention for patients with chronic patellar instability or malalignment. Important technical considerations for surgical correction regard appropriate tensioning of the medial soft tissue restraints and repair or reconstruction of the medial patellofemoral ligament. Medial patellofemoral ligament reconstructions provide good outcomes when indicated and if appropriately performed.[24] From a retrospective study comparing a novel derotational high tibial osteotomy and an Elmslie–Trillat–Fulkerson proximal–distal realignment, superior outcomes have been observed after derotational tibial osteotomy than in patients undergoing proximal–distal realignment, with significant improvement in gait patterns and functional scores.[25] Correction of tibial torsion reduces the valgus vector through more phases of the gait cycle than a proximal–distal realignment.

Lateral ankle injuries and instability

The lateral ligament complex of the ankle is commonly injured in recreational and professional athletes. Initial treatment is usually conservative, involving rest, ice, administration of anti-inflammatory drugs, brace wearing/plaster, partial weightbearing. Physical therapy and functional rehabilitation are also recommended. Although acute lateral ankle sprains usually respond to conservative management, chronic lateral instability resulting in reduced sport activity may occur in 15–20%, with an 80% reinjury rate in younger individuals.[26,27]

The anterior talofibular ligament (ATFL) is usually involved, whereas the calcaneofibular ligament (CFL) is insufficient in 15% of patients. With the aim of re-establishing stability and function without compromising ankle motion, high-demand patients with chronic lateral ankle instability are often candidates for surgery. Although anatomical and non-anatomical autologous tendon graft reconstructions using peroneus brevis, plantaris, semitendinosus, and gracilis tendons have been proposed,[28] arthroscopic and arthroscopically assisted plication and anchor fixation techniques may be used to reconstruct the lateral ligament complex of the ankle, attaching the anterior talofibular ligament to talus and/or fibula.[29] To date, better results have been reported with anatomical than non-anatomical techniques, and the anatomical Broström–Gould repair is considered a reliable alternative to more invasive and technically demanding reconstructions, which preserves ankle motion and provides functional stability.[29] The Brostrom procedure, repairing the ATFL and CFL, is thought to restore hindfoot kinematics, but the Gould modification aims to repair the ruptured lateral ligaments, and reinforces the construct with the inferior extensor retinaculum, providing additional support against inversion load, and similar biomechanical stability compared to the combined repair of the ATFL and CFL.[29]

Tendon ruptures

Tendon ruptures most frequently involve the Achilles tendon, the thickest and strongest tendon of the human body. Most (75%) acute ruptures occur during recreational activities in men 30–40 years of age.[30] There is no agreement on the best management. Recent well-conducted randomized controlled trials (RCTs) show that

conservative and 'classical' (i.e. open) surgical management in an unselected population produce similar functional results, but operative management provides lower rerupture rate, early functional treatment, less calf atrophy, and stronger push-off, at the expense of long incisions, wound complications such as infections, and, occasionally, painful scars.[31]

In athletes, operative management followed by a short period of immobilization in a cast produces excellent results.[32] Minimally invasive repair techniques have been developed to reduce postoperative complications associated with open surgical procedures. These procedures provide accurate opposition of the tendon ends, improve cosmesis, and protect against wound breakdown, but reruptures and sural nerve damage have been reported.[33] Percutaneous techniques have comparable clinical effectiveness and lower complication rates than open procedures, are safe and effective in older individuals, in diabetic patients, and in high-performance athletes.

Tendinopathy

Tendinopathies are sport-related overuse injuries responsible for disability of most major tendons, including the Achilles, patellar, rotator cuff, and forearm extensor tendons. The term tendinopathy includes alterations of the tendon proper and, but is not limited to, the histopathological features of tendinosis, which presumes the presence of degenerative changes on histology, with no clinical or histological signs of intratendinous inflammation.[34] The essential lesion of tendinopathy includes a failed healing response, in which the healing process appears incomplete, with haphazard proliferation of tenocytes, intracellular abnormalities in tenocytes, disruption of collagen fibres, and increase in non-collagenous matrix.[35] What may appear clinically as an acute tendinopathy is actually an advanced failure of a chronic healing response with no histological nor biochemical evidence of inflammation.[36] These alterations lead to a mechanically less stable tendon, probably more susceptible to damage.[37] Inflammation is involved only in the initiation, but not in the propagation and progression of the disease process, whereas failed healing and tendinopathic features seem to be associated with chronic overload and exert a deleterious effect.[38] Although the diagnosis of tendinopathy is usually clinical, MRI and US should be used to better define and understand the location of the lesion.

Management

Different strategies have been proposed, but we have focused on the novel therapies emerging for management of tendinopathy.

Exercises

Eccentric exercises are thought to promote collagen fibre cross-link formation within the tendon, and facilitate tendon remodelling, protect the tendon from increased stresses, and thus prevent reinjury,[39] but the evidence of histological changes following a programme of eccentric exercise is lacking, and the mechanisms by which eccentric exercises may help to relieve the pain of tendinopathy remain unclear. It is possible that eccentric exercises do not just exert a beneficial mechanical effect, but also act on pain mediators, decreasing their presence in tendinopathic tendons. In general, eccentric exercises produce a positive effect, with no reported adverse effects.[39] Excellent clinical results have been reported in both athletic and sedentary patients, but these results have not been confirmed by other studies. The association of eccentric training with shock wave therapy produces higher success rates than those observed after eccentric loading alone or shock wave therapy alone.[40]

Extracorporeal shock wave therapy

Extracorporeal shock wave therapy (ESWT) is supposed to stimulate soft tissue healing and inhibit pain receptors. There is no agreement about using repetitive low-energy ESWT with no local anaesthesia, or high-energy ESWT with local or regional anaesthesia.[41] Low-energy ESWT has been proposed for tendinopathy to stimulate soft tissue healing and inhibit pain receptors.[41] In the scenario of Achilles tendinopathy, low-energy ESWT or eccentric exercises provided comparable results in an RCT, with outcomes superior to those observed after no intervention.[40] The results were disappointing in another study.[42]

Injections

The role of corticosteroids in the management of tendinopathy is still debated, and the evidence supporting the widespread use of intratendinous injections of corticosteroids is scanty, controversial, and disappointing. A meta-analysis of the effects of corticosteroid injections has showed little benefit. The use of ultrasound imaging needle guidance improves the safety of corticosteroid injections, keeping the needle outside the peritendinous space, to inject the fluid only in the Kager triangle, for the Achilles tendon, or in the Hoffa body, for the patellar tendon.

High-volume injections of normal saline solution, corticosteroids, and anaesthetics produce local mechanical effects of stretching, breaking, or occlusion of new blood vessels. This action on the vessels would induce either trauma or ischaemia on the accompanying nerve supply, reducing the pain in symptomatic patients with resistant Achilles tendinopathy. Preliminary studies have showed reduced pain and improved short- and long-term outcomes after management with high-volume injections of patients with Achilles[43] or patellar[44] tendinopathy, regardless of their symptoms. This modality of treatment is safe, relatively inexpensive, and allows a quick return to sports. The injection is performed under ultrasound guidance, so that corticosteroids have no direct action on the tendon itself.

Sclerosant therapy

Sclerosing treatment with polidocanol results in a moderate improvement of symptoms of tendinopathy, but the majority of athletes still have reduced function and substantial pain after 24 months of follow-up. Medium- or long-term outcomes still require investigation.

Surgery

Operative treatment aims to excise fibrotic adhesions, remove or debride areas of failed healing, restore vascularity, and stimulate viable cells to synthesize proteins to favour the healing process.[33] Multiple longitudinal tenotomies seem to trigger neoangiogenesis in the Achilles tendon and increase blood flow, promoting an environment which stimulates healing.[45] Percutaneous longitudinal tenotomies are suggested when conservative management fails in patients with isolated tendinopathy, a well-defined nodular lesion less than 2.5 cm long, and intact paratenon,[46] whereas they are ineffective in patients with pantendinopathy. This procedure is simple, can be performed in an ambulatory setting using local anaesthesia without tourniquet, with minimal complications and no long-term morbidity. Percutaneous longitudinal US-guided internal tenotomy of the Achilles tendon requires the use of high-resolution US

to properly locate the tendinopathic area and to perform the initial stab incision.[46] Radiofrequency microtenotomy is safe and effective in managing patients with chronic tendinopathy. Technically, this procedure is simple to perform and allows a rapid and uncomplicated recovery. This management could induce acute degeneration and/or ablation of sensory nerve fibres, explaining the long-term pain relief.

In tendinopathic tendons, the pathological neovascularization and nerve ingrowth are considered as a possible cause of the pain. Endoscopy, electrocoagulation, and minimally invasive stripping have been proposed to disrupt the abnormal neoinnervation, and interfere with the pain sensation caused by tendinopathy. Tendoscopy allows endoscopic access to the posterior tibial tendon, peroneal tendons, and Achilles tendon, the posterior aspect of the ankle and subtalar joints, and extra-articular structures of the hindfoot such as the os trigonum, the flexor hallucis longus, and the deep portion of the deltoid ligament.[35]

Summary of management of tendinopathy

In general, physical therapy with a 12 week programme of eccentric exercises is the first approach to a patient with tendinopathy. If patients are unresponsive, ESWT is suggested, but the evidence on its efficacy is scanty. Otherwise, injections could be considered. Operative management is proposed after at least 3–6 months of nonoperative management. However, patients should be informed that symptoms may recur after conservative and operative measures.

Regenerative therapies

There is increasing interest in the sports medicine community about providing endogenous growth factors directly to the injury site, using autologous blood products to potentially facilitate healing and earlier return to sport after injury. Despite this interest, and apparent widespread use, there is a lack of high-level evidence from RCTs assessing the efficacy of such products in treating ligament and tendon injuries.

PRP is an autologous concentrate of human platelets in a small volume of plasma, containing biologically active factors, responsible for haemostasis, synthesis of new connective tissue, and revascularization.[47] The term 'PRP' is used for two different liquid formulations: L-PRP contains 5–8 times more platelets and more leucocytes than peripheral blood; P-PRP, in which leucocytes are absent, has a moderate increase in platelet count (1.5–2.5-fold above baseline). Many questions about the best volume and frequency of the injections, the ideal period between multiple injections, mechanism of platelet activation, and degranulation are still unanswered.

First used in the 1980s to promote physiological wound healing of cutaneous ulcers, the use of PRP has spread to a wide range of specialist areas.[47] PRP has been used to enhance the healing of meniscus defects and muscle injuries, stimulate chondrocytes to engineer cartilaginous tissue, reduce pain and produce better and more balanced synovial fluid in arthritic knees, improve outcomes after total knee arthroplasty and subacromial decompression, accelerate bone formation, stimulate the healing of ACL injury central defects, improve the outcome of operated ruptured Achilles tendons, reduce pain in chronic tendinopathies, and prevent and reverse intervertebral disc degeneration. Although some trials report a positive effect, more recent well-designed studies report no beneficial effect, and possibly detrimental effects, of PRP.

In sports medicine, intramuscular PRP injections were initially prohibited, while all other routes of administration, such as peritendinous, were permitted. However, the different PRP formulations were not found to increase muscle growth beyond return to a normal physiological state. Although the prohibition for intramuscular injections of PRP was removed in the 2011 prohibited list, sporting authorities will continue to review PRP use as new medical and scientific information becomes available.[48] Because of the relative safety of these products, basic science, clinical discovery and patient-oriented research should be interdependent rather than successive steps.

CHAPTER 163

Amyloidosis

Philip N. Hawkins

Introduction

Amyloidosis is a disorder of protein folding in which normally soluble proteins are deposited in the extracellular space as insoluble fibrils that progressively disrupt tissue structure and function.[1] More than 25 different unrelated proteins can form amyloid in vivo, and clinical amyloidosis is classified according to the fibril protein type (Table 163.1). The term amyloid is erroneously derived from the Greek for 'starch-like', and the term has been retained despite the protein nature of the deposits having been recognized well over 100 years ago. Protein misfolding and aggregation have increasingly been recognized in the pathogenesis of various other diseases, but amyloidosis—the disease directly caused by extracellular amyloid deposition—is a precise term with critical implications for patients with a specific group of life-threatening disorders.

Amyloid deposition is remarkable in its diversity; it can be systemic or localized, acquired or hereditary, life-threatening or merely an incidental finding. Clinical consequences occur when accumulation of amyloid is substantial enough to disrupt the structure of tissues or organs, leading to impairment of their function. The pattern of organ involvement varies within and between types of amyloidosis, but clinical phenotypes overlap greatly. In systemic amyloidosis, virtually any tissue may be involved and the disease is often fatal, although prognosis has improved as the result of increasingly effective treatments for many of the conditions that underlie it. Greater understanding of the pathogenesis of the disease allowing for improved diagnosis and clinical characterization, along with rational therapies and better supportive care including haemodialysis and solid organ transplantation have also favourably influenced the prognosis. Localized amyloid deposits are confined to a particular organ or tissue, and range from being clinically silent through to having serious consequences such as haemorrhage in the respiratory or urogenital tracts, or space-occupying effects. In addition to the disorders that are classified as a type of amyloidosis, local amyloid deposition is a pathological feature of uncertain significance in various other important diseases including Alzheimer's disease, the prion disorders, and type 2 diabetes mellitus, which are beyond the scope of this chapter.

Pathogenesis of amyloid

Amyloidosis defies the dogma that tertiary structure of proteins is determined solely by their primary amino acid sequence.

Amyloid-forming proteins can adopt two completely different stable structures, the transformation involving massive refolding of the native form into one that predominantly consists of β-sheet and which can autoaggregate with like molecules in a highly ordered manner to produce characteristic, rigid, non-branching amyloid fibrils 10–15 nm in diameter and of indeterminate length.[2] Acquired biophysical properties that are common to all amyloid fibrils include insolubility in physiological solutions, relative resistance to proteolysis, and ability to bind Congo red dye in a spatially ordered manner that produces the diagnostic green birefringence under cross-polarized light.[3]

There are several circumstances in which amyloid deposition occurs. The first is a consequence of a sustained abnormally high concentration of certain proteins that are normally present at very low levels, such as serum amyloid A protein (SAA) in chronic inflammation and β_2-microglobulin in renal failure, which underlie susceptibility to AA and $A\beta_2M$ amyloidosis respectively. A second situation is when there is a normal concentration of a normal, but to some extent inherently amyloidogenic, protein over a very prolonged period, such as transthyretin in senile amyloidosis (ATTR) and β-protein in Alzheimer's disease. The third situation requires the presence of an acquired or inherited variant protein with an abnormal and markedly amyloidogenic structure, such as certain monoclonal immunoglobulin light chains in AL amyloidosis and the genetic amyloidogenic variants of transthyretin, lysozyme, apolipoprotein AI, fibrinogen Aα chain, etc., in hereditary amyloidosis. The genetic and/or environmental factors that influence individual susceptibility to and the timing of amyloid deposition remain unclear, but once the process has begun, further accumulation of amyloid is unremitting so long as the supply of the respective precursor protein continues. Although it is not clear why only the 20 or so known amyloidogenic proteins adopt the amyloid fold and persist as fibrils in vivo, a major unifying theme is that amyloid precursors are relatively unstable. Even under physiological conditions they populate partly unfolded states involving loss of tertiary structure but retention of β-sheet secondary structure, which can autoaggregate into protofilaments and thence mature amyloid fibrils. Seeding may play a facilitating role, consistent with observations that accumulation of amyloid can be remarkably rapid following its initiation.

Amyloid deposits consist mainly of these protein fibrils, but they also contain some common minor constituents, including certain

Table 163.1 Classification of amyloidosis[a]

Type	Fibril precursor protein	Clinical syndrome
AA	Serum amyloid A protein	Systemic amyloidosis usually with predominant renal involvement associated with acquired or hereditary chronic inflammatory diseases. Formerly known as secondary or reactive amyloidosis
AL	Monoclonal immunoglobulin light chains	Systemic amyloidosis potentially involving many organ systems associated with myeloma, monoclonal gammopathy, occult B-cell dyscrasias. Formerly known as primary amyloidosis
ATTR	Normal plasma transthyretin	Senile systemic amyloidosis with predominant cardiac involvement (senile cardiac amyloidosis)
ATTR	Genetic variants of TTR (e.g. ATTR Met30, Ala60, Ile122)	FAP, often with prominent amyloid cardiomyopathy. Predominant cardiac involvement without neuropathy with certain mutations, e.g. TTR Ile122
$A\beta_2M$	β_2-Microglobulin	DRA associated with renal failure and long-term dialysis. Predominant articular and periarticular involvement
$A\beta$	β-Protein precursor (and rare genetic variants)	Cerebrovascular and intracerebral plaque amyloid in Alzheimer's disease. Occasionally familial
AApoAI	Genetic variants of apolipoprotein AI (e.g. AApoAI Arg26, Arg60)	Autosomal dominant systemic amyloidosis. Predominantly non-neuropathic with prominent visceral involvement, especially nephropathy. Minor wild-type ApoAI amyloid deposits may occur in the aorta in aging individuals
AApoAII	Genetic variants of apolipoprotein AII	Autosomal dominant systemic amyloidosis with predominant renal involvement
AFib	Genetic variants of fibrinogen Aα chain (e.g. AFib Val526)	Autosomal dominant systemic amyloidosis. Non-neuropathic with predominant nephropathy
ALys	Genetic variants of lysozyme (e.g. ALys His67)	Autosomal dominant systemic amyloidosis. Non-neuropathic with predominant renal and gastrointestinal involvement. Rarely presents with hepatic rupture
ACys	Genetic variant of cystatin C (ACys Gln68)	Hereditary cerebral haemorrhage with cerebral and systemic amyloidosis, in Icelandic subjects
AGel	Genetic variants of gelsolin (e.g. AGel Asn187)	Autosomal dominant systemic amyloidosis. Predominant cranial nerve involvement plus lattice corneal dystrophy. Described and most common in Finland

DRA, dialysis-related amyloidosis; FAP, familial amyloid polyneuropathy; TTR, transthyretin.

[a]Not exhaustive and amyloid composed of peptide hormones, prion protein, and unknown proteins not included.

glycosaminoglycans (GAGs) and the normal circulating plasma protein serum amyloid P component (SAP), as well as various other trace proteins. SAP binds in a specific calcium-dependent manner to a ligand that is present on all amyloid fibrils but not on their respective precursor proteins.[4] This phenomenon is the basis for the use of SAP scintigraphy in some centres for diagnostic imaging and quantitative monitoring of amyloid deposits. Studies in knockout mice indicate that SAP contributes to amyloidogenesis.

Amyloid fibril-associated GAGs mainly consist of heparan and dermatan sulphates.[5] Their universal presence, restricted heterogeneity, and intimate relationship with the fibrils suggest that they may also contribute to the development or stability of amyloid deposits, a possibility that has lately been supported by the inhibitory effect of low-molecular-weight GAG analogues on the experimental induction of AA amyloidosis in both mice and human patients.[6]

Many of the pathological effects of amyloid can be attributed to its physical presence. Extensive deposits, which may amount to kilograms, are structurally disruptive and incompatible with normal function, as are strategically located smaller deposits, for example in glomeruli or nerves. It remains possible that amyloid fibrils or prefibrillar aggregates may also be directly cytotoxic in some circumstances, but, curiously, amyloid deposits appear to evoke little or no local inflammatory reaction in the tissues. The relationship between the quantity of amyloid deposited and the degree of associated organ dysfunction differs greatly between individuals and between different organs, and there is a strong impression that the rate of new amyloid deposition may be as important a determinant of progressive organ failure as the absolute amyloid load.

Treatments that substantially reduce the supply of amyloidogenic precursor proteins frequently result in stabilization or regression of existing amyloid deposits, and are often associated with preservation or improvement in the function of organs infiltrated by amyloid,[7,8] although the mechanisms by which amyloid deposits can be cleared are little understood at present.

Acquired amyloidosis

Acquired systemic amyloidosis is thought to be the cause of death in about 1 in 1300 patients in the United Kingdom, and is probably much underdiagnosed among elderly individuals, who are likely to be at greatest risk of developing it. Systemic AL amyloidosis is the most serious and commonly diagnosed type, and presently outnumbers referrals of AA amyloidosis to the United Kingdom National Amyloidosis Centre by a factor of 7:1. Although less serious, dialysis-related β_2-microglobulin amyloidosis affects about 1 million patients receiving long-term renal replacement therapy world wide, and causes much suffering. Senile transthyretin amyloidosis, which predominantly involves the heart, occurs in about one-quarter of individuals over the age of 80 years, a sector of the population that is ever rising.

Reactive systemic amyloidosis, AA amyloidosis

AA amyloidosis is a complication of chronic infections and inflammatory diseases, or indeed any condition that gives rise to overproduction of the acute-phase reactant, serum amyloid A protein (SAA). The amyloid fibrils are composed of AA protein, an N-terminal fragment of SAA, and AA amyloidosis occurs in up to about 1–5% of patients with rheumatoid arthritis, juvenile idiopathic arthritis, and Crohn's disease, and more frequently in those with lifelong autoinflammatory diseases such as familial Mediterranean fever.[9] Most patients present with proteinuric renal disease, and although liver and gastrointestinal involvement may occur at a later stage, clinically significant involvement of the heart and nerves is very rare.

The AA fibril protein is a single non-glycosylated polypeptide chain usually of mass 8000 Da comprising the 76-residue N-terminal portion of the 104-residue SAA. Smaller and larger AA fragments, even whole molecules, sometimes occur. SAA is an apolipoprotein of high-density lipoprotein particles and is the polymorphic product of a set of genes located on chromosome 11. SAA is highly conserved in evolution and is a major acute-phase reactant. Most of the SAA in plasma is produced by hepatocytes under transcriptional regulation by cytokines, especially interleukin 1 (IL-1), interleukin 6 (IL-6), and tumour necrosis factor (TNF). After secretion, SAA rapidly associates with high-density lipoproteins from which it displaces apolipoprotein AI. The circulating concentration can rise from normal levels of up to 3 mg/litre to over 1500 mg/litre within 24–48 hours of an acute stimulus, and can remain persistently high in the presence of chronic inflammation.

The AA protein is derived from circulating SAA by proteolytic cleavage, which can be produced by macrophages and by a variety of proteinases. However, it is not known whether cleavage of SAA occurs before and/or after aggregation of monomers during AA fibrillogenesis. Overproduction of SAA in the long term is a prerequisite for deposition of AA amyloid, but it is not known why the latter only occurs in some individuals in this situation. In mice, only one of the three major isoforms of murine SAA is the precursor of AA amyloid fibrils. Human SAA isoforms are more complex but homozygosity for particular types seems to favour amyloidogenesis, although there may also be ethnic differences in susceptibility.

The functions of SAA are not known, but may include modulating effects on reverse cholesterol transport and on lipid functions in the microenvironment of inflammatory foci. Regardless of its physiological role, the behaviour of SAA as an exquisitely sensitive acute-phase protein with an enormous dynamic range makes it an extremely valuable empirical clinical marker. It can be used to objectively monitor the extent and activity of all manner of infective, inflammatory, necrotic, and neoplastic diseases. Frequent long-term monitoring of SAA is vital in the management of all patients with AA amyloidosis since control of the primary inflammatory process sufficient to reduce SAA production is essential if amyloidosis is to be halted or enabled to regress. Automated immunoassay systems for SAA are available standardized on a World Health Organization International Reference Standard.[10]

AA amyloidosis occurs in association with chronic inflammatory disorders, chronic local or systemic microbial infections, and occasionally neoplasms, all of remarkable variety. In western Europe and the United States the most frequent predisposing conditions are idiopathic rheumatic diseases. The lifetime incidence of AA amyloidosis in patients with rheumatoid arthritis (RA) and juvenile idiopathic arthritis (JIA) in Europe is up to 1–5%, although for reasons that are not clear the incidence appears to be lower in the United States, and may generally be decreasing. Amyloidosis is exceptionally rare in systemic lupus erythematosus (SLE) and related connective tissue diseases, and in ulcerative colitis since these conditions provoke only a very modest acute-phase response. Tuberculosis and leprosy are important causes of AA amyloidosis in some parts of the world. Chronic osteomyelitis, bronchiectasis, chronically infected burns and decubitus ulcers, and the chronic pyelonephritis of paraplegia are other well-recognized associations. Hodgkin's disease and renal carcinoma, which often cause a major acute-phase response, are the malignancies most commonly associated with systemic AA amyloid. Curiously, about 7% of patients with AA amyloidosis do not have a clinically obvious chronic inflammatory disease, and these patients are prone to be assumed to have AL amyloidosis in error. Although it remains impossible to identify the aetiology of the causative acute-phase response in many such patients, the commonest identifiable pathologies in such cases in our own series have been hitherto undiagnosed inherited periodic fever syndromes and cytokine-secreting Castleman's disease tumours of the solitary plasma cell type, located in either the mediastinum or the gut mesentery.

The clinical features of AA amyloidosis are dominated by renal involvement, although histologically AA amyloid deposits are widely distributed. More than 90% of patients present with nonselective proteinuria due to glomerular deposition, and nephrotic syndrome may develop before progression to endstage renal failure. Haematuria, isolated tubular defects, nephrogenic diabetes insipidus, and diffuse renal calcification occur rarely. Kidney size is usually normal, but may be enlarged, or, in advanced cases, reduced. Endstage chronic renal failure is the cause of death in 40–60% of cases but acute renal failure may be precipitated by hypotension and/or salt and water depletion following surgery, excessive use of diuretics, or intercurrent infection, and may be associated with renal vein thrombosis. The second most common presentation is with organ enlargement, such as hepatosplenomegaly or occasionally thyroid goitre, with or without overt renal abnormality, but in all cases amyloid deposits are widespread at the time of presentation, which is the basis for diagnosis through random rectal and other biopsies. Histological involvement of the heart is frequent, but rarely results in cardiac failure. Gastrointestinal dysfunction is common in advanced disease, presenting predominantly with diarrhoea and occasional bleeding.

AA amyloidosis can present clinically early in the course of an associated inflammatory disease, but the incidence increases over time. The median duration of chronic inflammatory disease prior to diagnosis of amyloid is about 20 years, though it can be as little as just 1 year.[9] Prognosis is closely related to the degree of renal dysfunction and the effectiveness of treatment for the underlying inflammatory condition. In the presence of persistent, uncontrolled inflammation, 50% of patients with AA amyloidosis die within 10 years of diagnosis, whereas if the causative acute-phase response can be persistently suppressed proteinuria can resolve, renal function may be retained, and the prognosis is much better (see 'Treatment of amyloidosis' below). Availability of haemodialysis and renal transplantation prevents early death from uraemia per se,

and despite amyloid deposition in extrarenal tissues the prognosis is quite similar to other causes of endstage renal failure.

Amyloidosis associated with immunocyte dyscrasia, AL amyloidosis

Systemic AL, formerly known as 'primary', amyloidosis occurs in about 2% of individuals with monoclonal B-cell dyscrasias.[11] AL fibrils are derived from monoclonal immunoglobulin light chains, which are unique in each patient and which explains the substantial heterogeneity of AL amyloidosis in terms of organ involvement and overall clinical course. Virtually any organ other than the brain may be directly affected, but involvement of the kidneys, heart, liver, or peripheral nervous system is most often associated with clinical consequences. Early symptoms are often non-specific, including marked fatigue. The underlying monoclonal gammopathy is often missed by routine screening techniques with potential to further delay the diagnosis, which even under favourable circumstances tends to be made at an advanced stage when the deposits are extensive. This emphasizes the need to consider AL amyloidosis as a potential diagnosis in a range of vague clinical presentations, and the need for prompt appropriate investigations, such as biopsy of affected organs and sensitive serum free light-chain analysis to identify associated subtle B-cell dyscrasias.[8]

AL amyloid fibrils are derived from the N-terminal region of monoclonal immunoglobulin light chains and consist of the whole or part of the variable (V_L) domain. The molecular mass of the fibril subunit protein therefore varies between about 8000 and 30 000 Da. Monoclonal light chains are unique to each individual, and the propensity for some to form amyloid fibrils is inherent to their particular structure. Only a small proportion of monoclonal light chains are amyloidogenic, but it is not possible to identify these with any certainty from their class or abundance.

The inherent 'amyloidogenicity' of certain monoclonal light chains has been demonstrated in an in-vivo model in which purified Bence Jones proteins were injected into mice.[12] Animals receiving light chains from patients with AL amyloid developed typical amyloid deposits composed of the human protein, whereas animals receiving light chains from myeloma patients without amyloid did not. AL fibrils are more commonly derived from λ than κ light chains, despite the fact that κ isotypes predominate among both normal immunoglobulins and monoclonal gammopathies. Some amyloidogenic light chains have distinctive amino acid replacements or insertions compared with non-amyloid monoclonal light chains, including replacement of hydrophilic framework residues by hydrophobic ones, changes that can promote aggregation and insolubility. Certain light-chain isotypes, notably $V\lambda_{VI}$, are especially amyloidogenic, and there is a degree of concordance between some isotypes and their tropism for being deposited as amyloid in particular organ systems. For example, the $V\lambda_{VI}$ isotype often presents with dominant renal involvement whereas the $V\lambda_{II}$ isotype frequently involves the heart.

The associated B-cell dyscrasias in systemic AL amyloidosis are heterogeneous and include almost any clonal proliferation of differentiated B lymphocytes, including multiple myeloma, Waldenström's macroglobulinaemia, and occasionally other malignant lymphomas or leukaemias. However, well over 80% of cases are associated with low-grade and otherwise 'benign' monoclonal gammopathies that are often difficult to demonstrate. Histological studies indicate that an element of minor and clinically insignificant amyloid deposition occurs in up to about 10% of patients with myeloma, and similarly in a much proportion of patients with monoclonal gammopathy of undetermined significance (MGUS). The cytogenetic abnormalities that commonly occur in multiple myeloma and MGUS, such as 14q translocations and 13q deletion, have also been observed in AL amyloidosis, but their prognostic significance has not been fully elucidated.

Systemic AL amyloidosis accounts for about 1 in 1500 deaths in the United Kingdom and occurs equally in men and women. The age-adjusted incidence of AL amyloidosis in the United States is estimated to be between 5.1 and 12.8 per million persons per year, which is equivalent to approximately 3000 new cases per year. The median age at presentation is 65 years, but it can sometimes occur in young adults and is probably underdiagnosed in older people, in whom monoclonal gammopathies have the highest prevalence.

The clinical features of AL amyloidosis are protean.[13] The heart is affected in 90% of AL patients, in 30% of whom restrictive cardiomyopathy is the presenting feature and in up to 50% of whom it is ultimately fatal. Other cardiac presentations include arrhythmias and angina. Renal AL amyloid has the same manifestations as renal AA amyloid, but the prognosis is worse. Gut involvement may cause motility disturbances (often secondary to autonomic neuropathy), malabsorption, perforation, haemorrhage, or obstruction. Macroglossia occurs rarely but is almost pathognomonic of AL type. Hyposplenism sometimes occurs in both AA and AL amyloidosis. Painful sensory polyneuropathy with early loss of pain and temperature sensation followed later by motor deficits is seen in 10–20% of cases and carpal tunnel syndrome in 20%. Autonomic neuropathy leading to orthostatic hypotension, impotence, and gastrointestinal disturbances may occur alone or together with the peripheral neuropathy, and has a very poor prognosis. Skin involvement takes the form of papules, nodules, and plaques usually on the face and upper trunk, and involvement of dermal blood vessels results in purpura occurring either spontaneously or after minimal trauma and is quite common. Articular amyloid is rare but may superficially mimic acute polyarticular RA, or it may present as asymmetrical arthritis affecting the hip or shoulder. Infiltration of the glenohumeral joint and surrounding soft tissues occasionally produces the characteristic 'shoulder pad' sign. A rare but serious manifestation of AL amyloid is an acquired bleeding diathesis that may be associated with deficiency of factor X and sometimes also factor IX, or with increased fibrinolysis. It does not occur in AA amyloidosis, although in all types of systemic amyloidosis there may be serious bleeding in the absence of any identifiable factor deficiency due to widespread vascular deposits.

Dialysis-related amyloidosis, β_2-microglobulin amyloidosis

β_2-microglobulin amyloid deposition occurs in patients with dialysis-dependent chronic renal failure, and predominantly in articular and periarticular structures.[14] The amyloid fibril precursor protein is β_2-microglobulin, which is the invariant chain of the MHC class I molecule, and is expressed by all nucleated cells. It is synthesized at an average rate of 150–200 mg per day and is normally filtered freely at the glomerulus and then reabsorbed and catabolized by the proximal tubular cells. Decreasing renal function causes a proportionate rise in concentration.

β$_2$-Microglobulin amyloidosis was first described in 1980 and occurs in patients who have been on dialysis for several years, or very occasionally those with longstanding severe chronic renal impairment. Dialysis-related amyloidosis (DRA) has mostly been recognized in the haemodialysis population but it also occurs in patients on continuous ambulatory peritoneal dialysis (CAPD). Relatively few patients are maintained on peritoneal dialysis for the 5–10 years required to develop symptomatic β$_2$-microglobulin amyloid, but histological studies of early subclinical deposits suggests that the incidence of DRA is similar among patients receiving the two modalities of dialysis. Indeed, β$_2$-microglobulin amyloid deposits are present in 20–30% of patients within 3 years of commencing dialysis for endstage renal failure.

The clinical features are largely confined to the locomotor system. Carpal tunnel syndrome is usually the first clinical manifestation of β$_2$-microglobulin amyloidosis. Some individuals develop symptoms within 3–5 years and by 20 years the prevalence is almost 100%. Older patients appear to be more susceptible to the disease, and tend to exhibit symptoms more rapidly. Amyloid arthropathy tends to occur a little later but eventually affects the most patients on dialysis. The arthralgia of β$_2$-microglobulin amyloidosis affects the shoulders, knees, wrists, and small joints of the hand and is associated with joint swelling, chronic tenosynovitis and, occasionally, haemarthroses. Spondylarthropathies are also recognized, as is cervical cord compression. β$_2$-Microglobulin amyloid deposition within the periarticular bone produces typical appearances of subchondral erosions and cysts which can contribute to pathological fractures particularly of the femoral neck, cervical vertebrae and scaphoid. Although β$_2$-microglobulin amyloidosis is a systemic form of amyloid, manifestations outside the musculoskeletal systemic are rare, but there have been reports of it causing congestive cardiac failure, gastrointestinal bleeding, perforation, and pseudo-obstruction.

Senile transthyretin (ATTR) amyloidosis

Microscopic, clinically silent systemic deposits of wild-type 'senile' transthyretin (TTR) amyloid are common in older people, involving the heart and blood vessel walls, smooth and striated muscle, fat tissue, renal papillae, and alveolar walls. In contrast to most other forms of systemic amyloidosis, including hereditary transthyretin amyloid caused by point mutations in the TTR gene, the spleen and renal glomeruli are rarely affected. The brain is not involved. Senile TTR amyloidosis almost always presents clinically with restrictive cardiomyopathy, and deposits in other tissues rarely ever attain clinical significance. About one-quarter of patients can be demonstrated to have gastrointestinal amyloid deposits on rectal biopsy. Most patients are at least 70 years of age, and there is very strong male preponderance.

Localized AL amyloidosis

Localized deposits of AL amyloid can occur almost anywhere in the body and are consequent on the presence of a focal monoclonal B-cell dyscrasia within the affected tissue, which is hard to demonstrate. Characteristic sites include the skin, airways, conjunctiva, and urogenital tract. They may be nodular or confluent and are associated with a usually inconspicuous focal infiltrate of clonal B cells producing amyloidogenic light chains. Progression

of localized AL amyloid into a truly systemic disease is exceedingly rare, and conservative management is usually appropriate. It is also rare for the focal B-cell dyscrasia to become systemic and to require treatment in its own right.

Localized orbital AL amyloid presents as mass lesions which can disrupt eye movement and the structure of the orbit. Localized laryngeal AL amyloidosis is a well-recognized syndrome that is often amenable to direct or laser excision, but hereditary systemic ApoAI amyloidosis can also present in this manner. Amyloidosis presenting in the bronchial tree is virtually always localized AL type, as are solitary or multiple amyloid nodules within the lung tissue. If accessible, bronchoscopic lasering of stenotic lesions can relieve symptoms. In contrast, diffuse alveolar-septal parenchymal deposition is commonly a manifestation of systemic AL amyloidosis. There are anecdotal reports that inhaled steroids may benefit pulmonary symptoms. Breast amyloidosis is associated with Sjögren's syndrome in some cases, and MALT lymphoma should be excluded. Lichenoid and macular forms of cutaneous amyloid are distinct and are thought to be derived from keratin or related proteins, whereas nodular cutaneous amyloidosis deposits are generally localized AL type, but the latter can sometimes be a manifestation of systemic AL amyloidosis. Localized urogenital AL deposits are often incidental findings but may present with haematuria or, less commonly, obstruction. They can occur anywhere from the renal collecting system to the urethra, although are most usually identified within the bladder. Management is conservative or with transurethral laser resection when symptoms occur; cystectomy is rarely required.

Hereditary systemic amyloidosis

Hereditary systemic amyloidosis is caused by deposition of amyloid fibrils derived from genetically variant proteins, and is associated with mutations in the genes for TTR, cystatin C, gelsolin, lysozyme, fibrinogen A α-chain apolipoprotein AI and, in just a few families, apolipoprotein AII. These diseases are all inherited in an autosomal dominant pattern with variable penetrance, and present clinically at various times from teenage to old age, though usually in mid-adult life. By far the commonest hereditary amyloidosis is caused by TTR variants, which usually presents as the syndrome of familial amyloid polyneuropathy with peripheral and autonomic neuropathy. Cystatin C amyloidosis presents as cerebral amyloid angiopathy with recurrent cerebral haemorrhage and clinically silent systemic deposits, and has been reported only in Icelandic families. Gelsolin amyloidosis presents with cranial neuropathy but is also extremely rare. Apolipoprotein AI, lysozyme and fibrinogen A α-chain amyloidosis present as non-neuropathic systemic amyloidosis that can affect any or all the major viscera, with renal involvement usually being prominent. Since a family history is quite often absent, these latter conditions are readily misdiagnosed as acquired 'primary' AL amyloidosis, and are less rare than previously thought. Indeed, recent routine use of DNA analysis suggests that 5–10% of patients presenting with systemic amyloidosis of non-AA type have hereditary forms of the disease.[15] It is imperative that hereditary amyloidosis is identified correctly, since prognosis, treatment, and implications for family members differ substantially as compared with acquired amyloidosis.

Familial amyloidotic polyneuropathy, variant transthyretin (ATTR) amyloidosis

Familial amyloidotic polyneuropathy (FAP) is associated with heterozygosity for point mutations in the gene for TTR. It is an autosomal dominant syndrome with peak onset between the third and seventh decades.[16] More than 100 variant forms of TTR are associated with FAP, and the amyloid fibrils are derived from a mixture of variant and wild-type TTR protein. There are probably several thousand patients with FAP in the world. The disease is characterized by progressive and disabling peripheral and autonomic neuropathy and varying degrees of visceral amyloid involvement, prominently including cardiac amyloidosis which can be the sole clinical feature in some cases. Deposits within the vitreous of the eye are well recognized, and are pathognomonic, whereas deposits in the kidneys, thyroid, spleen, and adrenals are usually asymptomatic. There are well-characterized foci of FAP associated with the most common variant, substitution of methionine for valine at residue 30 (TTR Met30), in Portugal, Japan, and Sweden, but FAP has been reported in most ethnic groups around the world. There is considerable phenotypic variation in the age of onset, rate of progression, involvement of different systems, and disease penetrance generally, even sometimes within a given family. Typically the disease progresses inexorably, causing death within 5–15 years.

Familial amyloid polyneuropathy with predominant cranial neuropathy

This is a very rare dominant form of hereditary amyloidosis that presents in mid to late adult life with cranial neuropathy, lattice corneal dystrophy and a mild distal peripheral neuropathy.[17] It was originally described in Finland but has since been reported in other ethnic groups. There may be skin, renal, and cardiac manifestations but these are usually covert and life expectancy approaches normal. There is no specific treatment and the disorder is progressively disfiguring and very distressing its late stages. The mutant gene responsible encodes a variant form of gelsolin, which is an actin-modulating protein. The functional role of circulating gelsolin is unknown but may be related to clearance of actin filaments released by apoptotic cells.

Non-neuropathic hereditary systemic amyloidosis

A physician in Germany named Ostertag first described the syndrome of hereditary systemic amyloidosis in 1932. He reported two families with dominantly inherited renal amyloidosis without neuropathy. This syndrome is now known to be caused by mutations in the genes for lysozyme, apolipoprotein AI and AII and fibrinogen A α-chain. Hitherto thought to be exceedingly rare, it has lately been demonstrated that many affected patients do not have a family history and up to 5% of patients presenting with systemic amyloidosis have a hereditary non-neuropathic type. This has led to widespread use of DNA screening in specialist amyloidosis centres.

Hereditary lysozyme systemic amyloidosis has been described in association with six lysozyme variants, all of which are extremely rare. Most patients present in middle age with proteinuria and very slowly progressive renal impairment.[18] There are usually substantial amyloid deposits in the liver, spleen, and upper gastrointestinal tract; dry eyes due to lacrimal gland involvement is an early diagnostic clue. Curiously some patients with the least rare histidine-67 variant present as young adults with hepatic rupture,[19] but most present later on with renal dysfunction. Cutaneous petechial haemorrhage from a young age is a peculiar feature in patients with the threonine-56 variant. Many patients suffer few symptoms despite substantial amyloid deposits, but acute gastrointestinal haemorrhage or perforation is a frequent cause of death.

Apolipoprotein AI is a major constituent of high-density lipoprotein. There are 14 known amyloidogenic variants, 11 of which are single amino acid substitutions, two are deletions, and one a deletion/insertion. The resulting clinical syndromes vary but are often associated with substantial amyloid deposits in the liver, spleen, and kidneys. Some mutations are associated with predominant cardiomyopathy and, in the case of the arginine-26 variant, a FAP-like syndrome.[20] Several C-terminal variants are associated with hoarseness due to laryngeal amyloid deposits. Other clinical consequences associated with particular mutations include male infertility and skin lesions. The majority of patients eventually develop renal failure but liver function usually remains well preserved despite extensive hepatic amyloid deposition. Normal wild-type apolipoprotein AI amyloid is itself weakly amyloidogenic, and is the precursor of small amyloid deposits that occur quite frequently in aortic atherosclerotic plaques.

Hereditary fibrinogen A α-chain amyloid was first identified in a family in 1993, since when eight further amyloidogenic mutations have been described. These include five single amino acid substitutions, three frame shifting deletion mutations, and a deletion–insertion mutation. Much the commonest mutation results in the substitution of valine for glutamic acid at position 526, which most often presents in the absence of a family history due to low penetrance. Indeed, nearly 5% of patients referred to the United Kingdom National Amyloidosis Centre with a presumed diagnosis of acquired AL amyloidosis have had hereditary fibrinogen A α-chain amyloidosis.[21] Most patients present in late middle age with proteinuria or hypertension and progress to endstage renal failure during the following 5 years or so. Amyloid deposition occurs in the kidneys, spleen, and sometimes the liver, but it is usually asymptomatic in the latter two sites. The majority of patients have an excellent outcome with renal replacement therapy.

Diagnosis and investigation of amyloidosis

The diagnosis of amyloidosis generally requires histological confirmation, although the mere demonstration of amyloid deposition does not by itself establish that it is clinically significant. While amyloidosis does not occur in the absence of amyloid deposits, the latter may be an incidental histological finding, especially in older subjects. The pathognomonic tinctorial property of amyloid deposits in tissue is apple green/red birefringence when stained with Congo red dye and viewed in intense light through cross-polarized filters. Immunohistochemical staining of amyloidotic tissue sections is the most accessible method for characterizing amyloid fibril protein type, but it does not always produce definitive results, especially in AL type. Amyloid deposits can be quite patchy and histology can never provide information about the overall whole body load or distribution of amyloid deposits, nor does it permit monitoring of the natural history of amyloidosis or its response to treatment. In order to overcome these problems we developed radiolabelled human SAP as a specific, non-invasive, quantitative in-vivo tracer for amyloid deposits, and have used it as a routine tool in our clinical practice for 20 years. We have performed some 10 000 studies,

and scintigraphy and metabolic turnover studies with labelled SAP have contributed greatly to knowledge of amyloidosis and, especially its diagnosis, monitoring and response to treatment.

Histological diagnosis of amyloid

The diagnosis of amyloid is most frequently made following biopsy of the kidneys, liver, heart, gut, peripheral nerve, lymph node, skin, thyroid, or bone marrow. When a possible diagnosis of amyloidosis has already been considered, biopsy of subcutaneous fat or rectum is less invasive and is positive in about 50–80% of patients with systemic AA or AL types. Biopsies of affected organs have a higher yield but a greater risk of haemorrhage and other complications.

The Congo red stain, and its resultant green birefringence when viewed with high intensity polarized light, is the pathognomonic histochemical test for amyloidosis,[22] although other fluorochromes and metachromatic stains continue to be used quite widely. Congo red is unstable and must be freshly prepared every 2 months or less. Thick sections of 5–10 μm and inclusion in every staining run of a positive control tissue containing modest amounts of amyloid are critical.

Immunohistochemistry is the most accessible method for characterizing the type of amyloidosis, although its success varies with fibril type and it depends on availability of a suitable tissue sample that contains neither too little nor too much amyloid.[23] Antibodies to serum amyloid A protein are commercially available and virtually always stain AA deposits, as is the case with antibodies to β_2-microglobulin in haemodialysis-associated amyloid. In AL amyloid, the deposits in fixed specimens are stained convincingly with antibodies to κ or λ immunoglobulin light chains in only about two-thirds of cases, since the technique is hampered by abundant polyclonal immunoglobulin background and because the light-chain fragments in AL fibrils are chiefly variable domain and unique for each monoclonal protein. Immunohistochemical staining of TTR and other hereditary amyloid fibril proteins may require pretreatment of sections with formic acid, alkaline guanidine, or deglycosylation, and, even then, do not always yield definitive results.

Electron microscopy identifies amyloid as straight, rigid non-branching fibrils, of indeterminate length, and 10–15 nm in diameter. A diagnosis of amyloidosis made through electron microscopy alone should be regarded with caution since other fibrillar deposition diseases occur. Immunogold staining of amyloidotic biopsies can sometimes be diagnostic of fibril protein type when standard immunohistochemistry under light microscopy has not produced definitive results.

Problems of histological diagnosis include inadequate tissue samples, for example the failure to obtain submucosal vessels in a rectal biopsy, and indeed the failure to identify any amyloid in a target organ biopsy never completely excludes the diagnosis. The unavoidable sampling problem means that biopsies cannot reveal the extent or distribution of amyloid generally. Experience with Congo red staining is required if clinically important false-negative and false-positive results are to be avoided. Immunohistochemical staining requires positive and negative controls, including demonstration of specificity of staining by absorption of antisera with the respective antigens.

Non-histological investigations

Myocardial amyloid deposits cause a restrictive type of cardiomyopathy.[24] Two-dimensional echocardiography showing small, concentrically thickened ventricles, diastolic dysfunction with or without various degrees of global systolic impairment, dilated atria, homogeneously echogenic valves, and 'sparkling' echodensity of ventricular walls is virtually diagnostic of cardiac amyloidosis (Figure 163.1). However, clinically significant diastolic impairment may be difficult to detect even by comprehensive Doppler and other functional studies, and can sometimes occur in the absence of left ventricular wall thickening. Newer echocardiographic techniques such as strain and strain rate measurements can be helpful. Cardiac MRI is emerging to be of value, including the peculiar phenomenon of diffuse subendocardial late gadolinium enhancement which appears to be strongly suggestive of amyloid. Electrocardiography characteristically shows reduced voltages, presumably reflecting replacement of myocardium by amyloid, although this finding is less common in cardiac amyloid of TTR type than AL type. Localization of isotope-labelled calcium-seeking tracers in the heart has poor sensitivity and specificity and is of no routine clinical value.

Elevation of serum N-terminal pro brain natriuretic peptide (NT-proBNP) and cardiac troponin concentrations occur in many types of cardiac dysfunction and in chronic kidney disease. However, significant cardiac AL amyloidosis is excluded by normal values of NT-proBNP.[25] Cardiac troponin and NT-proBNP concentrations appear to be powerful predictors of prognosis and survival after chemotherapy in AL amyloidosis, and a staging system for newly diagnosed AL amyloidosis patients using these two biomarkers has been proposed.

In cases of known or suspected hereditary amyloidosis the gene defect must be characterized. If amyloidotic tissue is available the fibril protein may be identified immunohistochemically and the corresponding gene can then be studied, but when no tissue is
Fig. 163.1 Echocardiographic four-chamber view in a patient with cardiac AL amyloidosis showing concentric thickening of the ventricular walls, dilated atria, and thickened valves. Doppler flow studies demonstrated restrictive physiology, but systolic function was relatively well preserved.

available, screening of the genes for known amyloidogenic proteins must be undertaken.

Biochemical and immunochemical analyses for the presence in the plasma of genetically variant amyloidogenic variant proteins also exist, but DNA analysis is the most direct approach. However, it remains essential to corroborate DNA findings by confirming one way or another that the respective protein is indeed the main constituent of the amyloid.

Proteomic analyses of amyloidotic material are increasingly being used in specialist centres, enabling amyloid deposits in ever smaller samples to be characterized.[26]

Radiolabelled serum amyloid P component scintigraphy

The universal presence in amyloid deposits of SAP, derived from circulating SAP, is the basis for use of radioiodine-labelled SAP as a diagnostic tracer in amyloidosis.[27] No localization or retention of labelled SAP occurs in healthy subjects or in patients with diseases other than amyloidosis. Radioiodinated SAP has a short (24 hour) half-life in the plasma and is rapidly catabolized with complete excretion of the iodinated breakdown products in the urine. However, in patients with amyloidosis, the tracer rapidly and specifically localizes to the deposits, in proportion to the quantity of amyloid present, and persists there without breakdown or modification (Figure 163.2). Most experience has been gained with SAP labelled with the pure gamma emitter iodine-123. The associated dose of radioactivity is less than 4 mSv and well within accepted safety limits for diagnostic nuclear medicine imaging. The uptake of tracer into various organs can be precisely and repeatedly quantified.
Fig. 163.2 Posterior whole body I[123]-serum amyloid P (SAP) component scintigraphy demonstrating systemic amyloid deposits in the spleen, adrenal glands, and kidneys of a patient with AA amyloidosis (left), and throughout the bones of a patient with AL amyloidosis (right). Major uptake of I[123]-SAP into bones only occurs in amyloidosis of AL type.

Important observations regarding amyloid, which have been made for the first time in vivo, include the following: the different distribution of amyloid in different forms of the disease; amyloid in anatomic sites not available for biopsy (adrenals, spleen); major systemic deposits in forms of amyloid previously thought to be organ-limited; a poor correlation between the quantity of amyloid present in a given organ and the level of organ dysfunction; a non-homogeneous distribution of amyloid within individual organs; and evidence for surprisingly rapid progression and regression of amyloid deposits with different rates in different organs. The long-held belief that amyloid deposition is irreversible and inexorably progressive is evidently incorrect, and simply reflects the persistent nature of the conditions that underlie it. Many case reports have described improvement in amyloidotic organ function when underlying conditions have been controlled, suggesting regression of amyloid, and serial SAP scintigraphy provided the means to prove this is indeed the case. Regression of amyloid has been observed when the supply of amyloid fibril precursor proteins has been reduced in AA amyloidosis by vigorous control of rheumatic inflammation, in AL amyloidosis by suppression of the clonal plasma cell disease by cytotoxic drugs, in haemodialysis-associated amyloidosis after renal transplantation, and in hereditary TTR and fibrinogen A α-chain amyloidosis following liver transplantation. It is now clear that amyloid deposits exist generally in a state of dynamic turnover, with encouraging implications for patient management. Labelled SAP studies thus make a valuable contribution to the diagnosis and management of patients with systemic amyloidosis, and are performed routinely at the NHS National Amyloidosis Centre at the Royal Free Hospital, London.

Assessment of organ involvement by amyloid

Internationally agreed consensus criteria for defining organ involvement in systemic amyloidosis were published in 2005 (Table 163.2).[28] Organ involvement by amyloid is variously defined clinically, histologically, and according to organ function and through other specialized investigations. ECG and two-dimensional Doppler echocardiography are the mainstays for assessing cardiac involvement, as are estimates of glomerular filtration and proteinuria for renal involvement. Liver size and serum alkaline phosphatase provide simple and accessible, but not overly sensitive, measures of liver involvement. In contrast, amyloid involvement of the gastrointestinal tract, lungs, soft tissues and nervous system are much less amenable to precise definitions and are even more challenging to monitor quantitatively over time.

Natural history and prognostic factors

Systemic amyloidosis is almost always a progressive disease which without successful treatment usually results in death within months to several years. Median survival of patients with AA amyloidosis whose underlying inflammatory disease is not well suppressed is in the order of 5–10 years. The prognosis in FAP is similar, but is usually much better in non-neuropathic hereditary types, i.e. those associated with mutations in apolipoprotein AI, fibrinogen A α-chain, and lysozyme. The prognosis of systemic AL amyloidosis is generally worse than AA and hereditary types, and median survival in some quite recent series was only 12–15 months. Important factors that influence prognosis are the extent and severity of organ involvement, availability of

Table 163.2 Diagnostic criteria for organ involvement by amyloid

Organ involvement	Consensus criteria[a]
Heart	Echocardiogram demonstrates a mean wall thickness >12 mm, no other cardiac cause found
Kidney	Proteinuria >0.5g/24 h, predominately albumin
Liver	Total liver span >15 cm in the absence of heart failure or alkaline phosphatase >1.5 times the institutional upper limit of normal
Nerve	Peripheral: clinical; symmetric lower extremity sensorimotor peripheral neuropathy
	Autonomic: gastric-emptying disorder, pseudo-obstruction, voiding dysfunction not related to direct organ infiltration
Gastrointestinal tract	Direct biopsy verification with symptoms
Lung	Direct biopsy verification with symptoms
	Interstitial radiographic pattern
Soft tissue	Tongue enlargement, clinical
	Arthropathy
	Claudication, presumed vascular amyloid
	Skin
	Myopathy by biopsy or psudohypertrophy
	Lymph node (may be localized)
	Carpal tunnel syndrome

[a]As reported by Gertz et al., *Am J Hematol* 2005;**79**:319–328.

supportive measures including renal dialysis and organ transplantation, and the potential for and effectiveness of reducing the supply of the respective amyloid fibril precursor protein through intervention.

Systemic AL amyloidosis is not only the commonest type, but also the most heterogeneous in its organ involvement, presentation, and clinical course. One-half of deaths are due to cardiac involvement, and in patients in whom heart failure is evident at presentation, median survival is 6 months. There has been much recent effort to define prognostic factors in AL amyloidosis, and staging systems are in development. Symptomatic or substantial echocardiographic evidence of cardiac amyloid is associated with a prognosis of only 6–12 months. Patients with liver involvement and hyperbilirubinaemia above 35 μmol/litre rarely survive more than 4 months. Significant autonomic neuropathy, progressive clonal disease unresponsive to chemotherapy, and a bone marrow plasmacytosis of over 20% are also associated with poor outcomes. A large whole-body amyloid load on SAP scintigraphy and evidence of accumulation of amyloid on follow-up SAP scans are further poor prognostic features. A better prognosis is associated with proteinuria or peripheral neuropathy as the dominant clinical feature, substantial suppression of underlying clonal disease by chemotherapy, and regression of amyloid deposits on serial SAP scintigraphy. Elevated serum concentrations at diagnosis of the cardiac biomarkers troponin and B-natiuretic peptide (BNP) or its more stable precursor, NT-proBNP, are associated with a poor outcome, as is the absence of any early fall in their concentrations following chemotherapy.[29]

Treatment of amyloidosis

Localized amyloid masses can only be treated surgically. The twin aims of management in systemic amyloidosis are reduction of the supply of amyloid fibril precursor proteins so that amyloid deposition diminishes and gradual regression of existing deposits may occur, and scrupulous general care, including dialysis and organ transplantation if necessary, to keep patients alive long enough for this to take effect. Awareness of the compromised functional reserve of amyloidotic organs and extreme care to protect renal function are critically important. Rational management has been greatly facilitated by the recent availability of routine assays for circulating SAA in AA amyloidosis, and serum free light chains in AL type, and outcomes are much better in centres with specialist expertise.

Treatment of AA amyloidosis

Treatment of the chronic inflammatory conditions responsible for AA amyloidosis, to reduce production of SAA, ideally to normal healthy baseline levels, dramatically improves survival and is associated with arrest of amyloid deposition and frequently regression of deposits (Figure 163.3). Plainly, treatment varies depending on the nature of the inflammatory disorder, but successful pharmacological approaches have ranged from non-specific immunosuppression in inflammatory arthritis using chlorambucil, to highly specific inhibition of IL-1 in patients with periodic fever syndromes.[9] Inflammatory arthritis underlies AA amyloidosis in two-thirds of cases, and biological agents targeting the key cytokine mediators of inflammation—TNFα, IL-1, and IL-6—potently
Fig. 163.3 Serial anterior I[123]-serum amyloid P (SAP) component scintigraphy demonstrating regression of hepatic and splenic AA amyloid deposits in a patient with rheumatoid arthritis, which remitted completely following treatment with oral chlorambucil. The scan on the left was obtained at presentation and the follow-up scan on the right was performed 2 years later.

suppress the acute-phase response in many patients with RA, JIA, and seronegative spondyloarthropathies. These drugs can also be effective in some patients with Crohn's disease. Regular prophylactic treatment with colchicine is highly effective in suppressing inflammatory disease activity in familial Mediterranean fever, in which it substantially prevents development and/or progression of AA amyloidosis.

Surgical treatments include excision of solitary cytokine-secreting Castleman's tumours and amputation of osteomyelitic limbs, and rarely excision of other inflammatory lesions.

A surprising finding among patients with AA amyloidosis is that of clinically covert inflammatory disease, which cannot be characterized, in about 7% of patients. Many such patients are presumed to have primary AL amyloidosis at presentation, emphasizing the need to perform confirmatory immunohistochemically in all cases. Anti-inflammatory treatment must be empiric in such cases but should be guided, as is the case in all patients with AA amyloidosis, by frequent SAA measurements.

Treatment of AL amyloidosis

The objective of treatment in AL amyloidosis is to suppress production of the amyloidogenic monoclonal light chains in the hope that progression of the disease will be slowed down, halted, or reversed (Figure 163.4). However, many patients have advanced multisystem disease at diagnosis and tolerate chemotherapy poorly. Quantitative measurements of serum free light chains using the robust, sensitive, Freelite immunoassay are usually the most effective means for evaluating the early effects of chemotherapy and the need for ongoing treatment.[8] Chemotherapy must be tailored to the individual patient, balancing the ideal for complete remission of the clonal disease with the need to minimize treatment toxicity and indeed

Fig. 163.4 Serial posterior I[123]-serum amyloid P component (SAP) scintigraphy demonstrating regression of splenic and renal AL amyloid deposits in a patient whose low-grade monoclonal gammopathy was suppressed by high-dose melphalan and stem cell rescue. The scan on the left was obtained at presentation in 1998 and the follow-up scan on the right was performed 3 years later.

treatment-related mortality. Certain organs affected by amyloid tend to fare better than others following treatment. Proteinuria and liver function often improve when the clonal disease is adequately suppressed, whereas cardiac disease, macroglossia, and peripheral nerve function tend to improve extremely slowly if at all.

Many different chemotherapy regimes are in current use, ranging from low-intensity oral melphalan and prednisolone through various intermediate dose drug combinations to high-dose chemotherapy with autologous peripheral stem cell rescue. The new agents bortezomib and lenalidomide, recently introduced for myeloma, are also showing great promise in AL. Some of the more commonly used regimes are reviewed briefly below.

Autologous peripheral blood stem cell transplantation (ASCT), also known as high-dose melphalan therapy, was first reported in AL amyloidosis in 1996, and several series have reported clinical benefit in up to 80% of patients who survived this arduous procedure. In the largest reported series, comprising 394 patients, complete clonal disease responses occurred in 41%, and median survival of such patients had not been reached after 10 years of follow-up.[30] However, treatment-related mortality associated with ASCT has been consistently problematic and substantially greater than in multiple myeloma, reflecting the compromised function of multiple organ systems by amyloid. Even just stem cell mobilization entails significant risks in patients with AL amyloidosis. Causes of death include cardiac arrhythmias, intractable hypotension, multiple organ failure, and gastrointestinal bleeding. Patient eligibility criteria for ASCT have been developed, favouring those without overt cardiac involvement, two or less vital organ systems clinically involved by amyloid, no history of gastrointestinal bleeding, and age less than 65 years, though despite this treatment-related mortality remains up to about 13% even in the most experienced centres. The role of ASCT in AL amyloidosis remains controversial and its apparently good outcome may reflect selection of fitter patients with good prognosis.[31] Only one randomized trial has been performed, in France using oral melpahalan and dexamethasone (Mel-Dex) as the comparator; no difference in response rates were demonstrated and treatment-related mortality (24%) was significantly higher within the ASCT arm.[32] This study was, however, relatively small.

Oral Mel-Dex has been used widely during the past 10 years, having been shown in open studies to be relatively well tolerated and associated with combined complete and partial clonal response rates of around 67% and median overall survival of about 5 years.[32] However, median time to haematological response is slow at over 4 months, and its potential for depleting bone marrow stem cell reserve is an issue in patients who may subsequently be considered for ASCT. Renal dose adjustment is required and long-term leukaemogenesis of this regimen has yet to be excluded.

Oral cyclophosphamide, thalidomide, and dexamethasone (CTD) has emerged as the most commonly used first-line treatment for AL amyloidosis in the United Kingdom.[33] Thalidomide has been used extensively in combination therapies for myeloma, but typical doses above 200 mg daily are poorly tolerated in AL amyloidosis, especially in patients with cardiac involvement or autonomic/peripheral neuropathy. However the CTD regimen comprising daily low-dose thalidomide, weekly oral cyclophosphamide, and intermittent pulses of dexamethasone, which can be risk-adapted utilizing still lower doses of thalidomide and dexamethasone in high-risk patients, is reasonably well tolerated and associated with a combined partial and complete clonal response rate of around
75%. Fatigue and fluid retention remain troublesome toxicities of this regimen. Patients with nephrotic syndrome are at particular risk of venous and arterial thrombosis, and should receive thromboprophylaxis. CTD has the advantages of being a stem-cell sparing oral regimen that does not require dose adjustment in renal impairment, and is more rapidly acting than Mel-Dex.

Bortezomib is a proteasome inhibitor developed for myeloma that is emerging as one of the most effective and rapidly acting therapies in the treatment of AL amyloidosis. Partial or complete clonal responses following bortezomib-based therapy were recently reported in 70% of 94 patients with relapsed or refractory haematological disease, including complete responses in 25%.[34] Furthermore, median time to clonal response was only 1 month and this subsequently translated into improved amyloidotic organ function in 30% of cases. Major toxicities included peripheral and autonomic neuropathy but, unlike myeloma cytopenias, were rare, most likely due to the smaller plasma cell burden in the bone marrow. Optimal dosing, long-term efficacy, and use of other agents in combination with bortezomib are being investigated.

Lenalidomide is a new thalidomide analogue that has lately also been investigated in several small studies in AL amyloidosis.[35] Maximum tolerated dose is typically about 15 mg daily. Efficacy is markedly improved when it is administered with dexamethasone, producing associated clonal response rates of about 67%, including complete responses in about 29%. Toxicity from infections, even without neutropenia, appears to be surprisingly high, especially in patients with severe renal or cardiac impairment. Time to haematological response is relatively slow, but lenalidomide remains an attractive treatment option in patients with severe neuropathy in whom thalidomide or bortezomib are relatively contraindicated. Use of lenalidomide in combination regimens and its potential as a maintenance therapy are currently being studied.

Melphalan and prednisolone given in oral cycles was the first treatment shown to have efficacy in AL amyloidosis,[36] but since responses are very slow and occur in only about 20% of cases this approach has generally been superseded. Other therapies that are occasionally used include intermediate dose intravenous melphalan (12.5–25 mg/m^2), principally in patients who cannot tolerate dexamethasone, and allogeneic bone marrow transplantation, which is associated with treatment-related mortality of 40% and for which there is little knowledge as yet regarding long-term benefit.[37]

Treatment of hereditary amyloidosis and organ transplantation

At present, other than transplantation to replace failed organs and in certain cases liver transplantation to remove the source of amyloidogenic proteins of hepatic origin, treatment of hereditary systemic amyloidosis is limited to managing symptoms. The liver is the source of plasma TTR and over 700 liver transplants have been performed for treatment of hereditary TTR amyloidosis since this 'surgical gene therapy' approach was introduced in 1991.[38] In younger patients carrying the common Met30Val amyloidogenic mutation the outcome is generally good, with arrest of neuropathy and regression of visceral amyloid, but vitreous amyloid may subsequently progresses, perhaps because some TTR is also produced within the eye. Cardiac amyloid may also progress, due to accumulation of wild-type TTR on the existing myocardial deposits. In some older Met30Val patients and in patients with other amyloidogenic TTR mutations, liver transplantation has failed to arrest either amyloid deposition or progression of clinical disease. The livers of patients with hereditary TTR amyloidosis contain only microscopic amyloid deposits in the blood vessels and interstitial tissues, and retain normal liver function. A large number of domino liver transplants have therefore been conducted in recipients with various terminal liver diseases for whom normal livers were not available.[39] This has certainly prolonged their lives, but the first such recipient has now developed symptomatic systemic TTR amyloidosis 8 years after transplantation.[40]

In an AFib patient who had received two consecutive renal transplants and then developed amyloidotic liver failure, combined liver and kidney transplantation was dramatically successful,[41] and several more AFib patients have now received liver transplants. These operations have demonstrated that the liver is the sole site of synthesis of plasma fibrinogen, but clinical outcomes in the long term following the combined transplant approach have not yet been shown to be superior than solitary renal transplantation. Patients with apolipoprotein AI amyloidosis can develop kidney, liver, and cardiac amyloidosis, and various organ transplants have been performed, with generally excellent results in this particular type of amyloidosis.[42]

Supportive treatment

Supportive therapies remain a critical component of management of amyloidosis. For cardiac amyloidosis, the mainstay of treatment is diuretics coupled with fluid restriction, daily weighing, and a low-salt diet, while vasodilating drugs and beta-blockers are generally best avoided.[43] Refractory oedema may respond well to the addition of spironolactone and intermittent doses of metolozone. Salt-poor albumin infusions can also occasionally be helpful. Dysrhythmias may respond to amiodarone or to pacing. In renal amyloidosis, rigorous control of hypertension is vital, and ACE inhibition and/or angiotensin II blockade is often recommended in the context of proteinuria. Renal dialysis may be necessary, and is usually both feasible and acceptably tolerated. In autonomic neuropathy, fludrocortisone 100–200 μg/day can be helpful in some patients, but may simply exacerbate fluid retention. Midodrine is an effective pressor agent, starting at a dose range of 2.5 mg building up to 15 mg thrice daily. Midodrine exerts its actions via activation of the alphaadrenergic receptors of the arteriolar and venous vasculature, producing an increase in vascular tone and elevation of blood pressure. Its chief adverse effect is supine hypertension, and other pressor agents must be coadministered with caution. Gastroparesis causing symptoms of early satiety and nausea can be managed with prokinetic agents such as metaclopramide, along with advice about small, frequent meals of soft consistency. Diarrhoea due to amyloid gut involvement or autonomic neuropathy may respond to loperamide and codeine phosphate. Malnutrition is not uncommon and is often underestimated. Significant weight loss should be treated with protein and vitamin supplementation and the patient should be reviewed by an experienced dietitian. Feeding via gastrostomy may occasionally be required. Amyloid and chemotherapy-related peripheral neuropathy can be disabling and difficult to treat. Analgesia including opioids and non-steroidal anti-inflammatory drugs (NSAIDs), amitriptyline, venlafaxime, anti-epileptics, TENS, and/or gabapentin/pregabalin have all been used, although anecdotal reports suggest limited efficacy. Withdrawal or dose-reduction

of any neurotoxic chemotherapies such as thalidomide or borte-zomib should be considered.

New treatments and future directions

Elucidation of aspects of the molecular pathogenesis of amyloid and amyloidosis has led to the development of various novel approaches to therapy. These include treatments developed to stabilize and maintain circulating amyloid precursor proteins in their normal confirmation, agents that inhibit the interaction between amyloid fibrils and glycosaminglycans, immunotherapy approaches, and depletion of SAP. All of these potential new therapies have entered clinical testing, offering real promise that specific anti-amyloid therapies may become available within the next few years.

CHAPTER 164

Autoinflammatory diseases

Helen J. Lachmann and Philip N. Hawkins

Introduction

The concept of autoinflammatory disease, i.e. chronic multisystem inflammatory disorders without evidence of cell-mediated or humoral autoimmunity, began with the molecular characterization of monogenic inherited periodic fever syndromes. The term autoinflammatory was coined in 1999 but the concept has evolved to encompass a variety of acquired disorders that are broadly thought to be due to disturbances in the innate immune system (Table 164.1). Features of autoinflammatory disorders include recurrent episodes of fever and generalized inflammation affecting the eyes, joints, skin, and serosa, but many systems may be involved, and the rigid distinction between autoinflammatory and autoimmune disorders has become less clear as progress has been made in characterizing their pathogenesis.[1] Elucidation of the molecular basis of the cyropyrin-associated periodic syndrome (CAPS) has transformed understanding of regulation and importance of interleukin (IL)-1 in autoinflammatory disease. It now seems clear from both basic research and clinical studies that disordered regulation of IL-1 and nuclear factor-κB (NFκB) underlie the pathogenesis of the autoinflammatory syndromes. Clinical outcomes in autoinflammatory diseases have been transformed by the availability of IL-1-blocking drugs, and there is increasing interest in the role of autoinflammatory mechanisms in various common acquired diseases. These include diabetes types 1 and 2 and ischaemic heart disease, which are major scourges of the developed world (and increasingly of the developing world), and trials of IL-1 blockade are under way in both.

This article focuses on the inherited periodic fever syndromes (Table 164.2), and periodic fever, aphthous stomatitis, pharyngitis, and adenitis (PFAPA) and Schnizler's syndrome.

Inherited periodic fever syndromes

Familial Mediterranean fever

Familial Mediterranean fever (FMF) is much the commonest of the inherited syndromes. It was first described in 1945 and the term 'familial Mediterranean fever' was introduced in 1958.

Genetics and pathophysiology

The gene associated with FMF, *MEFV*, encodes a protein called pyrin. *MEFV* is constitutively expressed in neutrophils, eosinophils, monocytes, dendritic cells, and synovial and peritoneal fibroblasts, and is upregulated in response to inflammatory activators such as interferon-γ and tumour necrosis factor alpha (TNFα); 5′- and 3′- sequences are known to contribute to regulation of gene expression and polymorphisms may play a role in susceptibly to FMF. More than 200 coding variants have been reported, and 90 in association with FMF. These encode either single amino acid substitutions or deletions (Infevers registry database http://fmf.igh.cnrs.fr/ISSAID/infevers/).[2] Disease-causing mutations are clustered in exon 10, in the SPRY domain of pyrin, but are also found in exons 1, 2, 3, 5, and 9. Mutations in both *MEFV* alleles can be found in 80% of patients with FMF, and although the vast majority of individuals with a single mutated allele remain healthy, up to 20% of FMF patients have a single identified mutation.[3] The methionine residue at position 694 appears critical for pyrin's function: three different mutations involving M694 have been identified; homozygosity for M694V is associated with a severe phenotype; and heterozygous deletion of this residue has been associated with autosomal dominant FMF. Two or more mutations on a single allele can also cause dominant FMF, although pseudo-dominant inheritance due to consanguinity or a high prevalence of carriers is much commoner.

One particular variant, E148Q encoded in exon 2, has an allele frequency of 10–20% in Asian populations, and up to 1–2% in

Table 164.1 Examples of acquired diseases with a presumed autoinflammatory component

SoJIA and adult-onset Still's disease	Recurrent pericarditis	Granulomatous diseases:
		Crohn's disease and ulcerative colitis
		Sarcoidosis
		Giant cell arteritis
		Takayasu's arteritis
Behçet's syndrome	Recurrent uveitis	Crystal deposition diseases
		Gout
		Pseudo-gout
		Atherosclerosis
Psoriasis	Schnitzler's syndrome	Diabetes types 1 and 2
	PFAPA	Asbestosis and mesothelioma

PFAPA, periodic fever, aphthous stomatitis, pharyngitis, and adenitis; SoJIA, systemic-onset juvenile inflammatory arthritis.

Table 164.2 The autoinflammatory conditions of known genetic aetiology

Periodic fever syndrome	Gene	Mode of inheritance	Typical age at onset	Potential precipitants of attacks	Distinctive clinical features	Characteristic laboratory abnormalities	Treatment
FMF	*MEFV* Chromosome 16	Autosomal recessive (dominant in rare families)	Childhood/ early adult	Usually none Occasionally menstruation, fasting, stress, trauma	Short severe attacks Colchicine responsive Erysipelas-like erythema	Marked acute-phase response during attacks	Colchicine
TRAPS	*TNFRSF1A* Chromosome 12	Autosomal dominant, can be de novo	Childhood	Usually none. Sometimes travel, stress, fasting, menstrual cycle	Prolonged symptoms	Marked acute-phase response during attacks. Low levels of soluble TNFR1 when well	Anakinra, etanercept, high-dose corticosteroids
MKD	*MVK* Chromosome 12	Autosomal recessive	Infancy	Immunizations	Diarrhoea and lymphadenopathy	Elevated IgD and IgA, acute-phase response, and MVA during attacks	Anti-TNF and anti-IL-1 therapies
CAPS	*NLRP3* Chromosome 1	Autosomal dominant	Infancy	Exposure to cold environment, or none	Cold-induced fever, arthralgia, rash, eye inflammation, sensorineural deafness and conjunctivitis, chronic aseptic meningitis, deforming arthropathy	Varying but marked acute-phase response most of the time	Anti-IL-1 therapies
NALP12 associated periodic syndrome	*NALP12* *Chromosome 19*	Autosomal dominant	Infancy	Cold exposure or known	Cold-induced fever, urticarial rash, arthralgia and sensorineural deafness	Acute-phase response during attacks	None speciific
DIRA	*IL1RN* *Chromosome 2*	Autosomal recessive	Infancy	None	Sterile multifocal osteomyelitis, periostitis, and pustulosis	Marked acute-phase response most of the time	Anti-IL-1 therapies
PAPA	*PSTPIP1 (CD2BP1)* Chromosome 15	Autosomal dominant	Childhood	None	Pyogenic arthritis, pyoderma gangrenosum, cystic acne	Acute-phase response during attacks	Anti-TNF therapy
Blau's syndrome	*NOD2 (CARD15)* Chromosome 16	Autosomal dominant	Childhood	None	Granulomatous polyarthritis, iritis, and dermatitis	Sustained modest acute-phase response	Corticosteroids, maybe biologicals
Majeed's syndrome	*LPIN2* *Chromosome 18*	Autosomal recessive	Neonatal	None	CRMO, dyserythropoietic anaemia, inflammatory dermatosis	Microcytic congenital dyserythropoietic anaemia	NSAIDS and corticosteroids
DITRA	*IL36RN* *Chromosome 2*	Autosomal recessive	Childhood to middle age	Sometimes stress, pregnancy, or drugs	Generalized sterile pustular rash and fever	Neutrophilia and raised acute-phase response	None specific
JMP and CANDLE syndromes	*PSMB8* *Chromosome 6*	Autosomal recessive	Neonatal to childhood	None	Erythematous rash, arthralgia/arthritis, joint contractures in JMP, progressive lipodystrophy	Raised acute-phase response, mixed myeloid, neutrophilic, and histiocytic infiltrate in affected skin	Partial response to IL-6 blockade has been reported

See text for abbreviations.

white Europeans. Although E148Q can cause FMF when an exon 10 mutation is also present, homozygosity for E148Q alone is not generally associated with FMF. There is however some evidence that carriers may have an augmented response to some types of non-FMF inflammation.[4]

The expression of *MEFV* is regulated in a very complex fashion at RNA and protein levels.[5] Neither the structure nor the function of pyrin has been fully characterized and its subcellular localization appears to vary according to cell type and isoform. The putative 781 amino acid protein has sequence homologies with proteins of apparently disparate function and cellular localization, and it appears to bind to several components of the inflammasome and modulate their activity. The pyrin SPRY domain appears to interact with NALP3, caspase-1m and its substrate pro-IL-1, and overexpression studies have shown inhibition of caspase 1 activation with reduced secretion of IL-1β.[6] Many of pyrin's interactions appear to involve its 100 amino acid N-terminal pyrin (PYD) death domain. The PYD domain occurs in more than 20 human proteins, including NLRP3 (the variant protein in CAPS), which all appear to be involved in the assembly and activation of apoptotic and inflammatory complexes through homotypic protein–protein interactions that regulate caspase 1 and thus modulate production of IL-1. Recent work suggests that pyrin may be cleaved by caspase 1 and that pyrin variants may serve as more efficient substrate than the wild-type protein.[7] The resulting N-terminal PYD cleavage fragments may be translocated to the nucleus where they could potentiate activation of NFκB through interaction with the adapter protein, apoptosis-associated speck-like protein with a caspase-recruitment domain (ASC) or with NFκB-p65.

Clinical features

FMF is commonest in Eastern Mediterranean populations but occurs worldwide. The prevalence of FMF is estimated to be 1/250 to 1/500 among Sephardic Jews and 1/1000 in the Turkish population. Carrier frequency exceeds 1 in 4 in some populations, prompting speculation that the FMF trait may have conferred survival benefit, possibly through enhanced resistance to microbial infection mediated via an upregulated innate immune response.[8] Sexes are affected equally and the disease usually presents in childhood.

Attacks of FMF occur irregularly and apparently spontaneously although some may be precipitated by minor physical or emotional stress, the menstrual cycle, or diet. Attacks evolve rapidly and symptoms resolve within 72 hours. Fever with serositis are the cardinal features, and diagnostic criteria for FMF have been validated in both adults and children.[9,10] Peritonitis that can mimic an acute surgical abdomen occurs in 85% of cases, and 40% of patients will have undergone surgery for a presumed acute surgical abdomen before diagnosis. Characteristically unilateral pleuritic chest pain occurs in 40%. Headache with meningitic features has been reported particularly in children, but the nervous system is not usually involved. Orchitis occurs in less than 5%, most commonly in early childhood. Joint involvement usually affects the lower limbs: arthralgia is common in acute attacks, usually subsiding within a couple of days; chronic destructive arthritis is rare. Erysipelas-like rash is seen in 20%, usually around the ankles. A degree of myalgia occurs with acute attacks, and up to 20% of patients complain of persistent calf muscle pain on exertion. Protracted febrile myalgia is a rare entity that presents with severe pain in the lower limbs or abdominal musculature, persisting for weeks, and can be accompanied by a vasculitic rash; it usually responds to corticosteroids.

Acute attacks are accompanied by a neutrophil leucocytosis, raised erythrocyte sedimentation rate (ESR), very high calcitonin levels, and an intense acute-phase response.[11] Investigations may be required to exclude other diagnoses, but imaging during attacks is usually unrewarding.

Diagnosis is supported by DNA analysis but remains clinical, centring on the history of recurrent self-limiting attacks of fever and serositis that respond to prophylactic treatment with colchicine. Genetic results must be interpreted cautiously, given that some individuals with paired pathogenic *MEFV* mutations never develop FMF, and others with heterozygous 'carrier' status can do so.

Treatment

Supportive measures, particularly analgesia, are required during acute attacks. The mainstay of management is long-term prophylactic treatment with low-dose colchicine. This was discovered serendipitously in 1972,[12] and has transformed the outlook of the disease. Continuous treatment with colchicine at a dose of 1–2 mg daily in adults prevents or substantially reduces symptoms of FMF in at least 95%, and almost completely eliminates the risk of AA amyloidosis.

Colchicine was recently licensed by the United States Food and Drug Administration for the treatment of FMF from the age of 4 years upwards. Long-term treatment is advisable in all patients with FMF and mandatory in those who have AA amyloidosis. Although colchicine is very toxic in acute overdose, low doses are generally very well tolerated. Diarrhoea is the commonest side effect and can often be avoided by gradual introduction of the drug. Despite theoretical concerns, there is no evidence that colchicine causes infertility or birth defects, and it can be taken safely during breastfeeding.[13] Introduction or dose escalation of colchicine during an acute FMF attack is not generally effective. Genuine resistance to colchicine is probably very rare and may be associated with polymorphisms of the drug transporter gene *ABCB1*.[14] There have lately been reports of long-term benefit from treatment with IL-1 inhibitors, and to a lesser extent etanercept in 'refractory' patients.[15,16]

Tumour necrosis factor receptor-associated periodic syndrome

Genetics and pathophysiology

Tumour necrosis factor receptor-associated periodic syndrome (TRAPS), an autosomal dominant disease, is associated with mutations in the 10-exon gene tumour necrosis factor receptor superfamily 1A (*TNFRSF1A*).[17] TNF is a key mediator of inflammation with actions including induction of pyrexia, leucocyte activation, induction of cytokine secretion, and expression of adhesion molecules. Tumour necrosis factor receptor 1 (TNFR1) is a member of the death domain superfamily and consists of an extracellular region containing four cysteine-rich domains, a transmembrane domain, and an intracellular death domain. Binding of circulating TNF results in trimerization of the receptor and induction of NFκB with increased production of proinflammatory cytokines and potentially apotosis via caspase 8, although activation of NFκB can also result in inhibition of apoptosis via cellular caspase 8-like inhibitory protein (cFLIP). The mechanism(s) by which heterozygous

TRFRSF1A mutations cause TRAPS remain unclear and probably differ between mutations.[18–20] Most TRAPS-associated mutations lie within exons 2–4 and about one-half are missense substitutions which disrupt structurally important cysteine–cysteine disulphide bonds in the extracellular domain. Under normal circumstances, TNF signalling is terminated by metalloproteinase-dependent cleavage of a proximal region of the extracellular domain. This also releases soluble TNFR1, which competes with cell-surface receptors in binding of circulating TNF. Cleavage of some TNFR1 variants is impaired, producing a 'shedding defect', but this is not the case in all TRAPS-causing mutations. It is thought that mutant misfolded receptors may give rise to enhanced or prolonged signalling, possibly through retention within the endoplasmic reticulum, resulting in mitochondrial stress and production of reactive oxygen species. Recent data suggest that cellular expression of mutant TNFR1 is itself an inflammatory signal, perhaps by activation of distinct intracellular signalling pathways with a proinflammatory outcome in a TNF-independent fashion.[21]

Clinical features

TRAPS was described in 1982 as familial Hibernian fever,[22] reflecting the Irish/Scottish ancestry of early patients, but the disease has subsequently been reported in many ethnic groups. The sexes are equally affected. Approximately 60% of patients report a family history of similar symptoms. Mean age at first symptoms is 7 years and the disease burden is high, with a median of 60 days of TRAPS-related illness per year.

Attacks in TRAPS are far less distinct than in FMF. Febrile episodes typically last more than 10 days and symptoms are near continuous in one-third of patients. The clinical picture varies: more than 95% experience fever and 90% have arthralgia or myalgia that typically follows a centripetal migratory path; abdominal pain occurs in 75%, and skin manifestations including migratory patches, erysepela-like erythema, oedematous plaques (often overlying areas of mylagic pain), urticaria, and discrete reticulate or serpiginous lesions occur in 60% of patients. Other features include headache, pleuritic pain, lymphadenopathy, periorbital oedema, and conjunctivitis. There are also reports of central nervous system (CNS) manifestations and imaging findings resembling multiple sclerosis.[23] Indeed the common polymorphism R92Q has been suggested as a susceptibility factor for multiple sclerosis.[24] Symptoms are almost universally accompanied by a marked acute-phase response, and genetic testing is central to diagnosis.

Two TNFRSF1A variants, P46L and R92Q, which may be associated with mild TRAPS,[25] are present in approximately 10% of healthy West Africans and 2% of healthy whites respectively. The vast majority of carriers of these variants are entirely well and the mechanisms by which they cause inflammatory disease in a minority remains obscure.

Treatment

Acute attacks respond to high-dose corticosteroids but in severe disease the cumulative doses required are considerable, necessitating addition of maintenance therapy. There is no evidence that conventional steroid-sparing immunosuppressant agents are of any benefit in TRAPS, and specific anti-cytokine agents are currently the only effective long-term treatment. Etanercept has been used for more than a decade and is effective in some patients, although responses are frequently partial and wane over time.[26] Paradoxically,

infliximab exacerbates disease and should be avoided.[27] Recent reports suggest that IL-1 blockade with anakinra is frequently extremely effective in TRAPS, and anti-IL-1 agents are now becoming the maintenance treatment of choice.[28]

Mevalonate kinase deficiency

Genetics and pathophysiology

Mevalonate kinase deficiency (MKD), also known as hyperimmunoglobulin D and periodic fever syndrome (HIDS), is an autosomal recessive disease caused by mutations in the mevalonate kinase (*MVK*) gene.[29] More than 100 mutations have been described, spanning the 11-exon gene, the commonest of which encode MVK variants V377I and I268T. MVK is the enzyme following HMG-CoA reductase in the pathway involved in cholesterol synthesis. This pathway is also responsible for farnasylation and geranylgerylation. Most HIDS-causing MVK mutations are missense variants that reduce enzyme activity by 90–99%.[30] Other mutations resulting in near complete absence of enzyme activity cause a much more severe disease, mevalonicaciduria (MVA), features of which include stillbirth, congenital malformations, psychomotor retardation, ataxia, myopathy, failure to thrive, and early death.

It is not yet known how MVK deficiency causes inflammation, though reduction in prenylation due to a relative deficiency of substrate for the geranylgeranyl pathway seems more likely to be responsible than accumulation of mevalonic acid. The relationship of the isoprenoid pathway to inflammation is of interest given the anti-inflammatory properties of drugs that are widely used to inhibit cholesterol synthesis. The RhoA and Rac1 GTPases require to be geranylgeranylated to function properly, and this has been demonstrated to be reduced both in MKD[31] and by HMG-CoA reductase inhibition with simvastatin. Various effects of statins on caspase-1 activation and IL-1 secretion have been postulated, and clinical studies have suggested conflicting results as a trial of simvastatin in six patients with MKD suggested minor benefit[32]; but two children with MVA were reported to have developed severe flares of inflammatory disease following statin treatment.[33]

Clinical features

MKD affects an estimated 200–600 individuals. It was described in the Netherlands in 1984 and the carriage rate of *MVK* V337I is 1 in 350 in the Dutch population,[34] but MKD has been reported in many other ethnic groups including Arabs and South-East Asians. The disease occurs equally in both sexes and usually presents in the first year of life.[35]

Attacks are irregular, typically lasting 4–7 days, and are characteristically provoked by vaccination, minor trauma, surgery, or stress, perhaps triggered by a reduction in MVK activity associated with increased body temperature. Attacks of MKD typically comprise fever, cervical lymphadenopathy, hepatomegaly and splenomegaly, and abdominal pain with vomiting and diarrhoea. Headache, eye inflammation causing conjunctivitis or keratitis, arthralgia, large-joint arthritis, erythematous macules and papules, and aphthous ulcers are also common. Retinitis pigmentosa has been reported, perhaps linked to the metabolic defect. MKD may partially ameliorate in adult life. Clinical criteria have recently been proposed to guide genetic testing.[36]

Diagnosis of MKD was thought to be supported by a high serum IgD concentration but this is non-specific, as it occurs in other fever syndromes, does not correlate with disease severity, and is not

universal.[37] More accessibly, serum IgA concentration is elevated in 80%. Attacks are accompanied by an acute-phase response, leucocytosis and the transient presence of mevalonic acid in the urine. A mutation in both alleles of the *MVK* gene can be identified in most patients.

Treatment

Treatment is largely supportive, including non-steroidal anti-inflammatory drugs (NSAIDs), although responses to etanercept[38] and anakinra are reported.

Cryopyrin-associated periodic syndrome

CAPS comprises an overlapping severity spectrum of three separately described diseases: familial cold autoinflammatory syndrome (FCAS); Muckle–Wells syndrome (MWS); and chronic infantile neurological, cutaneous and articular syndrome (CINCA), known in the United States as neonatal onset multisystem inflammatory disease (NOMID).

Genetics and pathophysiology

CAPS is an autosomal dominant disease associated with mutations in *NLRP3/CIAS1*, a gene that encodes the death domain protein known as cryopyrin or NLRP3.[39] Approximately three-quarters of patients with FCAS and MWS have a family history of similar symptoms. CINCA is usually due to de-novo mutation. More than 100, mostly missense, mutations have been reported; the majority are in exon 3 but there are also variants in exon 4 and 6 and in a number of introns.

NLRP3 is expressed in granulocytes, dendritic cells, B and T lymphocytes, epithelial cells of the oral and genital tracts, and chondrocytes. It encodes a member of the death domain superfamily that has a pyrin (PYD) domain, a nucleotide-binding site (NBS) domain, and a leucine-rich repeat (LRR) motif. It is thought that recognition via the LRR of a variety of danger signals, including intracellular pathogen-associated molecular patterns (PAMPs), crystals such as uric acid and cholesterol, and fibres such as asbestos, results in conformational change and association of NLRP3 with other death domain superfamily proteins to form a multimeric cytosolic protein complex, known collectively as the inflammasome.[40,41] This brings molecules of pro-caspase-1 into close proximity, leading to proteolytic activation and release of the active catalytic domains p20 and p10. Active caspase-1 cleaves pro-IL-1β into its biologically active 17 kDa fragment, and also upregulates NFκB expression thereby increasing IL-1 gene expression.

Clinical features

Most known patients are of European descent but cases have been described from South Asia and elsewhere. Onset of disease is usually in early infancy, often from birth, and there is no sex bias.

The term FCAS, for the mildest form of CAPS, was coined recently, but the disorder was first described in 1940 as recurrent episodes of cold-induced fever, arthralgia, inflamed eyes, and rash. In 1962 a British kindred with what became called MWS was reported with almost daily attacks of urticarial rash, inflamed eyes, arthralgia, and fever, complicated by progressive sensorineural deafness, and a high incidence of AA amyloidosis. At the most severe end of the spectrum is CINCA. This presents neonatally with multisystem involvement including the skin, skeletal system, and CNS. Bony overgrowth and premature ossification may occur particularly in the skull and knees; chronic aseptic meningitis results in

developmental retardation; blindness due to a combination of anterior chamber inflammation and optic atrophy and sensorineural deafness are common.

Clinical disease is accompanied by an acute-phase response, leucocytosis, thrombocytosis, and anaemia. When deafness occurs, it tends to progress in a stepwise fashion through childhood. Characteristic bony abnormalities may be evident radiologically. Anterior eye examination can show inflammatory changes ranging from conjunctivitis and acute anterior uveitis to keratitis and band keratopathy. Fundoscopy may show disc oedema, disc atrophy, and choroiditis. Brain MRI may show features consistent with chronic meningeal inflammation and elevated intracranial pressure. A mutation in *NLRP3* can be identified in almost all patients who can be characterized clinically as FCAS or MWS, but mutations are only found in about 50% of children with classical CINCA, in whom other genes may be implicated or there may be mosaicism.

Treatment

Inhibition of IL-1 produces rapid clinical and serological remission in CAPS. It is hoped that early anti-IL-1 therapy may prevent long-term complications, not only of AA amyloidosis in adults but potentially progressive neurological and physical disability in children. Daily injections of anakinra (recombinant receptor antagonist) have been reported to be effective in small case series, whereas two new longer-acting IL-1 inhibitors: canakinumab, a fully human anti-IL-1β antibody and rilonacept, an IL-1 Trap, have been tested in phase 3 trials, and are licensed for the treatment of CAPS with good safety to date.

NALP12-associated periodic fever syndrome

This autosomal dominant syndrome was described in 2008. Presentation is in infancy with features of cold induction, fever, arthralgia and myalgia, urticaria, and sensioneural deafness. The nonsense and splice site mutations identified in NALP12 appear to reduce the inhibitory effect of the protein on NFκB signalling.

Deficiency of the IL-1 receptor antagonist

Deficiency of the IL-1 receptor antagonist (DIRA) is an autosomal recessive disease described in 2009.[42] It is due to mutations in *IL1RN* that result in total deficiency of IL-1 receptor antagonist. The disease has been reported in a handful of families of various ethnic origins. The disease presents in the neonatal period with a pustular rash, joint swelling, multifocal osteitis of the ribs and long bones, heterotopic ossification, and periarticular soft tissue swelling.[43] Treatment is IL-1 blockade with anakinra.

Pyogenic sterile arthritis, pyoderma gangrenosum, and acne syndrome

Pyogenic sterile arthritis, pyoderma gangrenosum, and acne (PAPA) syndrome is an autosomal dominant disease caused by mutations in the proline serine threonine phosphatase-interacting protein 1 (*PTSTPIP*) gene that encodes a protein also known as CD2 binding protein 1 (CB2BP1). The underlying pathogenesis remains poorly understood although there is evidence that CD2BP1, an important component of cytoskeletal organization which interacts with actin, also interacts with pyrin and disease-associated mutations appear to potentiate this.[44] PAPA is characterized clinically by pyoderma gangrenosum, severe acne, and recurrent pustular sterile arthritis

typically precipitated by minor trauma. Responses to corticosteroids are disappointing and case reports suggest that therapy with infliximab or anakinra may be effective.

Blau's syndrome

This syndrome is an autosomal dominant disorder characterized by non-caseating granulomatous infiltration[45] presenting in early childhood with a triad of a tan-coloured erythematous rash, polyarticular synovitis often causing camtodactyly, and uveitis. It is associated with missense mutations in NOD2/CARD15. This member of the death domain superfamily has also been implicated in familial Crohn's disease.

Majeed's syndrome

This autosomal recessive syndrome characterized by chronic recurrent multifocal osteomyelitis (CRMO), congenital dyserythropoietic anaemia, and inflammatory dermatosis was described in 1989. Disease onset is usually in the neonatal period and attacks consist of fever, pain, and the appearance of periarticular soft tissue swelling. Long-term complications of growth retardation and flexion contractures are well recognized. It is due to mutations in *LPIN2*, a gene of unknown function.[46]

Generalized pustular psoriasis or deficiency of IL-36 receptor antagonist

Generalized pustular psoriasis (GPP) or deficiency of IL-36 receptor antagonist (DITRA) is characterized by recurrent episodes of a generalized sterile pustular rash accompanied by neutrophilia, a marked acute-phase response, and fever. Age at onset varies from childhood to the sixth decade. Episodes may be precipitated by stress, pregnancy, or drugs and can be life threatening. GPP was found to be a recessively inherited autoinflammatory disease in 2011 when separate groups reported that it was due to recessive mutations in *IL36RN* on chromosome 2.[47] This encodes a member of the IL-1 superfamily, IL-36 receptor antagonist, which blocks the recruitment of the IL-1RL2 receptor complex, thus inhibiting downstream activation NFκB and MAP kinases.

Joint contractures, muscle atrophy, microcytic anaemia, and panniculitis-induced lipodystrophy; chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature

Joint contractures, muscle atrophy, microcytic anaemia, and panniculitis-induced lipodystrophy (JMP syndrome) was first described in Japan in 1984 and subsequently in two white families. Affected patients are homozygous for the p.Thr75Met mutation in the proteasome subunit, β-type, 8 (*PSMB8*) gene.[48]

Chronic atypical neutrophilic dermatosis with lipodystrophy, and elevated temperature (CANDLE syndrome) seems to be a very similar disease characterized by a neonatal onset of intermittent fevers, erythematous rash with a mixed myeloid, neutrophilic, and histiocytic infiltrate, arthralgia/arthritis, and progressive lipodystrophy with raised inflammatory markers. Patients have also been found to carry *PSM8* mutations with evidence of dysregulation of the interferon signalling pathway.[49]

PSMB8 encodes a catalytic subunit of the 20S immunoproteasomes. These appear to be activated by interferon and are responsible for generation of antigenic epitopes presented by major histocompatibility complex (MHC) class I molecules as well as removing ubiquitinated intracellular proteins. It has been suggested that the mutations may disrupt antigen processing via reduced chymotrypsin-like proteasomal activity and/or increase intracellular stress and apotosis via accumulation of uubiquitin-rich cytoplasmic aggregates, although the mechanisms by which this causes the disease phenotype are unknown.

Autoinflammatory diseases of unknown aetiology

Periodic fever, aphthous stomatitis, pharyngitis, and adenitis

The diagnosis of PFAPA is suggested by the presence of a recurrent fever of early onset and at least one of: oral aphthous ulcers, cervical lymphadenopathy, or pharyngitis, in the absence of recurrent upper respiratory tract infections or cyclic neutropenia. Characteristically the children are entirely well between attacks. Median age at presentation is 2.5 years, and almost all present by their fifth birthday. The 'acronym' symptoms are frequently not all present during a single attack. In general the prognosis is good and most children will outgrow their symptoms within a decade.

A recent paper has shown that 16% of patients who fulfilled the diagnostic criteria for PFAPA in fact had an inherited periodic fever syndrome and another 18% carried a fever gene mutation or polymorphism.[50]

For many clinicians the strongest diagnostic pointers are the extreme regularity of attacks. Padeh et al. suggested that the dramatic response to a single oral dose of corticosteroids is sufficiently unique that it could be used as a diagnostic criterion.[51] Cimetidine and colchicine has been tried with variable reports of success. Tonsillectomy is the only treatment for which there is evidence from trials; more than 50% of children appear to have excellent long-term results. However, these data may be biased. Many centres selectively refer children with persistently enlarged tonsils for surgery, and it is possible that responses may occur preferentially in this subgroup.

Schnitzler's syndrome

This was described in 1974 and is characterized by a chronic urticarial rashes, a monoclonal immunoglobulin M (IgM) gammopathy, and systemic inflammation usually presenting as fever. The median age at onset is 51 years. There is a slight male preponderance and the majority of cases are of white European ethnicity.[52] The monoclonal protein appears central to the pathogenesis although the mechanism remains unclear, and is apparently unrelated to abundance of the paraprotein. About one-fifth of patients eventually progress to overt plasma cell malignancy. Chemotherapy does not appear to relieve the syndrome and should only be used for conventional haematological indications. The treatment of choice is IL-1 blockade, which completely abolishes symptoms although it has no effect on the paraprotein concentration.

Panniculitides

Cord Sunderkötter and Luis Requena

Introduction

Panniculitis is a skin disorder which can be associated with rheumatological diseases (e.g. systemic lupus erythematosus, dermatomyositis or rheumatoid arthritis) (Table 165.1) as well as with adverse events secondary to rheumatological therapies (e.g. post-steroid panniculitis, erythema nodosum, infective panniculitis). The different forms of panniculitis have varying incidences and prevalences: Erythema nodosum is the most frequent one, having an annual incidence of at least 52 per million.[1]

The term panniculitis denotes inflammation that originates primarily in the panniculus adiposus, i.e. in the subcutaneous fatty tissue. The panniculitides are primarily classified according to histopathological criteria.[2–4] The subcutaneous fat or panniculus is organized into lobules, which consist of lipocytes (adipocytes), separated by thin septa of connective tissue. The septa are mostly composed of collagen fibres and elastic tissue, and contain vessels and nerves. Each individual lobule is supplied by a central arteriole or small artery. There are no anastomoses between adjacent lobules so that disrupted blood flow or obstruction of the central arteriole causes necrosis of the adipocytes with ensuing inflammatory reaction.

The panniculitides are first classified according to the denser localization of the inflammatory infiltrate in the panniculus. In a mostly septal panniculitis the infiltrate involves primarily the septa with small veins and arteries, while in a mostly lobular panniculitis it is mostly found in the lobules.[2] However, this is not a 'black and white' distinction, as an inflammatory infiltrate involves both the septa and lobules to some extent.

The second differentiation concerns the absence or presence of vasculitis (Box 165.1).[5–7] Polyarteritis nodosa (PAN) presents as septal panniculitis with vasculitis of the small arteries or arterioles within the septa while erythema nodosum is a septal panniculitis without vasculitis.[3,4] Additional criteria for classification involve the composition of the inflammatory infiltrate, the cause, and an underlying or associated disease (e.g. infections, lupus erythematosus).

Panniculitis generally results from an immunological or inflammatory response in the subcutis to different triggers, such as autoimmune diseases, foreign bodies, trauma, or infections.

The clinical hallmark of panniculitis is a subcutaneous nodule (a mass with a thickness of at least 1 cm), often, but not always located on the lower limb. The nodules are usually not sharply defined due to their location in the deep skin (explanation: the deeper an

(Immune complex) vasculitis	Septal panniculitis with leukocytoclastic vasculitis

infiltrate is localized in the skin, the less well defined it appears on inspection or palpation, similar to an unknown object under a thick instead of a thin mattress). For clinical diagnosis the following qualities are helpful:

- **Colour**: the nodules usually take a red-violaceous hue. A bright erythema from dilated superficial vessels is a sign of early or acute panniculitis (e.g. in erythema nodosum); brown colour indicates deposition of haemosiderin engulfed by macrophages and is a sign of a non-acute lesion.

- **Consistency**: fluctuancy indicates fluid or pus (e.g. in infective or pancreatic panniculitis), calcification is seen in the panniculitis of dermatomyositis.

Box 165.1 Classification of panniculitides

Mostly septal panniculitides

With vasculitis

◆ Medium-sized vessels: (cutaneous and classical) polyarteritis nodosa

Without vasculitis

◆ Erythema nodosum
◆ Rheumatoid nodule
◆ Subcutaneous granuloma annulare
◆ Necrobiotic xanthogranuloma
◆ Necrobiosis lipoidica
◆ Deep morphoea

Mostly lobular panniculitides

With vasculitis

◆ Small vesssels in lobuli of panniculus: nodular vasculitis (erythema induratum of Bazin)
◆ Small vesssels in dermis and panniculus: erythema nodosum leprosum

Without vasculitis

• Calciphylaxis (with vascular calcification)
• Lupus panniculitis
• Panniculitis in dermatomyositis
• Cold panniculitis
• Pancreatic panniculitis
• α_1-Antitrypsin deficiency panniculitis
• Infective panniculitis
◆ Factitial panniculitis
◆ Traumatic panniculitis
◆ Subcutaneous sarcoidosis
◆ Poststeroid panniculitis
◆ Subcutaneous fat necrosis of the newborn
◆ Sclerema neonatorum
◆ Sclerosing panniculitis

Shortened version of the table by Requena and Yus.[3]

◆ **Location**: the involvement of areas other than lower legs is indicative for certain forms of panniculitis, e.g. in lupus panniculitis or cold-induced panniculitis.

◆ **Lipoatrophy**: deep, atrophy-forming gullies are a result of a preceding inflammation in the panniculus and when localized in the face or upper trunk they are characteristic for lupus panniculitis.

◆ **Scar**: indicative of previous ulceration.

◆ **Ulceration**: ulcers are a major secondary feature as they are indicators for panniculitides associated with vasculitis and subsequent ischaemic necrosis. They are also due to:

• vasculopathy such as the calcified vessels found in calciphylaxis or arteriosclerotic vessels in necrobiosis lipoidica
• caseous necrosis associated with *Mycobacterium tuberculosis*
• trauma of exposed, pre-damaged tissue (e.g. in necrobiosis lipodica).

Once the clinical findings indicate a panniculitis, an appropriate biopsy is mandatory in most cases for exact determination of the type of panniculitis and for differential diagnosis. The biopsy must meet certain requirements for adequate histopathological analysis. It should:

◆ be taken from an early lesion, i.e. rather from brightly red than from brownish parts of nodules, and not from necrotic or ulcerated tissue

◆ include the subcutis.

Therefore an excisional biopsy should be performed down to the fascia. The sample should be sent to a pathologist or dermatopathologist with sufficient experience in panniculitis to avoid a laconic diagnosis of merely lobular, septal, or mixed panniculitis, which will not be of much diagnostic help given the often sparse and monotonous clinical criteria.

There are no clinical studies, guidelines, or National Institute for Health and Clinical Excellence (NICE) guidances for the panniculitides. When no underlying condition or cause can be identified, anti-inflammatory therapies often ameliorate panniculitides.

Mostly septal panniculitis, not associated with vasculitis

Erythema nodosum

Erythema nodosum (EN) is the most common form of panniculitis and a typical example of septal panniculitis. The incidence is highest between 20 and 30 years of age[8] and there is a female: male ratio of approximately 3–6: 1. EN is a cutaneous process in response to many different provoking factors. The aetiopathogenesis includes disturbed regulation of neutrophils with increased levels of reactive oxygen intermediates. In sarcoidosis, EN is associated with a nucleotide exchange (G→A) at position 308 of the gene promoter for tumour necrosis factor alpha (TNF).[9]

The number of triggers is large (Box 165.1).[10] The most common trigger in children is an infection of the upper respiratory tract with haemolytic *Streptococcus pyogenes*[8]; in adults it is sarcoidosis. The triad of EN, bilateral hilar adenopathy, and arthralgias with fever is an early manifestation of sarcoidosis (Löfgren's syndrome), but is also encountered in tuberculosis and infections with streptococci or *Coccidioides immitis*. In contrast, Behçet's disease, though sometimes described to be associated with EN, rather appears to be more often accompanied by EN-like lesions of a mostly lobular panniculitis with leucocytoclastic vasculitis.[11]

EN presents with a sudden symmetrical appearance of painful, tender, warm, erythematous nodes or plaques, usually on the shins (Figure 165.1). In children EN may present unilaterally on the palms and soles. The lesions show dynamic evolution from bright red to livid-red to purplish within a few days, then assume a characteristic

Fig. 165.1 Non-ulcerating nodes of erythema nodosum on the shins.

bruise-like appearance. They never ulcerate, but heal after about 2 weeks without scarring. New crops of lesions may arise for 3–8 weeks. Acute attacks of EN may be accompanied or preceded by fever, malaise, fatigue, headache, arthralgia, or gastrointestinal disturbances and even episcleral lesions. Clinical variants described under the name of erythema nodosum migrans and subacute nodular migratory panniculitis belong histopathologically to the spectrum of EN.

A biopsy is recommended when the differential diagnosis is not clear. The histopathological hallmark is the presence of Miescher's radial granulomas (small, well-defined nodular aggregations of small macrophages or other myeloid cells (immature neutrophils) around a central stellate or banana-shaped cleft) (Figure 165.2). The diagnostic procedure to search for triggers should include history, laboratory tests (complete white blood count, urine analysis, anti-streptolysin titres (optimally repeated after a 2 week interval to detect a rise of at least 30%), chest radiograph (to check for e.g. Löfgren's syndrome, *Chlamydia pneumoniae*, and in endemic areas for coccidioidomycosis or histoplasmosis) (Box 165.2). An intradermal tuberculin test or interferon (IFN) release assay is performed when tuberculosis cannot be ruled out.
Although usually EN regresses spontaneously within 2 months it may be painful and may reappear, warranting symptomatic therapy. This should be aimed at the causative agent or the underlying condition, if identified and treatable. The highest level of published evidence (e.g. uncontrolled study with 28 patients) is for potassium iodide.[12] If short bed rest is not sufficient, non-steroidal anti-inflammatory drugs (NSAIDs; aspirin, indomethacin, or naproxen) provide pain relief and even resolution. If the lesions persist longer, potassium iodide (3 × 150–300 mg daily) often improves symptoms after 2 weeks (saturated solution, preferably in orange juice or other soft drink to make it more palatable).[13] The mechanism of action of this therapy may include inhibition of neutrophil chemotaxis and reactive oxygen release.[13] Colchicine is helpful especially in presence of Behçet's disease, hydroxychloroquine in presence of lupus erythematosus (LE). Systemic corticosteroids are rarely indicated.

Rheumatoid nodule

The firm, usually asymptomatic subcutaneous nodules with a predilection for the elbows and fingers (size from a few millimeters to 3-4 cm) often indicate a more aggressive course of RA. Rarely, they also appear in systemic lupus erythematosus. Surgically excision is only indicated in case of ulceration or pain.

Subcutaneous variants of dermal disorders presenting as panniculitis

There are inflammatory disorders which (1) originate in the dermis, but frequently extend into the subcutis or (2) feature an exclusively subcutaneous form (panniculitis). None of them has a tight correlation to rheumatological disease, but they need to be considered in order to establish a differential diagnosis.

Profound (linear) morphoea

This variant of morphoea is completely situated in the subcutaneous fat. It leaves a linear depressed subcutaneous atrophy, sometimes accompanied by hyper- or hypopigmentation. It is not a subtype of systemic sclerosis and so does not present with sclerodactyly or vasculopathy.

Fig. 165.2 Histology of erythema nodosum, showing an inflammatory infiltrate mostly in the septae of the subcutaneous tissue (pannus) (leading to a mostly septal panniculitis). The small insert depicts so-called Miescher's radial granulomas, i.e. small, well-defined nodular aggregations of small macrophages around a central stellate or banana-shaped cleft.

1. Infections

◆ Bacterial infections: haemolytic streptococci, atypical and typical mycobacteria, *campylobacter*, chlamydia, *Mycoplasma pneumoniae*, shigella, yersinia

◆ Viral infections: Herpesviridae, hepatitis B and C, HIV

◆ Fungal infections: coccidioidmycosis and other systemic fungi

◆ Protozoal infections: amoebiasis, toxoplasmosis

2. Drugs

◆ Sulfonamides and many others

3. Malignant diseases

4. Miscellaneous conditions

◆ Sarcoidosis, adult Still's disease, ankylosing spondylitis, antiphospolipid antibody syndrome, Behçet's disease, granulomatosis with polyangiitis, IgA nephropathy, lupus erythematous, pregnancy, recurrent polychondritis, rheumatoid arthritis, Sjögren's syndrome, Sweet's syndrome, Takayasu's arteritis, ulcerative colitis (more often than Crohn's disease; occurrence of EN often signals a flare of the disease)

Shortened version of the table by Requena and Yus.[10]

Eosinophilic fasciitis (Shulman's syndrome)

Another variant of morphea, characterized by rapid onset of symmetric woody induration of the limbs and, less frequently, the trunk. The sclerotic process gives the connective tissue a homogeneously eosinophilic appearance. It may follow vigorous exercise or intake of simvastatin. Prednisone often is efficacious (40–60 mg daily until response, then tapering over the next months).[14] Without treatment complete recovery may take several years.

Subcutaneous granuloma annulare

Subcutaneous granuloma annulare presents with skin-coloured, rarely faintly violaceous subcutaneous nodules on shins, buttocks, hands and head with no visible inflammatory changes on the skin surface. It occurs more frequently in children.

Painful or cosmetically disturbing lesions may warrant treatment by cryotherapy, excision, intralesional injection or topical, occlusive application of corticosteroids.

It belongs to a spectrum of granulomatous diseases which are probably an immune-mediated reaction to a number of underlying, mostly rheumatological conditions and which encompass rheumatoid papules or interstitial granulomatous dermatitis with arthritis (includes palisaded neutrophilic dermatitis).

Necrobiosis lipoidica

This plaque-like panniculitis is often, but not exclusively found in patients with diabetes mellitus. The yellow-brown, firm plaques are usually located bilaterally on the shins. They show a slightly depressed atrophic centre, transparent for partially teleangiectatic vessels, and surrounded by a sharply defined, elevated erythematous margin. They enlarge gradually and may ulcerate, while resolution is rare. Progression may be halted by intralesional injection or by occlusive dressings with glucocorticoids.

Necrobiotic xanthogranuloma

This is rare and occurs in patients with IgG paraproteinemia, multiple myeloma, or other lymphoproliferative disorders. Clinical characteristics are several large, sharply demarcated, indurated plaques of yellow-orange to red-violaceous hue with telangiectasia and with a tendency to ulcerate spontaneously. Its predilection for the periorbital area makes the chronic progressive disease a cosmetic problem. It only rarely responds to treatments.

Mostly septal panniculitis, associated with vasculitis

Classical and cutaneous polyarteriitis nodosa (cutaneous arteritis)

PAN is a classic example of a vasculitis of medium-sized vessels (arterioles) and septal panniculitis.

Cutaneous PAN is a variant which is probably more common than classical PAN (referred to as cutaneous arteritis by the revised nomenclature of the Chapel Hill Consensus Conference).[6] The subcutaneous nodules in PAN are surrounded by livedo racemosa (often sparse) and some of them ulcerate due to stenotic occlusion of vessels. The livedo intermingles with postinflammatory hyperpigmentation to form the so-called 'starburst pattern'. Cutaneous PAN may be accompanied by elevated sedimentation rate, slight fever, arthralgia or myalgia, or even mononeuritis multiplex, but these symptoms remain restricted to the affected skin area (often the leg) and are not associated with involvement of systemic organs. It is sometimes associated with streptococcal infections or viral hepatitis.

Panniculitis with leucocytoclastic vasculitis

Leucocytoclastic vasculitis is a descriptive term for vasculitis of the small vessels referring to the degradation of neutrophils (leucocytoclasia, nuclear dust) which is always observed when there is a high number of neutrophils. Its most common occurrence is in vasculitis caused by immune complexes which usually affects postcapillary venules in the superficial dermis. In rare cases leucocytoclastic vasculitis is observed around postcapillary venules of the septa (leading to mostly septal panniculitis with vasculitis). It shows subcutaneous erythematous nodules due to a deeper infiltrate accompanied by extravasation of blood, but usually no ulceration.

Mostly lobular panniculitis not associated with vasculitis

Lupus panniculitis

Lupus panniculitis is a clinical variant of LE and synonymous with LE profundus. It presents as a recurrent panniculitis and may also be encountered in rheumatoid arthritis or Sjögren's syndrome.

About 1–3% of cutaneous LE cases present with lupus panniculitis. The female/male ratios vary from 2:1 to 9:1 (reviewed in Fraga and Garcia-Diez[15]).

The pathophysiological pathways are probably similar to those in other forms of cutaneous LE, but they do not include high UV sensitivity.

The nodules and/or plaques arise deep in the subcutaneous tissue. The overlying skin may be normal, but can also be affected by discoid lupus. Unlike most other forms of adult panniculitis, the lesions have a predilection for the face, shoulders, upper arms, and buttocks. In rare cases subcutaneous tissue is affected in the breast ('lupus mastitis', clinically and radiologically difficult to distinguish from breast cancer), the orbital (frequent in black South Africans), or the preauricular region.

Resolution of the nodules typically results in lipoatrophy (Figure 165.3). The ensuing depression of lesions on shoulders and upper arms are a hallmark of lupus panniculitis which allow diagnosis even without other cutaneous manifestations of LE.

Lupus panniculitis may be the only clinical manifestation of LE or appear before or after onset of discoid or systemic LE.[15]

However, patients with LE and lupus panniculitis usually have a mild disease course.[4] There may be an association with ensuing or simultaneous occurrence of subcutaneous panniculitis-like T-cell lymphoma. In contrast to lupus panniculitis it usually neither appears on the face nor resolves with lipatrophy.[16]

Local occlusive dressings with potent corticosteroids are helpful when applied early.

Treatment of first choice is hydroxychloroquine. Thalidomide is also effective, but potentially toxic.

Panniculitis in dermatomyositis

Panniculitis is less frequent in dermatomyositis than in LE,[17] but may occur subclinically with only histologically visible evidence.

Fig. 165.3 Lipoatrophy in lupus panniculitis.

Fig. 165.4 Panniculitis in dermatomyositis.

As in lupus it may occur with or without the other cutaneous manifestations of dermatomyositis. It presents as an erythematous, tender nodule which often calcifies. It may be located on the thighs (Figure 165.4), arms, buttocks, and abdomen, and it may occur in juvenile dermatomyositis. It is responsive to the same systemic treatment as dermatomyositis, in particular to (high-dose) glucocorticoids with the accompanying use of steroid-sparing agents.

Cold panniculitis

Cold panniculitis is a form of panniculitis physically induced by cold exposure. There are two forms: (1) an apparently common response to cold exposure in infants and many children, induced on their cheeks or chins after prolonged cold exposure; (2) a response to cold exposure on the thighs and buttocks of (usually obese) young females wearing tight-fitting trousers, during riding or cycling.

Fat tissue in infants has a higher saturated fatty acid content, which gives it a higher solidification point and probably higher vulnerability to cooling. Cheeks and chins are areas in infants which are rich in subcutaneous fat and easily exposed to cold. In the adult form, tight clothing is supposed to obstruct blood supply and thermoregulation in areas rich in subcutaneous fat.

Clinical diagnosis is made by the appearance of indurated erythematous plaques or nodes with ill-defined margins 2–3 days after cold exposure (which may include sucking ice creams). Exposure to cold should be limited. Affected adults should wear protective and loose trousers.

Pancreatic panniculitis

This fairly characteristic form of panniculitis has been associated with primary or secondary pancreatitis, the latter due to e.g. carcinoma of pancreas (acinar cell carcinoma type), pseudocysts, or anatomical malformations (vasculopancreatic fistulas). It may be the presenting symptom of pancreatitis. The aetiology is unclear. Release of pancreatic lipase into the blood and its accumulation in the pannus may be the actual explanation.

Clinically, the erythematous subcutaneous nodules often ulcerate spontaneously and release an oily brown material, which results from liquefaction necrosis of adipocytes (Figure 165.5). The distal parts of the lower extremities, around the ankles and knees, are areas of predilection. It can be accompanied with panniculitis in periarticular fat tissue, manifesting as arthritis. In immunosuppressed

Fig. 165.5 Nodular vasculitis on the back of the lower legs with ulcerated nodes.

Fig. 165.6 Infective panniculitis by haematogeneous spread.

patients mucormycosis may cause panniculitis with similar histopathological features.[18] Pancreatic panniculitis improves with successful therapy of the underlying pancreatic disease.

α_1-Antitrypsin deficiency panniculitis

Patients with hereditary, homozygous α_1-antitrypsin or α_1-protease inhibitor deficiency develop emphysema, hepatitis, liver cirrhosis, vasculitis, angioedema, and panniculitis.

α_1-Antitrypsin is a serine protease inhibitor that inhibits activity of several proteases, most prominently of trypsin, but also of chymotrypsin, neutrophilic and pancreatic elastase, serine proteases, collagenase, thrombin, plasmin, factor VIII, and kallikrein. Consequently this deficiency results in disorders of innate immune response, blood coagulation, and fibrinolysis, and generally in abnormal activation of proenzymes and peptide hormones.

The subcutaneous nodules are mostly located in the skin of the lower abdomen and around the buttocks. They tend to ulcerate and to release an oily material from necrotic fat lobules similar to pancreatic panniculitis.

Trauma and surgical debridement are precipitating factors and should be avoided. Dapsone is an effective treatment when panniculitis has developed. In severe forms of the disease (severe emphysema and liver failure), protease inhibitor concentrate should be supplemented.

Infective panniculitis

Soft tissue infection commonly involves the subcutaneous tissue and would therefore present as a form of panniculitis. This type of infective panniculitis occurs as a consequence of primary or direct inoculation of bacteria or certain fungi[19] due to trauma or also indwelling catheters. It therefore often begins in or involves the dermis.

A second type of infective panniculitis results from haematogenous dissemination of infectious microorganisms (mostly certain bacteria or fungi[19]; Figure 165.6) and presents as a panniculitis in the strict sense, both histologically (usually as lobular panniculitis, without relevant involvement of the dermis) and clinically with several nodules or subcutaneous abscesses on the legs or on the gluteal area, abdominal or thoracic wall, arms, or fingers. Fluctuation is present, but may not be palpable when the abscesses are deeply located.

Haematogenous dissemination is seen particularly, but not exclusively, in immunocompromised hosts. This includes patients treated

for rheumatological diseases, while rheumatological diseases also tend to develop their own forms of panniculitis (e.g. lupus panniculitis). Therefore it is important to always take infective panniculitis into consideration in differential diagnosis of patients with rheumatic disease and panniculitis.

When in doubt, especially in presence of immunosuppression or signs of infection, a biopsy should be performed for both histology and for microbiological culture and/or detection of microbial nucleic acids. In immunocompromised patients infectious microorganisms are numerous in the tissue, thus facilitating diagnosis. Likewise, the presence of neutrophils in a lobular panniculitis should always prompt cultures of the biopsy specimen. Panniculitis due to hematogenous spread is more deeply seated than local infection, and the blood vessels are thrombosed and filled with infective organisms. Bacteraemia may in addition cause small-vessel vasculitis due to non-physiological local activation of endothelial cells and transmigrating neutrophils[20] (especially in infections with lipopolysaccharide-containing Gram-negative bacteria).

Therapy always encompasses systemic administration of antibiotics or antifungals.

Incision and drainage may be indicated depending on the extent of infection; early mycobacterial lesions (Buruli ulcer) can be excised.

Poststeroid panniculitis

Poststeroid panniculitis is a rare form which occurs in children in whom high doses of systemic corticosteroids were discontinued or decreased quickly. It is to be distinguished from glucocorticoid-induced lipoatrophy.

Clinically, erythematous subcutaneous nodules appear 1–10 days after discontinuation of high doses of gluocortiocids in those areas where the preceding glucocorticoid therapy has led to the highest accumulation of fat (e.g. cheeks). Its histopathology is indistinguishable from the subcutaneous fat necrosis of the newborn, showing necrotic adipocytes and histiocytes containing crystallized lipids.

Poststeroid panniculitis resolves after some weeks without residual lesion unless it has caused ulceration, which then leaves atrophic scars on the cheeks. Resuming high-dose systemic corticosteroid and moderate tapering is helpful.

Factitial panniculitis

Factitial or artifactual panniculitis is a response to mechanical, physical, or chemical injuries to the subcutaneous tissue. The injuries may be inflicted on purpose or by accident, or be iatrogenic. Iatrogenic injury is due to subcutaneous implantation of different materials for cosmetic or therapeutic reasons (e.g. paraffin, silicone, or polymethylsiloxane for augmentation of breasts or genitalia, or for correcting facial wrinkles)[21] or due to subcutaneously injected drugs (e.g. gold salts, pethidine (in the US meperidine), povidone iodine, vaccines), or due to extravasation of cytotoxic drugs such as antracyclines or taxanes.

In case of psychiatric disorders with personality aberrations some patients inject themselves with harmful substances such as acids, alkalis, mustard, milk, microbiologically contaminated material, urine, and faeces.

Oily materials (paraffin, vegetable oils, impurities e.g. in liquid silicone) cause a foreign body reaction in the subcutis, in some cases with a time lag of up to 30 years. In addition, immunological reactions and ischaemia by local drug-induced vasoconstriction may play a pathogenic role.

Self-induced panniculitis is usually localized in areas accessible to manipulation and often looks bizarre, without similarities to defined dermatoses. It is inherent to the disorder that patients may appear otherwise psychologically inconspicuous and are often not consciously aware of their manipulations, so that attempts to enforce the diagnosis are futile. However, occlusion of affected areas by bandages and ensuing lack of new lesions may help the physician's diagnosis.

A biopsy is recommended, as histopathology may provide hints for the cause, such as refractile foreign material seen on polarizing light microscopy.[22]

Patients with self-inflicted factitial panniculitis need psychiatric treatment. Materials implanted for cosmetic reasons should be removed and the reaction treated with glucocorticoids.

Traumatic panniculitis

Traumatic panniculitis may be considered a special form of facticial panniculitis, caused by accidental blunt trauma.

Calciphylaxis

Calciphylaxis is a disease in which calcification of the walls of cutaneous vessels results in livedo racemosa and often in large painful necrosis and ulceration. It is often, but not exclusively, associated with chronic renal failure. It occurs in about 4% of patients undergoing haemodialysis. The course in patients with calciphylaxis and renal failure show a high mortality of about 80% due to infection and sepsis.

There are two forms: (a) uraemic or renal calciphylaxis in patients with endstage renal failure undergoing haemodialysis or having received kidney transplantation; (2) non-renal form in patients without significant renal failure.

Both forms have features in common: (1) calcification of cutaneous small and medium-sized blood vessels (often arterioles, as seen in long-standing lesions of atherosclerosis) in the panniculus and parts of the dermis, (2) intimal hyperplasia with fibrosis, (3) intraluminal thrombi, and (4) mostly lobular panniculitis with necrosis and sometimes lobular calcifications.

Calciphylaxis should be distinguished from an entity called benign nodular calcification in which the course correlates more strongly with abnormalities of calcium–phosphorus metabolism.

Predispositions in non-renal calciphylaxis are primary hyperparathyroidism, collagen vascular diseases, malignant tumours, or hepatic cirrhosis. In the renal form they are hypercalcaemia, hyperphosphataemia, or hyperparathyroidism. Additional factors may be local trauma, arterial hypertension, posthemodialysis metabolic alkalosis, or intake of inorganic metal salts. Aetiopathogenesis involves a disturbed balance between procalcifying (calcium, phosphate, parathyroid hormone) and anticalcifying factors (fetuin A, pyrophosphate, matrix-Gla-protein). Reductions of the latter are caused e.g. by prolonged intake of vitamin K antagonists.[23–25]

There are two forms of independent aetiology : (1) ulcerating calciphylaxis, often located on areas rich in fat tissue such as trunk, buttocks, proximal thighs, more rarely on lower legs; the respective large, deep, non-healing ulcers are painful due to ischaemia; (2) non-ulcerating calciphylaxis is often located on distal legs and sometimes distal arms; it is often associated with violaceous, sometimes patchy or reticulated, livedo reticularis.

A biopsy confirms the diagnosis, but is only indicated when in doubt, as it can trigger an additional ulcer.

For therapy, the standard procedure is normalization of calcium and phosphorus serum levels by cinacalcet[9] (which is preferable to an irreversible parathyroidectomy), chelating agents (sodium thiosulfate often provides pain relief within 3 weeks and stimulates wound healing) and discontinuation of vitamin K antagonists or their replacement by heparin. A diet poor in calcium and phosphorus, and low-calcium haemodialysis, can also be helpful.

Sclerosing panniculitis (lipodermatosclerosis, hypodermitis sclerodermiformis)

This is a synonym and more appropriate term[26] for a complication of chronic venous insufficiency which, despite its common occurrence, causes diagnostic confusion. Most on the lower calf present as an indurated plaque with oedema, either with hyperpigmentation in the chronic forms or with bright erythema in the acute form (often confused with erysipelas). Often a marked reduction of the circumference of the distal lower leg occurs (like an inverted bottle), resulting from extensive deep sclerosis and ensuing atrophy of the subcutaneous fat.

Mostly lobular panniculitis associated with nodular (nodose) vasculitis (erythema induratum Bazin)

Nodular vasculitis is a lobular panniculitis with a primary vasculitis involving mostly the small blood vessels of the fat lobule (postcapillary venules) and only rarely small or medium sized vessels in the septae.[27] Vasculitis may not be visible in all histological sections, so that several sections need to be analysed, but it appears to be the primary event of this disease, as it is observed in biopsy sections of early lesions.[27]. In presence of tuberculosis (usually with hyperergic reaction) it has been referred to as erythema induratum Bazin.

Nodular vasculitis (like EN) appears to present a (hyper)reactive response to tuberculosis or other microbial antigens such as streptococci, candida, or *M. leprae*.[28] Exposure to cold and chronic venous insufficiency may provide additional or even the only eliciting factors.

Tender erythematous subcutaneous plaques and nodules arise on the posterior aspect of the calf. It occurs mostly in middle-aged women with lipoedema (column-like lower legs), livedo reticularis, or erythrocyanosis surrounding follicular pores. In the course of the disease most, but not all, nodules ulcerate. Healing is slow and leaves atrophic scars.

In cases where association with *M. tuberculosis* is suspected, INF-γ release assays are helpful for diagnosis and monitoring treatment.[29] Compression and NSAIDs or potassium iodide may alleviate symptoms when no cause can be detected or treated.[28,30]

Conclusion

The term panniculitis denotes an inflammation that originates primarily in the subcutaneous fatty tissue. It is characterized histopathologically according to the major or denser localization of the infiltrate as mostly septal panniculitis and mostly lobular panniculitis, and in those with and without vasculitis. The clinical hallmarks of panniculitis are subcutaneous nodules or plaques, often located on the lower limb. EN is the most common form of panniculitis and a typical example for septal panniculitis. It has multiple aetiological factors, the most frequent ones being infections and sarcoidosis.

Neutrophilic dermatoses

Pia Moinzadeh and Thomas Krieg

Introduction

The group of neutrophilic dermatoses (NDs) includes non-infectious skin diseases, which are characterized by a diffuse infiltrate of neutrophilic inflammatory cells throughout different layers of the skin. Patients suffering from NDs present with very heterogenous clinical features including either localized or generalized skin involvement as well as systemic symptoms. Depending on the localization of the inflammatory cells, i.e. subcorneal, intraepidermal, dermal, or subdermal, and the absence or presence of vessel damage, the group of ND can be subdivided into different subtypes (see Box 166.1).

Diagnosis of these disorders is based on clinical, laboratory and histopathological features (see Box 166.2) and requires a comprehensive assessment of all other possible conditions related to NDs. It is not uncommon that NDs are misdiagnosed due to mimicking other illnesses, which is risky for the patient because often inadequate treatment strategies are then used.

In this chapter we focus on those NDs in which the vessel wall is not affected; Behcet's disease and other vasculitides are discussed in other chapters (see Chapters 130–137).

Box 166.1 Neutrophilic dermatoses

- Sweet's syndrome
- Pyoderma gangrenosum
- Rheumatoid neutrophilic dermatitis
- Bowel-associated dermatosis–arthritis syndrome
- Subcorneal pustular dermatosis (Sneddon–Wilkinson syndrome)
- Behçet's disease
- Pustular psoriasis
- Acrodermatitis continua and palmoplantar pustulosis
- Acrodermatitis continua of Hallopeau
- Palmoplantar pustulosis
- Acute generalized exanthematous pustulosis
- Pustular bacterid (Andrew's disease)
- Neutrophilic eccrine hidradenitis

Sweet's syndrome—acute febrile neutrophilic dermatosis

Sweet's syndrome (SS), is one of the most frequently occurring entities of the group of NDs. It is defined by erythematous-livid, asymmetric, very painful plaques associated with non-specific systemic features, such as elevated temperature, arthralgias, weight loss, malaise, and elevated serum inflammation markers, such as

Histopathological investigation of the skin

Clarification of associated systemic diseases:

- Chest radiograph/CT
- Vascular studies (venous and arterial)
- Endoscopy
- Bone marrow aspirate

neutrophilia, increased erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) levels.[1] Due to the abrupt onset of a combination of cardinal attributes, such as systemic symptoms, skin lesions as well as typical histological features, it is also known as acute febrile neutrophilic dermatosis. The classical histopathological features are dense dermal infiltrates of neutrophils without any signs of vasculitis.

Epidemiology

SS appears to be predominantly a female disease (4:1), without any racial predilection. Most of the patients are between 30 and 50 years old, but paediatric cases have also been reported without any gender predilection.[1–2] Patients developing SS may initially attract attention with symptoms suggestive of a febrile upper respiratory tract infection, which precede the onset of further symptoms. Different infectious agents such as yersinia, staphylococcus, streptococcus, mycobacteria, cytomegalovirus, HIV, and hepatitis A, B, and C infections have been considered to function as a trigger of this condition.[1–2] Malignancies with predominantly haematological origin (leukaemia) and also drugs, such as granulocyte colony-stimulating factor (G-CSF), and pregnancy can cause SS.[3]

◆ **Classical SS** occurs more frequently in female patients (80%), often associated with an infection, inflammatory bowel diseases or also pregnancy,[4] with a relapse of skin lesions in 33% of patients and an initial episode between the age of 30 and 60 years.[3]

◆ **Malignancy-associated SS** occurs in male and female patients, without definitive gender predilection. These patients usually suffer from haematological malignancies (acute myelogenous leukaemia) or solid tumours (genitourinary, breast, gastrointestinal cancer).[3–4] It is much less associated with an infection prior to the development of skin lesions and the relapse of skin lesions is positively and very closely correlated with the discovery, cure, or relapse of the cancer itself.[3]

◆ **Drug-induced SS** can be caused by several drugs (antibiotics, anti-epileptics, anti-hypertensives, anti-neoplastics, anti-psychotics, NSAIDS, diuretics, contraceptives, etc.), however, the most frequently drug triggering SS is G-CSF. Following discontinuation of the triggering drug, the skin lesions frequently heal completely without the need for systemic treatment and relapse if the causing drug is represcribed.[3]

Aetiopathogenesis

The aetiopathogenesis is still not fully elucidated, but it is thought to be a multifactorial interaction of a hypersensitivity reaction due to infections, autoimmune diseases with the production of autoantibodies, immune complexe formation, drugs (G-CSF), physical factors and genetic predisposition (specific HLA serotypes), proteases, and malignancies.[2] Also the fact that more women develop SS and contraceptives are a possible trigger imply that the endocrine system and/or hormonal changes also may play a role.[5] The genetic background of SS is uncertain. Twenty-eight Japanese patients with SS showed an increased frequency of HLA-Bw 54, while in 38 white women no significant association could be confirmed.[5] The appearance of perivascular leucocytoclasis has been suggested to be associated with the vascular deposition of immune complexes, as a kind of hypersensitivity reaction type III, but immunohistochemical studies showed controversial results.[5]

Several studies have suggested, that a dysregulation of cytokine cascades with an increased secretion of cytokines may be involved in the development of SS, including interleukin (IL)-1[5], IL-2,[6] IL-3,[5] IL-6,[5] and IL-8,[5] interferon (IFN)-γ,[6] granulocyte colony stimulating factor (G-CSF), and granulocyte-macrophage colony-stimulating factor (GM-CSF).[5] Increased serum levels of IL-1, IL-2, and IFN-γ suggest that helper Th1 cells are involved in the aetiopathogenesis.[6] IL-1, a neutrophil chemoattractant, seems to play the central role in the development of SS by stimulating macrophages to secrete GM-CSF and IL-8.[6] Going et al. hypothesized a release of IL-1 into the dermis[7] and there is evidence of elevated serum levels of IL-1α and IL-1β in comparison to normal controls.[6] Meng et al. showed that a mutation of *NLRP3* genes can induce a sudden skin inflammation in mice with a dense neutrophil infiltration of the dermis similar to SS, due to excessive production of IL-1β.[8]

Recent studies have also shown that neutrophil/NK cells are observable in SS skin lesions,[9] and that a defect in the transcriptional regulation of *PTPN6* seems to be involved in the pathogenesis of SS and pyoderma gangrenosum (PG).[10]

Clinical features

The cutaneous lesions in patients with SS are well defined, tender, purple-red, non-pruritic nodules, papules, or sharply bordered plaques of erythematous and/or violaceous colour, which can become very painful; they are preferentially localized asymmetrically as single or multiple lesions in the face, neck, upper trunk, and proximal extremities (Figure 166.1).[4] A small subgroup of patients also may develop a localized form of SS, which is known as 'neutrophilic dermatosis of the dorsal hands'.[11] Furthermore a positive cutaneous pathergy phenomenon has been reported with lesions occurring after skin biopsies, cat scratches, or sunburn.[12–13]

Secondary to the oedema in the upper dermis, the lesions may occasionally be misdiagnosed as bullae or vesicules (pseudovesicular appearance),[14] they can develop into pustules and also can become ulcerated (more common in malignancy-associated SS) or enlarge to large, irregular but sharply bordered plaques.[3] Patients appear often dramatically ill, due to fever, which can occur several days to weeks prior to skin lesions, leucocytosis, arthralgias, myalgia, malaise, nausea, vomiting, and headache.[4,13] But not all patients present with the entire spectrum of clinical features.

Extracutaneous manifestations

Patients can also develop subcutaneous lesions as well as extracutaneous lesions, involving the bones (sterile osteomyelitis), ears (SS nodules next to the tympanic membrane), eyes (conjunctivitis, episcleritis, iridocyclitis), renal system (mesangiocapillary glomerulonephritis, haematuria, proteinuria), central nervous system (acute benign encephalitis, neurologic symptoms, pareses, polyneuropathy), liver (hepatomegaly, elevated liver enzymes), cardiopulmponary system (aortitis, cardiomegaly, heart failure, alveolitis with cough or dyspnoea), mouth (oral ulcers, bullae, vesicles), muscles (myositis), and spleen (splenomegaly).[3] SS can also overlap with other autoimmune rheumatic diseases, such rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), Sjögren's syndrome, sarcoidosis, Still's disease, or polychondritis.[2]

Histopathological features

Histopathology shows a dense diffusely distributed neutrophilic infiltrate in the superficial dermis, pronounced perivasculary with leucocytoclasia (fragmented neutrophil nuclei) and an oedema in

Fig. 166.1 Sweet's syndrome.

the papillary dermis, but without features of vasculitis. Besides the predominant cells, mature neutrophils and also eosinophils, lymphocytes, and/or histiocytes are occasionally present in the skin of SS patients. Patients with the subcutaneous form of SS show a very diffuse inflammatory infiltrate, involving the dermis but also the subcutaneous fat tissue.[15] These typical histopathological features in the skin, have also been reported in involved internal organs, with sterile neutrophilic inflammatory infiltrates.[3]

Diagnostic procedures

The diagnosis of classical and malignancy-associated SS is established, if patients meet two major and two of five minor criteria. The major criteria include (1) an abrupt onset of painful erythematous nodules, papules, or plaques and (2) typical histopathological findings, such as a dense neutrophilic infiltrate without evidence of leucocytoclastic vaculitis. The minor criteria are (1) elevated temperature; (2) an association with haematological or visceral malignancy, inflammatory, disease or pregnancy, or preceded by an upper respiratory tract infection, gastrointestinal infection, or a vaccination; (3) an excellent response to systemic steroid therapy or potassium iodide; and (4) abnormal laboratory tests (three of four) with an ESR in excess of 20 mm/hour, a high CRP, leucocytes in excess of 8000 with more than 70% of neutrophils.[2]

For the diagnosis of drug-induced SS all of the following criteria are required: (1) abrupt onset of painful erythematous plaques or nodules; (2) histopathological findings of dense neutrophilic infiltrates without the evidence of leucocytoclastic vasculitis; (3) fever above 38 °C; (4) a positive temporal relationship between the use of the drug and the clinical development of skin lesions or a relapse with readministration; and (5) a sudden disappearance of skin lesions after drug discontinuation or treatment with steroids.[2]

In malignancy-associated SS patients often present with leucopenia, lymphopenia, anaemia, and/or abnormal platelet counts.[1,5] In general it is very important to exclude infections with blood cultures, blood tests, urine analyses, and stool samples. Depending on the extracutaneous manifestations further investigations are necessary; patients with symptoms suggestive of central nervous system (CNS) involvement should be investigated, using brain SPECTs, CT scan, MRI, EEG, and/or cerebrospinal fluid (CSF) analysis. Urine analyses with evaluation of haematuria and/or proteinuria is helpful

to assess kidney involvement, while SS-associated liver involvement can be identified by elevation of liver enzymes. To exclude an underlying malignant process, patients should be investigated according to the recommendations of the American Cancer Society for the early identification of cancer in asymptomatic patients.[16]

Management

After approximately 6–8 weeks without treatment, most of the lesions resolve spontaneously, depending on the underlying disease, but very commonly patients develop new lesions recurrently. It is important to identify the underlying cause; if SS is triggered by a drug, the first step is to stop the drug and avoid similar (cognate) compounds. If the patient develops SS due to an infection, it is important to treat the infection, and if it is paraneoplastic, appropriate chemotherapy should be initiated.

Topical treatment options

In localized cases of SS topical and/or intralesional application of high-potency steroids can be effective.[3]

Systemic treatment options

SS shows a good response to systemic glucocorticoids (drug of first choice).[3] Skin and systemic symptoms tend to improve with glucocorticoids within 72 hours after starting therapy. Chronic relapsing disease may require the use of steroid-sparing immunosuppressive agents.

Alternative treatments include potassium iodide tablets or colchicine solution. Patients receiving potassium iodide therapy showed a resolution of symptoms and skin lesions within 3–5 days and patients who were initiated on colchicine therapy showed a resolution of skin and systemic symptoms after 2–5 days and normalization of the leucocytosis within 8–14 days.

Other treatments include indomethacin, clofazimine, dapsone, and ciclosporin. There have been reports of efficacy with mycophenolate mofetil, methotrexate, doxycycline, intravenous immunoglobulins, and etretinate.[2] The use of biologics such as infliximab or etanecept has been proposed for patients with SS and associated inflammatory bowel or rheumatic diseases.[17–18] Recent case reports support the use of anakinra in patients with SS because dysregulation of IL-1 secretion has been observed.[19]

Pyoderma gangrenosum

PG is a rare, non-infectious, chronic and relapsing, ulcerative skin disease. These skin lesions are defined as very painful, cutaneous ulcerations with a violaceous, undermined border surrounding a necrotic base (see figure 166.2).

Powell et al classified patients with PG into four different subtypes, such as ulcerative, pustular, bullous, and vegetative PG.[20] Many patients (50–70%) with PG suffer from concomitant diseases,[20–21] such as inflammatory bowel disease (ulcerative colitis, Crohn's disease), rheumatic disorders, monoclonal gammopathy, sarcoidosis or malignancies, mostly haematological background. Familial cases of PG have also been reported, especially a rare syndromic variant called PAPA (pyogenic sterile arthritis with PG and severe acne) syndrome.

Epidemiology

PG appears to be slightly more frequent in the female population in the age range 20–60 years.[20,22] A recently published retrospective

study showed a female to male ratio of 3:1 and a mean age of onset of 51.6 years. The general incidence of PG is between 3 and 10 per million inhabitants per year.[23]

Aetiopathogenesis

The pathogenesis is not completely known, but it has been reported that patients with PG may have a hyper-reactive response to trauma, and internal diseases with a further dysfunction of their immune system, that results in the excessive release of leucocytes, and cytokines such as IL-1and IL-8.[24–26] The release of IL-1β by T lymphocytes is associated with a clonal expansion of those cells and a clonal expansion of neutrophils and a release of large amounts of anti-matrix metalloproteinases-9, -10 and tumour necrosis factor alpha (TNFα), which together cause ulceration and progression of the disease.[27–28] Bister et al. hypothesized that a lack of anti-matrix metalloproteinase 1 and 26 on the borders of PG wounds retards normal wound healing.[28] These findings were also confirmed by a recent study which showed immunoreactivities of CD3 (pan T cell marker), CD163 (macrophage marker), myeloperoxidase (neutrophil marker), TNFα, IL-8 (cytokine chemotactic for neutrophils), IL-17, MMP2, MMP9 (proteinase-mediating tissue damage), and vascular endothelial growth factor (VEGF) which were significantly higher expressed in skin of patients with PG than in healthy controls, especially in the bullous or ulcerative form.[29] Also the interplay between IL-6 (as an inducer of acute-phase response), IL-8, and anti-phosphatidylserine-prothrombin antibodies may be closely associated with the development of PG.[30] IL-23 may play a critical role in the pathogenesis of PG; after treatment with ustekinumab (anti-IL-12/IL-23p40 monoclonal antibody), IL-23 expression decreased significantly accompanying with the complete healing of PG skin lesions.[31]

Furthermore, an alteration in the gene encoding protein tyrosine phosphatase non-receptor type 6 (*PTPN6/SHP1*) has been suggested to be one candidate gene involved in the pathogenesis of ND (PG and SS).[10]

Recent findings in familial cases, such as the PAPA syndrome, have shown that the proline-rich, glutamic acid-rich, serine-rich, and threonine-rich (PEST) family of protein tyrosine phosphatases (regulator of adhesion and migration) is linked to a cytoskeleton-associated protein (PSTPIP1). A mutation in this protein, especially missense mutations, creating A230T or E250Q variants has been reported to alter its interplay with pyrin and inflammasomes. Consequently it has been hypothesized that the mutations in the *PSTPIP1* gene lead to a hyperphosphorylation of PSTPIP1 accompanying with an increased affinity to pyrin. Thus pyrin seems to lose its inhibitory effect within a proinflammatory signalling pathway, causing an uncontrolled cleavage of pro-IL-1β into active IL-1β.[32] These proteins seems to be involved in PG and other autoinflammatory diseases and specifically in the PAPA syndrome.[33]

Clinical features

PG is characterized by ulcerative skin lesions, which usually start with a small follicular pustule that might occur on nearly all sides of the body (preferentially pretibial) and which progress rapidly to necrotic ulceration (Figure 166.2). Powell et al. classified four different subtypes, depending on clinical and pathological features:[20]

◆ **Ulcerative PG** presents initially as a small pustule with a surrounding inflammatory erythematous halo. These small pustules

enlarge within a few days into large, very painful ulcers with well-defined violaceous undermined borders and a purulent base.[20] The centre of these lesions typically begins to necrose and spread centrifugally. They can occur everywhere, although predominantly on the lower limbs or the trunk.[22] Ulcerative PG can appear also (in 25% of patients) after surgery (pathergy phenomenon)[22] as well as at peristomal sites associated with inflammatory bowel disease (IBD).[34]

◆ **Malignant PG** is a rare but very aggressive variant, which typically appears in the neck and/or head region, predominantly in male patients and possibly associated with systemic vasculitis (granulomatosis with polyangiitis (Wegener's)).[20]

◆ **Pustular PG** is characterized by multiple sterile pustules, mainly located on the extensor sites of the extremities and upper trunk, which do not enlarge into ulcerative skin lesions.[20] There is a close correlation with ulcerative colitis but also with other IBDs. Usually the skin lesions clear if the underlying condition, such as the IBD, is therapeutically controlled.

◆ **Bullous PG** is a less destructive form with painful superficial bullae, erosions, or ulcerations, often associated with leukaemia. These skin lesions appear often as groups on the dorsum of the hands, extensor surface of the arms, or the scalp, showing a tendency to converge.[35] Patients with this form of PG sometimes also show overlapping features with bullous SS. Those patients are more frequently associated with myeloproliferative disorders.[35]

◆ **Vegetative PG** is defined as a solitary, mild, superficial limited, chronic erythematous-livid plaque without a typical lilaceous border. The skin lesions are non-purulent and not undermined in comparison to the classical ulcerative PG, and are usually located at the trunk, mainly in adults and are rarely associated with systemic diseases.[20]

The combination of sterile pyogenic arthritis, PG, and acne is called PAPA syndrome, which is a rare autosomal dominant disease (mutations in the *CD2BP1/PSTPIP1* gene).[36]

Extracutaneous manifestations

Extracutaneous manifestations are commonly in the lungs (pleural effusion, lung nodules, cavitation, bronchial pneumonia, and/or abscess), joints (RA, osteoarthritis), eye (sclerokeratitis), liver

Fig. 166.2 Pyoderma gangrenosum.

(hepatitis, granulomas), and gastrointestinal tract, due to the inflammatory process.[2] Ulcerative and pustular PG forms are strongly associated with IBD. Many patients with ulcerative PG develop arthritis (up to 37%).[22] Immunosuppressed patients and patients with congenital and acquired hypogammaglobulinaemia may develop ulcerative PG lesions.[20] Patients with monoclonal gammopathy usually present ulcerative or bullous skin lesions, while in patients with malignant diseases bullous PG is most common.[20]

Histopathological features

Histopathological findings are diffuse neutrophilic infiltration involving the whole dermis, and also the follicular structures. Initially no vasculitic features are seen, in mature lesions focal vasculitic changes can be observed as a secondary phenomenon. In deeply ulcerated skin lesions a mixture of inflammatory cells and necrosis occur simultaneously.

Diagnostic procedures

A detailed medical history is essential and should include the development of skin lesion, severity of pain, progression, history of trauma or other causative factors, as well as symptoms of possible associated diseases. In addition to the physical examination of the patient, a biopsy and laboratory tests are required to exclude other diseases which may mimic PG. Depending on the type of skin lesion, other causes as well as other underlying systemic diseases should be ruled out by performing gastrointestinal tract studies, chest radiograph, and/or CT scans as well as bone marrow examinations.[35]

Management

The treatment in patients with PG is often very challenging for clinicians and patients.

Topical treatment options

Topical treatment of the wound is important for the therapeutic management of PG. Aggressive wound debridement should be avoided because of the risk of exacerbation (pathergy phenomenon).

There are different strategies to improve the PG lesions, such as the local injection of triamcinolone diacetate or the intralesional injection of ciclosporin. Topical tacrolimus 0.1%, and/or potent corticosteroids can be applied. Several studies and case reports have shown that hyperbaric oxygen,[37] topical sodium cromoglycate, topical 5-aminosalicylic acid, topical nitrogen mustard, or topical ciclosporin may improve PG lesions. In myelodysplastic syndromes the use of topical human platelet-derived growth factor (PDGF) has been reported.[20]

Systemic treatment options

Depending on the PG subtype it is necessary to use a combination of both local and systemic treatments. The drugs of choice, are oral or intravenous pulse glucocorticoids and ciclosporin.

Systemic glucocorticoids (prednisone) are usually used in a dosage of 1–2 mg/kg per day. In refractory cases it is also beneficial to use methylprednisolone in a dosage of 1 g daily for 1–5 days.

Vidal et al. showed that oral ciclosporin 5 mg/kg per day is probably the most effective treatment option, either as monotherapy or combined with systemic glucocorticoids. Other systemic steroid-sparing agents are azathioprine, methotrexate, sulfasalazine, and mycophenolate mofetil. In refractory cases cyclophosphamide may be helpful.[20] Skin grafting or skin substitution cell culture grafts in combination with immunosuppressive treatment have been used to treat selected patients. In refractory cases, especially with an underlying IBD, infliximab can be beneficial but the risk of its use has to be balanced.[38–39]

Rheumatoid neutrophilic dermatitis

Rheumatoid neutrophilic dermatitis (RND) is a rare disease and occurs in patients with active and severe RA[40] or seronegative arthritis,[41–42] mostly in middle-aged women. Patients present slightly painful and tender, erythematous, symmetric distributed papules, nodules, or plaques, located symmetrically over the extensor surfaces of the joints, affecting predominantly the dorsal parts of the hands and/or arms[43] but also the trunk, shoulders and neck. Sometimes the skin lesions show an urticarial-like appearance but they can also ulcerate.

Histopathological examination show diffuse but dense superficial and dermal infiltrates of predominantly neutrophils with a papillary dermal oedema and occasionally focal epidermal ulcerations, again without any signs of vasculitis. The cutaneous lesions tend to resolve spontaneously without treatment or with control of the associated underlying disease,[44] but hydroxychloroquine, dapsone, cyclophosphamide and topical steroids have also been reported to be effective.[42]

Bowel-associated dermatosis–arthritis syndrome

Bowel-associated dermatosis–arthritis syndrome, also known as bowel bypass syndrome, is a complication that can occur after jejunoileal bypass surgery, biliopancreatic diversion, and Billroth II gastrectomy.[45–46] Initially it was considered to be an immune-complex disease caused by bacterial overgrowth, but it can also occur without bowel bypass, in IBDs, peptic ulceration, diverticulitis, and liver diseases.[1] When associated with surgical procedures and blind bowel loops it can appear up to 6 years after the surgical intervention.[47–48]

It may also involve the musculoskeletal system (polyarthritis, polyarthralgia, myalgia, and tenosynovitis) and the skin accompanied with elevated temperature and diarrhoea.[46] Patients usually suffer from symmetrical, non-deforming polyarthritis predominantly located at the small joints, such as the wrists, ankles, metacarpophalangeal, interphalangeal, and metatarsophalangeal joints. The skin lesions are characterized by widespread pustular eruptions on an erythematous base, evolving rapidly within hours or days. They can also resemble erythema nodosum, panniculitis, ecchymoses, and/or nodular erythematous plaques.[49]

Histopathologically it is very similar to SS. The pathogenesis is still unclear but it is thought that because of the blind loops patients develop bacterial overgrowth associated with an accumulation of peptidoglycan, a bacterial antigen, which then lead to an immune-complex disease.[50] This consideration is supported by the fact that antibiotic treatment has been used successfully.[1] Lesions may resolve after 2–4 weeks without treatment but may relapse at intervals.[1,50] A combination of antibiotics with non-steroidal anti-inflammatory drugs (NSAIDs), colchicines, dapsone, and systemic corticosteroids, especially in patients with systemic symptoms, is effective. In cases with only cutaneous lesions, it is also possible to treat with topical or intralesional steroids. However, the only

Table 166.1 Rare neutrophilic dermatoses

Neutrophilic dermatoses	Characteristics
Acute generalized exanthematous pustulosis (AGEP)[52]	AGEP is characterized by multiple, small, itchy, non-follicular, intraepidermal and/or subcorneal localized pustules, appearing with a sudden onset and based on an erythematous, oedematous, and/or exanthematous background. Usually the skin lesions are localized intertriginous or facial, but can also appear at the trunk or the upper limbs. Occasionally the development of pustules may be associated with elevated temperature, which begins at the same day (< = 1 day). It can be triggered by acute infection, mercury, and drugs. Because AGEP is a self-limiting disease, in most cases a specific treatment is not necessary
Acrodermatitis continua of Hallopeau (ACH)[51]	ACH is a variant of pustular psoriasis, localized ungula or periungual, with a chronic and recurrent appearance of erythematous and pustular lesions. It is often very painful and usually starts at the distal phalanges. Due to the relapsing of pustules it can be associated with onycholysis and onychodystrophy in later stages. It can be very therapy-resistant. Several different treatment strategies have been described in case reports, such as topical treatment with corticosteroids, calcipotriol, tacrolimus, UV therapy and systemic treatment with corticosteroids, colchicines, ciclosporin, dapsone, methotrexate, infliximab, retinoids, PUVA, etanercept, and tetracyclines
Palmoplantare pustulosis (PPP)[51]	PPP is a rare, chronic and recurrent dermatosis, characterized by multiple sterile pustules and erythematous scaly plaques, located in the stratum corneum of palms and soles. It appears predominantly in female patients, especially in those with a positive smoking history. There are still discussions whether PPP is just a variant of psoriasis. Topical anti-inflammatory drugs provide limited help while ciclosporin, PUVA, methotrexate and biologicals have been reported to be helpful, but placebo-controlled studies are required
Pustular bacterid (Andrew's disease; PB)	PB is characterized by pustules located at the hands and/or feet with small petechiae in between the pustules. Again there are discussions whether this condition is just a variant of PPP. It has been reported that PB is triggered by upper respiratory tract infections and that it is associated with sternoclavicular hyperostosis or Tietze's syndrome. It has been suggested to classify patients as having PB, when they develop isolated sterile pustules with an erythematous rim, without family history for psoriasis and without further psoriatic lesions and coincidence with an infection as well as good response to antibiotics
Neutrophilic eccrine hidradenitis[51]	The clinical presentation varies a lot between patients with infiltrated papules or plaques, varying in colour from erythematous and hyperpigmented. Furthermore the symptoms can also vary between completely asymptomatic and very pruritic. Pustules can be localized in the papules/plaques or can occur independently on normal skin. The lesions can be isolated but also grouped or diffuse extended. It has been reported to be associated with haematological malignancies, especially acute myelogenous leukaemia (AML) after receiving chemotherapy
Behçet's disease[2]	Patients present with recurrent oral and/or genital ulcerations as well as with ophthalmological manifestations such as uveitis, choroititis, and retinitis. In addition, articular manifestations in form of seronegative arthritis, usually monoarticular, are seen as well as vascular and cardiopulmonary involvement (deep or superficial thrombophlebitis, pericarditis, cardiomyopathy, pleural effusion, embolism, fibrosis), gastrointestinal involvement in form of ulcerative lesions, rarely renal and neurological/psychiatric manifestations. Depending on the clinical symptoms, patients with oral lesions are treated locally with anti-inflammatory, anaesthetic and anti-septic drugs. In case of extensive disease the combination with systemic drugs is necessary.
Subcorneal pustular dermatosis (SCPD)[51]	SCPD is defined as a rare, chronic skin condition, occurring with symmetrical, fragile pustular eruption, localized at the trunk, intertriginous and at flexor aspects of the limbs or palmoplantar, sparing face and mucous regions. It is predominantly a disease of women aged 40–50 years and may be associated with IgA and IgG monoclonal gammopathy as well as myeloproliferative disorders, such as multiple myeloma. The pustules are initially very small, arise on normal skin are flaccid and rupture very easily. They pustules contain a purulent and clear portion of ichor. After rupturing they leave superficial scaling causing annular, circinate lesions, superficial desquamation, crusts, and occasionally also faint hyperpigmentation. Topical treatment with corticosteroids is regularly used but sometimes not sufficient. Topical application can be combined with systemic therapies such as with dapsone (drug of first choice), acitretin, phototherapy (UVA and UVB), as well as biologicals

curative intervention is still the surgical correction of the blind bowel loop.[1]

Other neutrophilic dermatoses

There are several other ND, which are either very rare or restricted to the skin. They are not discussed in detail in this chapter but are mentioned in Box 166.1 and Table 166.1.

Conclusion

The ND are a group of diseases accompanied by typical histopathological features, such as diffuse epidermal and/or dermal inflammatory, neutrophilic infiltrations, without any signs of vasculitis. Depending on the form of disease and the localization of neutrophilic cells in the skin, patients usually present with a variety of skin lesions, ranging from papules, nodules, and plaques to pustules and ulcerations. It is also very common for them to develop further systemic clinical features with leucocytosis, arthralgia, and myalgia.

The pathogenesis is still not completely known, but ND can be caused and induced by underlying systemic inflammatory diseases, malignancies, pregnancy, and/or medications.

CHAPTER 167

Sarcoidosis

Joachim Müller-Quernheim,
Gernot Zissel, and Antje Prasse

Introduction

A number of the characteristics of the disease known as sarcoidosis—such as erythema nodosum, dermatological manifestations, giant cells, epitheloid cells, and granulomata—were first described in the 18th and 19th centuries. Today sarcoidosis is regarded as a systemic disorder which can affect virtually any organ of the body. This is based on the work of Jörgen Schaumann, a Swedish dermatologist, who recognized that Besnier's lupus pernio and Boeck's multiple sarcoids are manifestations of the same disease and suggested the term 'lymphogranulomatosis benigna' for the disease since it seemed to involve predominantly the lymphatic system. In 1915 the disease was recognized as a systemic disease with predominantly intrathoracic manifestations.[1]

Epidemiology

By definition sarcoidosis is a rare disorder with a prevalence of less than 50 per 100 000 population in most countries. In Sweden, Norway, and Denmark the prevalence is marginally above this level. Sarcoidosis can be found in any country and there is an evident north–south gradient in the northern hemisphere and a south–north gradient in the southern hemisphere. Close to the equator its prevalence is much higher in populations living at high altitudes in a climate with subpolar conditions than in populations living at sea level. African Americans suffer from more severe courses than white Americans and have a higher prevalence. Most interestingly, sarcoidosis is extremely rare in Japan but myocardial manifestations are more frequent in Japan than in Western countries.

Disease definition

Sarcoidosis is a systemic disorder, which is diagnosed by demonstrating non-necrotizing granulomata accompanied by a compatible pattern of symptoms and the exclusion of other granulomatous disorders of non-infectious or infectious origin. A wide spectrum of manifestations can be observed in any organ and at any age. About 50% of the cases are diagnosed at an age of 20–40 years. However, a second peak of primary manifestation for women is observed around the age of 60. This results in a slight preponderance of the female gender.[2]

On the basis of its wide clinical spectrum it can be assumed that sarcoidosis is a final pathological pathway of several aetiologies. Its cause or causes are elusive, but some pathophysiological contributions of infectious agents such as commensals may be assumed. In aggregate, it may be viewed as a hyper-reactivity elicited by one or several aetiological agents encountered by an individual with a genetic susceptibility.[3]

Aetiopathogenesis

Genetics

The influence of the individual genetic background, and in particular the MHC genes, on sarcoidosis manifestation and specific phenotypes has been known for many years and some distinct phenotypes such as acute and chronic disease have recently been attributed to a limited number of MHC alleles. Acute sarcoidosis and Löfgren's syndrome is associated with *DRB1*01* and *DRB1*03* and chronic disease with *DRB*07*, *DRB*14*, and *DRB*15*.[4]

Furthermore, by the use of genome-wide association studies a number of biallelic genes have been discovered of which the minor alleles contribute to the genetic susceptibility of sarcoidosis. Some of these susceptibility genes have already been reproduced in independent cohorts. In the butyrophylin-like-2 (*BTNL2*) gene on chromosome 6, a member of the B7 family of costimulatory molecules, a truncated variant encoded by the *A* allele is observed in about 30% of white populations. This truncation leads to the loss of the membrane anchor of the molecule which is necessary for its inhibitory function in inflammatory mechanisms. The *A* allele confers an increased sarcoidosis risk with an odds ratio of 1.7. Its presence in a haplotype with a *HLA-DR* risk allele increases the odds ratio from 1.3 due to *HLA-DR* to 2.3 resulting from this combination. More gene variants have been associated with an increased sarcoidosis risk, e.g. annexin A11, some tumour necrosis factor (TNF)-promoter polymorphisms, *RAB23*, *CCR2*, *CCR5*, *IL23R*, *CARD15*, and many others. Of note, many of the named genes need to be confirmed as a susceptibility factor in independent cohorts and their roles in inflammatory processes of sarcoidosis are still elusive. Nevertheless, they might serve as therapeutic targets in the near future.[5]

Histology

The human organism generates granulomata whenever an antigen cannot be degraded and completely eliminated by its macrophages. In these cases multinucleated giant cells and epithelioid cells emerge which are the building blocks of non-necrotizing granulomata characterizing sarcoidosis.[6]

Non-necrotizing granulomata, the histological hallmark of sarcoidosis, are found in any involved organ but they are not pathognomonic. Most interestingly, necrotizing granulomata can also be observed in sarcoidosis, which broadens the spectrum of differential diagnosis. Hypersensitivity pneumonitis, mycobacterial disorders, and chronic beryllium disease have to be considered. In general, granulomata caused by *Mycobacterium tuberculosis*, granulomatosus with polyangiitis (Wegener's), or silicosis can easily be distinguished by histological examination. In lymph nodes, however, cat scratch disease and brucellosis have to be considered as differential diagnoses in the presence of non-necrotizing granulomata. Sarcoid-like lesions can also be observed in lymph nodes draining areas harbouring neoplastic disorders and in lymph nodes involved in a reconstitution syndrome of AIDS or common variable immunodeficiency (CVID).[7,8]

Immunopathogenesis

Next to non-necrotizing granuloma, activated T cells and macrophages can be found in affected tissues. These inflammatory processes are compartmentalized, i.e. they are most obvious in the organ involved but cannot be found in the blood, or only to a limited extent. Sarcoid alveolar macrophages exhibit characteristics known from dendritic cells. Thus, in contrast to normal alveolar macrophages they are capable of presenting antigen and of stimulating T cells. Moreover, they secrete cytokines which are involved in the Th1 immune response and are chemotactic for Th1 lymphocytes, such as interleukin (IL)-1, IL-6, IL-12, CC-chemokine ligand (CCL)-10, and TNF.

In aggregate, the recent literature suggests the following immunopathogenetic concept: in acute and chronic sarcoidosis resident T cells and macrophages, of the lung in most cases, become activated by an antigen which is presented by alveolar macrophages. Accessory molecule interactions cause a strong stimulation in acute sarcoidosis (Figure 167.1) and a weak to moderate stimulation in chronic sarcoidosis due to missing accessory signals (Figure 167.1). In both cases additional stimulating signals are delivered by the recognition of pathogen-associated molecular patterns (PAMPs) or damage-associated molecular patterns (DAMPs) by pattern recognition receptors (PRRs). In acute disease the activated macrophages increase their expression of costimulatory molecules and release chemokines such as CXCL10, attracting additional T cells of CD4/TH1 phenotype (Figure 167.1). These T cells become activated by macrophages with exaggerated accessory function and proliferate by autocrine IL-2 production (Figure 167.1). IL-18 and IL-12 released by activated alveolar macrophages induce and maintain the differentiation of the lymphocytes into Th1 cells, which in turn release interferon-γ which upregulates the activation of alveolar macrophages. Within those aggregates TNF and granulocyte–macrophage colony stimulating factor (GM-CSF) induce the
Fig. 167.1 Schematic depiction of immunopathological concepts for acute and chronic sarcoidosis: sufficient costimulatory signals and cytokine networking in acute disease allowing antigen elimination and complete resolution; low costimulation and strong cytokine networking towards scar formation in chronic disease. For further details see text.

fusion of these activated macrophages to multinucleated giant cells which build the non-necrotizing granuloma consisting of a core of multinucleated giant cells surrounded by epithelioid cells, fibroblasts, and T cells. The matrix within the granuloma or the giant cells binds and retains the granuloma-inducing agent (Figure 167.1.1D). These strong stimuli induce an extensive preponderance of TH1 lymphocytes and M1 macrophages in acute disease.

In marked contrast, in chronic disease the stimulatory processes result in low levels of TNF and other mediators. Noteworthy, CXCL10, IL-12 and IL-18 are found only at background levels which indicate a minor activation of alveolar macrophages (Figure 167.1). T-cell activation is also low due to lack of costimulation by alveolar macrophages and T-cell recruitment is minimal due to missing chemotactic factors. In this micromilieu the immigrating cells undergo only weak stimulation. Consequently, compared with acute disease the number of T cells in bronchoalveolar lavage (BAL) is reduced. Th1 commitment is incomplete because of insufficient levels of IL-12 and IL-18 (Figure 167.1). Nevertheless, activation of alveolar macrophages and release of TNF induce the generation of multinuclear giant cells and subsequently granuloma formation (Figure 167.1). IL-10 and the contact of alveolar macrophages with fibroblasts induce their differentiation into M2 macrophages releasing profibrotic CCL18 (Figure 167.1). CCL18 induces activation and matrix production by fibroblasts adjacent to granuloma, leading to fibrotic remodelling of the lung. Persistence of the disease-eliciting antigen or non-degradable remnants maintain inflammation with Th2 and M2 cells, which leads to a remodelling of the lower respiratory tract or any other involved tissue (Figure 167.1).

In acute disease however, the antigen contained in the granuloma is dissolved and eliminated. Consecutively, transforming growth factor beta (TGF-β) released by macrophages, epithelial cells, or cells of the granuloma itself leads to a downregulation of T-cell activation and TNF release of alveolar macrophages (Figure 167.1). This downregulation results in the disappearance of T-cell alveolitis and abrogates granuloma integrity. In most cases the granuloma will completely resolve or may leave only a minor scar (Figure 167.1).[6]

Aetiology

A number of recent studies demonstrate that a considerable percentage of sarcoidosis patients exhibit a specific immune response against mycobacterial antigens. Mycobacterial catalase G and propionibacterial DNA have been identified in sarcoid tissue. Interestingly, propionibacteria share a number of microbiological characteristics with mycobacteria. However, it is assumed that sarcoidosis is not of infectious aetiology but is based on an exaggerated immune response against PAMPs of harmless commensals. Serum amyloid A (SAA) and other proteins accumulate in the granuloma and serve to trap the aetiological agent, establishing a nidus which may give rise to chronicity. Moreover, SAA serves as a ligand for TLR2 and other receptors of innate immunity which stimulates macrophages and T cells. Inorganic substances such as beryllium and crystalline silica are also capable of inducing granulomatous immune responses which cannot be distinguished from sarcoidosis. Since sarcoidosis is a very heterogeneous disorder it can be assumed that not only one but several aetiological agents may induce the characteristic Th1 hyper-reactivity. At present genetic susceptibility and hyper-reactivity against PAMPs of harmless commensals seem to be key factors of sarcoid aetiology.[9,10]

Immunological disturbances in affected organs

The lung is easily accessible by BAL. Therefore, the immunological changes in the context of sarcoid inflammation have been studied in great depth in this organ and there is evidence that similar mechanisms take place in other organs. Great numbers of mononuclear cells and small numbers of polymorph nuclear cells immigrate to the alveolar space and typical changes in the BAL differential cell count can be used to estimate sarcoid activity. An increased CD4/CD8 ratio is observed in acute sarcoidosis, and in patients with a ratio above 3.5 spontaneous resolution is frequently observed, which suggests just follow-up in those without mandatory treatment indication to allow spontaneous resolution to take place. A slight increase of polymorphnuclear cells above the background of 3% is associated with progressing disease requiring treatment in the near future.[11]

Immunological disturbances in peripheral blood

In acute sarcoidosis in particular, numerous alterations can be observed in peripheral blood. The immigration of CD4+ T cells to the organ manifestations causes a depletion of these cells which might be accompanied by lymphocytopenia.[12] In contrast to the exaggerated Th1 response in organ manifestations peripheral blood cells are in an immunosuppressed state, which can be demonstrated by their reduced or absent response to recall antigens. This is in accordance with the observation of increased numbers of regulatory T cells and increased concentrations of anti-inflammatory cytokines such as IL-10 in peripheral blood.[6]

In a routine setting sequential tests of T-cell function such as ex-vivo cytokine release are not practicable and serum markers are desired. Several molecules shed by activated immune cells or epithelioid cells give rise to elevated serum levels which may be used to probe the corresponding immune processes. At present, useful parameters are available for granuloma burden, T-cell activation, and macrophage/monocyte activation.

Angiotensin converting enzyme (ACE) is secreted by epithelioid cells of granulomata and its serum level indicates the total body granuloma burden.[13] Its changes over time rather than absolute levels correlate with disease activity. Unfortunately, the sensitivity, specificity, and prognostic values of serum ACE are low. However, the detection of an insertion/deletion polymorphism of the *ACE* gene, which influences the ACE level of healthy individuals, enables the use of genotype-corrected normal values which result in a greater sensitivity and specificity of this biomarker.[14] Elevated ACE levels during the course of sarcoidosis are of no relevance for systemic blood pressure.

Neopterin, a small (250 Da) metabolite of the guanosine triphosphate pathway, is released by activated macrophages and monocytes. Elevated serum levels are found in sarcoidosis and can be used to monitor the activity of these cells which is usually found in patients with progressing disease. No correlations have been found between neopterin serum levels and biomarkers from BAL fluid.[11,15]

Soluble IL-2 receptor (sL-2R or sCD25) can be found in BAL fluid and serum of sarcoidosis patients and it is released by activated alveolar immune cells.[16] Increased serum levels can be found in cases with active inflammatory processes which require a closer follow-up because this biomarker is associated with progressive organ damage requiring therapy.[11,15]

Macrophage activation in combination with an elusive cofactor may induce an upregulated production of 1,25-(OH)$_2$-cholecalciferol (vitamin D$_3$) which causes hypercalcemia and hypercalcuria in up to 10% and 50% of patients respectively.

Clinical features

Acute and chronic disease

The wide heterogeneity of sarcoidosis manifestations poses a diagnostic challenge. In about 95% of cases symptomatic pulmonary involvement is observed and diagnostic workup leads to the diagnosis of sarcoidosis. An acute, highly symptomatic course can be discriminated from a chronic one with unspecific symptoms such as fatigue, dry cough, and dyspnoea on exertion. A frequent subphenotype of acute disease is Löfgren's syndrome, characterized by acute onset, fever, erythema nodosum, arthralgia, and bihilar lymphadenopathy. Erythema nodosum and fever usually remit spontaneously within a few weeks and corticosteroid therapy is rarely needed. It is more frequent in white people of northern European descent and only rarely observed in Asians and African Americans with sarcoidosis. In typical cases a diagnosis can be made without demonstrating non-necrotizing granuloma in an involved organ. However, follow-up is required to confirm the diagnosis by observing a spontaneous resolution. In non-Löfgren's sarcoidosis it is suggested to support the clinical diagnosis by demonstrating non-necrotizing granulomata in a biopsy of an organ with abnormalities in imaging, most frequently lung parenchyma or paratracheal lymph nodes.[2]

Chronic sarcoidosis is observed in about one-third of the patients. Its onset is usually insidious and heralded by constitutional complaints. It may even be discovered in asymptomatic individuals by routine chest radiographs. Nevertheless, it occasionally manifests itself as a medical emergency. Involvement of the eye, the heart, the central nervous system, or the development of hypercalcaemia may require immediate action. More than 90% of sarcoid patients will eventually develop pulmonary abnormalities easily recognizable on chest radiographs or tests of pulmonary function. Organ involvement differs with ethnicity. An epidemiological study of 736 patients in the United States gives data which can be used in most countries with a white population with or without African admixture (Table 167.1).[17]

The natural course of sarcoidosis is unpredictable in an individual patient: patients with advanced pulmonary infiltrates and splenomegaly may have spontaneous recovery, whereas others with asymptomatic hilar lymphadenopathy may develop severe disease. Generally, the more severe the clinical findings at the time of diagnosis and the more organ systems are involved by the disease, the more frequent adverse outcomes have been observed. Cutaneous sarcoidosis frequently indicates chronic and disseminated involvement. In an epidemiological study from Denmark with a median follow-up of 27 years an excess mortality from sarcoidosis and sarcoidosis-related diseases in patients with advanced radiological findings and impaired lung function was observed in the first 20 years. Although the mortality of the sarcoid cohort was higher than that of the general population, the difference was not statistically significant.[18]

Patients with predominantly abdominal manifestations may exhibit an acute onset and laboratory findings of systemic inflammation. Exclusively pulmonary, neurological, or dermatological manifestations are primarily observed in chronic disease.

Thoracic manifestations

The chest radiograph is rarely normal and most commonly reveals bilateral hilar lymphadenopathy and/or diffuse reticulonodular infiltrates in the pulmonary parenchyma. Usually the basal areas

Table 167.1 Percentage of sarcoidosis patients with specified organ involvement[17]

Organ involvement[a]	Percentage
Lungs	95.0
Skin (excluding erythema nodosum)	15.9
Lymph node	15.2
Eye	11.8
Liver	11.5
Erythema nodosum	8.3
Spleen	6.7
Central nervous system	4.6
Salivary gland	3.9
Calcium metabolism	3.7
Ear, nose, and throat	3.0
Heart[b]	2.3
Kidney	0.7
Bone and joints[b]	0.5
Muscle[b]	0.4

[a]In white Americans hypercalcaemia was significantly more frequent than in African Americans. In African Americans, however, there were significantly more frequently involvements of the eye, liver, bone marrow, extrathoracic lymph node, and skin involvement other than erythema nodosum.
[b]These numbers may rise with a more frequent use of MRI.

of the lung are spared. Lung function tests reveal a decrease in lung volumes (vital capacity and total lung capacity), a reduced diffusing capacity, and a mildly reduced arterial oxygen tension that may decrease further with exercise. An obstructive pattern of pulmonary function test or unspecific bronchial hyper-reactivity may appear in up to 50% of patients. Bronchial hyper-reactivity and pulmonary hypertension due to obstruction of pulmonary vessels by lymphadenopathy or granulomata in the vessel walls are also manifestations of intrathoracic sarcoidosis.[2] The radiographic changes can be categorized into four types, I–IV. Unfortunately, there is a large intra- and interobserver variation using this system. Therefore, these chest radiographic types should only be used to give a rough estimate of the intrathoracic involvement. For therapy decisions a detailed evaluation of radiographic changes in the lung parenchyma and the adenopathy over a longer course of the disease is required. Nevertheless, these radiographic types are of prognostic usefulness (Table 167.2).

Uncommon pulmonary manifestations include cavities, lymph node calcifications, pleural thickening and calcification, pleural effusions, and in very rare cases pneumothorax. In many cases of obvious and severe radiographic changes there is only modest lung function impairment. This discrepancy is typical for sarcoidosis and not seen in any other parenchymal lung disease. Dyspnoea on exertion may be caused by pulmonary hypertension in sarcoidosis patients secondary to different pathomechanisms; it is frequently seen in those requiring lung transplantation and heralds poor outcome.[19,20]

Table 167.2 Radiographic types of sarcoidosis according to Scadding[2] and their prognostic usefulness[18]

Radiographic type	Radiographic characteristics	Prognosis
0	No visible findings	–
I	Bilateral hilar lymphadenopathy	Spontaneous resolution in most cases
II	Bilateral hilar lymphadenopathy and parenchymal infiltration	Spontaneous resolution possible
III	Parenchymal infiltration without hilar adenopathy in regular chest radiograph	Spontaneous resolution in rare cases
IV	Advanced fibrosis with evidence of honeycombing bronchiectasis, hilar retraction, bulla, and cysts	Permanent organ damage

Table 167.3 Differential diagnoses of intrathoracic sarcoidosis

Radiographic type	Differential diagnoses
I	Tuberculous lymphadenitis
	Malignancies (Hodgkin's disease, non-Hodgkin lymphoma, bronchial carcinoma)
	Salmonellosis
	Histoplasmosis
II and III	Miliary tuberculosis
	Hypersensitivity pneumonitis
	Pulmonary metastasis
	Chronic beryllium disease
	Lymphangiosis carcinomatosa
	Hodgkin's disease
	Pulmonary Langerhans cell histiocytosis
	Bronchoalveolar carcinoma
IV	Post tuberculosis syndrome
	Pneumoconiosis
	Pulmonary fibrosis (idiopathic, drug hypersensitivity, associated with extrapulmonary or systemic disorders)
	Hypersensitivity pneumonitis

Differential diagnosis of intrathoracic sarcoidosis differs with radiographic type (Table 167.3).

In general pulmonary manifestations are no indication of immediate therapy, but a follow-up is indicated to establish a progressive course requiring therapy. This clinical approach avoids unnecessary therapy of stable or regressing disease. In rare cases fulminant pulmonary symptoms accompanied by advanced function defects may require immediate initiation of therapy.

Unfortunately, clinically relevant inflammatory activity leading to organ malfunction or permanent damage may not be indicated by serum biomarkers. This activity can only be identified by a follow-up using functional tests. ^{18}F-FDG-PET-CT has recently been introduced for the staging of sarcoid inflammatory activity. Hypermetabolism detected by this method correlates negatively with improvements in symptoms, lung function, or the above-mentioned serum markers in patients undergoing therapy, which generates interest in scanning for lung, heart or central nervous system (CNS) disease (Figure 167.2).[21,22]

Musculoskeletal manifestations

Many sarcoid patients report aching muscles, bones, and joints which are often accompanied by fatigue. However, sarcoid lesions can be clearly detected only in a minority of these patients. The exact percentage of patients with sarcoid musculoskeletal manifestations is unknown. In the past, clinicians did not search vigorously for musculoskeletal involvement because there was little clinical relevance. However, recent progress in PET and MRI techniques enables sensitive and non-invasive detection of sarcoid lesions in the musculoskeletal system.[23] Recent studies using these new techniques suggest a much higher frequency of sarcoid bone and muscle manifestations than previously thought.[23,24] Although acute sarcoid arthritis is often symptomatic, one-half of all patients with bone and muscle involvement are asymptomatic.

Blau's syndrome

Blau's syndrome, a monogenic disorder with systemic granulomatous manifestations, has to be distinguished from sarcoidosis. A mutation in the *NOD2* gene causes polyarticular lesions in about 95% of patients with a juvenile onset. In addition, cutaneous manifestations, eye disease, and phenotypes similar to Löfgren's syndrome, including erythema nodosum, were observed.[25]

Arthritis

Up to 70% of sarcoid patients report arthralgia.[26,27] There is an acute and a chronic arthritis form, of which the acute variant is far more common. Most often acute arthritis occurs within Löfgren's syndrome. Löfgren's syndrome includes acute arthritis of the ankles and sometimes also of the knees. In almost every patient with acute arthritis accompanying Löfgren's syndrome these manifestations
Fig. 167.2 In a patient with negative serum biomarkers but progressive pulmonary function defects ^{18}F-FDG-PET-CT fusion image shows hypermetabolism with increased standardized uptake value (SUV) which captures large areas of lung parenchyma (mottled yellow areas in the lung parenchyma, arrowheads). In the left lower lobe an intense uptake can be seen in a fibrotic area which did not change its configuration over an observation period of 24 months (arrow). In addition, an asymptomatic manifestation in the sternum is identified.

spontaneously resolve. Symptomatic treatment of acute arthritis with non-steroidal anti-inflammatory drugs (NSAIDs) is recommended. The chronic type of sarcoid arthritis is rare. Chronic granulomatous tendosynovitis, Jaccoud's type deformity, and dactylitis (sausage-like swelling of one or more digits) have been reported. Treatment options for chronic arthritis are prednisone, colchicine, hydrochloroquine, and infliximab.[27]

Bones

Osseous lesions are less common than arthritis.[26,27] Rough estimates assumed symptomatic osseous manifestations in less than 3% of all patients. However, modern techniques such as PET and MRI report a much higher incidence of asymptomatic lesions, which are detectable in approximately 13% of all patients, and severe courses are reported.[28] Osseous disease affects the proximal and middle phalanges and is associated with chronic disease. Typical findings are cystic lesions (osteitis cystoides Jüngling) of the proximal and middle phalanges, which are a sign of endstage disease. A nodular (focal) type of osseous lesions is rare and often accompanied with skin lesions (Figure 167.3). Osteoporosis can occur in the context of sarcoidosis but most often is associated with long-term prednisone treatment. Because of the disturbed vitamin D metabolism in sarcoidosis and the risk of hypercalcaemia it is recommended to treat sarcoid osteopenia using bisphosphonates; vitamin D and calcium supplementations are relatively contraindicated.

Muscle

Although many sarcoid patients suffer from diffuse muscle pain, fatigue, and reduced exercise capacity, the number of patients with detectable sarcoid muscle lesions is low (up to 13% in selected cohorts). Symptomatic muscle involvement in sarcoidosis can result in proximal muscle weakness, double vision, nystagmus (extraocular muscles), and dyspnoea due to diaphragm weakness. Muscle enzymes such as creatine kinase can be elevated.[29–31] A very important differential diagnosis is glucocorticoid-induced myopathy. Rarely, a painful nodular type of sarcoid lesion can be seen.

Hepatic manifestations

Hepatic involvement occurs in up to 50% of patients and CT imaging shows innumerable small hepatic nodules with low attenuation.
Fig. 167.3 MRI of sarcoid lesion of the right foot: hyperintense lesions in T2-weighted imaging.

The majority of hepatic manifestations are non-symptomatic. Patients presenting with symptoms complain about abdominal pain and pruritus. Abnormal liver function tests mandating therapy are rarely observed. Elevated alkaline phosphates and transaminases are frequently observed but elevated bilirubin levels occur only in cases progressing to cirrhosis. Differential diagnosis of sarcoid liver disease encompasses primary biliary cirrhosis, drug hypersensitivities, malignancies, and infectious disorders.

Myocardial manifestations

Cardiac sarcoidosis is a rare event which might be underdiagnosed because of the practical difficulties in demonstrating sarcoid inflammation within the myocardium. This might be overcome by the more frequent use of MRI and ^{18}F-FDG-PET-CT.[22,32] Myocardial involvement may cause sudden arrhythmias, brady-arrhythmias, heart failure, or even sudden death.

Neurosarcoidosis

The predilection sites of neurosarcoidosis are the base of the brain, resulting in cranial nerve palsy and neuroendocrine abnormalities with diabetes insipidus as the most frequent. Acute or chronic meningitis and peripheral neuropathy, including small-fibre neuropathy, are also observed and associate predominantly with a chronic course. Obstructive sleep apnoea syndrome (OSAS) is seen in patients with sarcoidosis not exhibiting the stigmata of metabolic syndrome and has to be distinguished from chronic fatigue which may result in sleepiness scores as high as in OSAS.[33]

Ophthalmologic manifestations

Ocular sarcoidosis can affect any part of the eye and manifestations range from asymptomatic to permanent vision loss. Anterior uveitis is the most common sarcoidosis lesion.

Dermatological manifestations

Specific sarcoid lesions exhibiting non-necrotizing granulomata include livid maculae, papules, nodules, infiltrated scars, and lupus pernio. They are mostly flesh coloured and asymptomatic. Lupus pernio may be disfiguring and requires corticosteroid therapy. Changes of papules and erythema in tattoos correlate well with systemic inflammatory activity of disease. Erythema nodosum and other lesions without granulomata are considered nonspecific lesions, with erythema nodosum being the most frequent.[34,35]

Therapy

Glucocorticoids are the mainstay of sarcoidosis therapy; however, studies on the long-term benefit, for prevention of pulmonary fibrosis, neurological defects, or increase survival, are inconclusive. United Kingdom guidelines on interstitial lung diseases, including sarcoidosis, were published in 2008 and describe an internationally accepted therapeutic approach.[36] A general rule is that therapy should be initiated when any organ function is threatened. Since sarcoidosis is not disabling in most patients treatment may be delayed in favour of careful monitoring to allow spontaneous resolution to take place, which is the case in about two-thirds of patients. In cases of highly symptomatic acute disease without mandatory indications for corticosteroid therapy, NSAIDs relieve symptoms and allow avoidance of corticosteroids.

Oral glucocorticoids are the first line in patients with progressive organ defects; inhaled corticosteroids cannot be used as a substitute or for sparing the systemic dose.[37] Treatment is initiated with 0.5-to 0.75 mg prednisolone/kg body weight per day for 4 weeks and tapered by 10 mg per 4 weeks depending on disease response. The above-mentioned biomarkers and pulmonary function tests can be used for monitoring. In most cases therapy can be terminated after 6 months when patients are asymptomatic and pulmonary function has improved, but refractory disease may need up to 24 months.[37] Whether a low-dose maintenance therapy for 6–12 months is of any benefit remains controversial. When glucocorticoids do not control the disease, intolerable side effects develop, or immediate relapse occurs, immunosuppressants can be used as corticosteroid-sparing additives. Azathioprine[38] and methotrexate [39] are generally accepted for this use. Mycophenolate mofetil and cyclophosphamide are alternatives but ciclosporin is of no benefit.[40] Lung transplantation should be considered in endstage disease and in particular in those with pulmonary hypertension.[41]

TNF has been identified as a pivotal mediator in refractory sarcoidosis,[6,42] which has led to clinical studies using a wide range of TNF inhibitors in monotherapy or as corticosparing agents. In this respect thalidomide and pentoxifylline have some potential.[43–45] Most interestingly, etanercept has no benefit in sarcoidosis[46] but even induces or exaggerates sarcoidosis, which may respond to monoclonal antibodies against TNF.[47] There are many case series demonstrating the usefulness of anti-TNF antibodies in sarcoidosis with much better benefit in extrathoracic than thoracic disease. A placebo-controlled trial with infliximab unequivocally showed a significant but small effect on restrictive lung function defect,[48] and a longer treatment period seems necessary.[49] The anti-inflammatory effects of infliximab correlated well with improvement in lung function and biomarkers including ^{18}F-FDG-PET-CT.[21]

Conclusion

Sarcoidosis is a systemic granulomatous disorder with predominant intrathoracic manifestations. However, in about 1% of patients musculoskeletal manifestations are observed and there is evidence that this number is a gross underestimation. There is a consensus that only symptomatic patients with organ malfunction due to disease activity receive prednisolone or immunosuppressive therapy, which is guided by biomarkers.

CHAPTER 168

Macrophage activation syndrome

Alexei A. Grom and Athimalaipet V. Ramanan

Introduction

Macrophage activation syndrome (MAS) is a potentially fatal complication of rheumatic diseases caused by excessive activation and expansion of T lymphocytes and macrophages characterized by the development of cytopenias, extreme hyperferritinaemia, liver dysfunction, and coagulopathy resembling disseminated intravascular coagulation (DIC).[1–5] The main pathognomonic feature of MAS is usually found in bone marrow: numerous well-differentiated macrophages actively phagocytosing normal haematopoietic elements. MAS is a life-threatening condition, and the reported mortality rates still reach 20–30%.[6,7]

Although MAS is increasingly reported in various inflammatory disorders, it is seen most frequently in systemic juvenile idiopathic arthritis (SJIA) and in its adult equivalent, adult-onset Still's disease.[6,8,9] About 10–15% of patients with SJIA develop overt MAS,[7] while mild 'subclinical' MAS may be seen in as many as one-third of patients with active systemic disease.[10,11] Systemic lupus erythematosus (SLE) and Kawasaki's disease are two other conditions in which MAS appears to occur more frequently than in other rheumatic diseases. MAS can occur during a flare of the underlying rheumatic disease or initial disease presentation, thus masking the clinical features of the underlying rheumatic disease.[12,13] In approximately one-half of cases, MAS is triggered by an infection,[6,14,15] but a change in drug therapy including introduction of biologics has also been reported in the literature as potential triggers.[2,16,17]

Macrophage activation syndrome and haemophagocytic lymphohistiocytosis

Since the predominant cell population in the inflammatory lesions in MAS are tissue macrophages, or histiocytes, exhibiting haemophagocytic activity, MAS is thought to be closely related to a group of histiocytic disorders collectively known as haemophagocytic lymphohistiocytosis (HLH).[18,19] HLH patients are often categorized as having either primary or secondary HLH.[20,21]

Patients in the primary category are those with clear familial inheritance or genetic causes. The term 'familial HLH' is often used to describe these patients. Familial haemophagocytic lymphohistiocytosis (FHLH) is a constellation of rare autosomal recessive immune disorders linked to defects in various genes all affecting the perforin-dependant cytolytic pathway (see later). The clinical symptoms of FHLH usually become evident within the first months of life. These patients have a clear risk of HLH recurrence and are not likely to survive long-term without haematopoietic stem cell transplantation. Though HLH in these patients can be associated with infections, the immunological trigger is often not apparent.

Secondary HLH tends to occur in older children and is more often associated with an identifiable infectious episode, most notably Epstein–Barr virus (EBV) or cytomegalovirus (CMV) infection. The group of secondary haemophagocytic disorders also includes malignancy-associated HLH. Patients with secondary HLH typically do not have a family history or known genetic cause of HLH. The exact relationship between HLH and MAS is an area of extensive investigations, and some rheumatologists believe that MAS should be categorized as secondary HLH occurring in a setting of a rheumatic disease.

In recent years, the distinction between primary and secondary HLH has become increasingly blurred as new genetic causes are identified, some of which are associated with less severe and somewhat distinct clinical presentations.[22] Some of these patients may present later in life due to heterozygous or compound heterozygous mutations in cytolytic pathway genes that confer a partial dominant negative effect on the cytolytic function.[23]

Pathophysiology

The main pathophysiologic feature of MAS is excessive activation and expansion of cytotoxic CD8+T cells and macrophages (or histiocytes). These activated immune cells produce large amounts of proinflammatory cytokines, creating a 'cytokine storm'. In clinically similar FHLH, the uncontrolled expansion of T cells and macrophages has been linked to decreased cytolytic activity of NK cells and cytotoxic CD8+T lymphocytes.[24–27] Although familial cases of MAS in SJIA have not been reported, as in FHLH, SJIA/MAS patients have functional defects in the cytolytic pathway[14] and these abnormalities are associated with specific polymorphisms in FHLH-associated genes.[28–30] Normally, NK cells and cytotoxic T lymphocytes induce apoptosis of cells infected with intracellular microbes or cells undergoing malignant transformation. In some

circumstances, NK cells and cytotoxic T lymphocytes may also be involved in induction of apoptosis of activated macrophages and T cells during the contraction stage of the immune response.[31,32] It has been proposed that in both HLH and MAS, failure to induce apoptosis due to cytolytic dysfunction leads to prolonged expansion of T cells and macrophages and escalating production of proinflammatory cytokines.[22] As a result of chronic stimulation with mainly T-cell-derived cytokines such as interferon (IFN)-γ and macrophage colony-stimulating factor (M-CSF), macrophages become haemophagoctyic. In addition to secreting multiple proinflammatory cytokines including interleukin (IL)-1, tumour necrosis factor alpha (TNFα), IL-6, and IL-18 responsible for many clinical manifestations of MAS,[33–35] the activated macrophages also produce a haemostatic tissue factor that contributes to the development of coagulopathy.

Clinical features

The clinical findings in MAS may evolve rapidly. Patients become acutely ill and develop high persistent fever, mental status changes, generalized lymphadenopathy, hepatosplenomegaly, and coagulopathy resembling DIC.[1–5] Haemorrhagic skin rashes from mild petechiae to extensive ecchymotic lesions are seen early in the course of MAS. At later stages, patients may develop epistaxis, haematemesis secondary to upper gastrointestinal bleeding, and rectal bleeding. Encephalopathy is another frequently reported clinical feature of MAS. Mental status changes, seizures, and coma are the most common manifestations of central nervous system (CNS) disease. Cerebrospinal fluid (CSF) pleiocytosis with mildly elevated protein has been noted in some studies.[2,3] Significant deterioration in renal function has been noted in several series, and was associated with particularly high mortality in one report.[7] Pulmonary infiltrates have been mentioned in several reports, and haemophagocytic macrophages can be found in bronchoalveolar lavage (BAL).[3,15]

The features that should raise immediate suspicion for MAS symptoms are typically found in laboratory evaluation. Sharp fall in at least two of three blood cell lines (leucocytes, erythrocytes, or platelets) is one of the early findings. The fall in platelet count is usually first to occur. Since bone marrow aspiration in these patients typically reveals significant hypercellularity and normal megakaryocytes,[3] such cytopenias are not likely to be due to inadequate production of cells. Increased destruction of the cells by phagocytosis and consumption at the inflammatory sites are more likely explanations.

Sharp fall in erythrocyte sedimentation rate (ESR) despite persistently high C-reactive protein (CRP) is another characteristic laboratory feature. Falling ESR probably reflects decreasing serum levels of fibrinogen secondary to fibrinogen consumption and liver dysfunction. Most patients with MAS develop marked hepatomegaly. Some develop mild jaundice. Liver function tests often reveal high serum transaminases activity but only mildly elevated levels of serum bilirubin. Moderate hypoalbuminaemia has been reported as well. Serum ammonia levels are typically normal or only mildly elevated, a feature that distinguishes MAS from Reye's syndrome.

One of the most striking laboratory findings in MAS is extreme hyperferritinaemia. Presumably, it occurs in response to the need to sequester free iron released during eryhtrophagocytosis. In MAS, increased release of free haemoglobin associated with erythrophagocytosis would require increased production of ferritin to sequestre excessive amount of free iron. Indeed, strikingly high levels of serum ferritin (>10 000 ng/dL) is highly suggestive of MAS. A review of ferritin levels in paediatric patients showed a cut-off value of 10 000 μg/litre to be 90% sensitive and 96% specific for the diagnosis of HLH.[36]

Additional laboratory findings in MAS include highly elevated serum levels of triglycerides. Another laboratory test that may help with the diagnosis is highly elevated serum levels of SIL2Ra, chains presumably originating from overly activated T cells.[10] This test is, however, usually performed only in specialized laboratories.

Increasingly, MAS is being recognized in lupus patients as a secondary complication.[37] As fever, cytopenias, and raised liver enzymes can be seen as part of disease activity in lupus, diagnosis of MAS is harder in lupus patients. In any lupus patient with active or inactive disease, the development of fever, cytopenia, and raised liver enzymes, MAS must be considered in the differential diagnosis. Raised levels of serum ferritin could help discriminate between active lupus and MAS complicating lupus. As infections secondary to lupus or due to medications is also likely, infectious aetiologies must be considered before the diagnosis is made. In the clinical setting of an ill child with lupus and diagnostic uncertainty, IVIG might be a useful therapeutic agent.

Diagnosis

There are no validated diagnostic criteria for MAS and early diagnosis depends on a high level of vigilance in children with SJIA, lupus, and Kawasaki's disease. Diagnosis is often difficult because of the similarities to sepsis-like syndromes. As a general rule, in a patient with active underlying rheumatological disease, persistent fevers, a fall in the ESR and platelet count (acute drop in platelet count in SJIA from high levels), particularly in a combination with increase in serum D-dimer and ferritin levels, should raise a suspicion of impeding MAS (see Table 168.1). Although the diagnosis of MAS can confirmed by the demonstration of haemophagocytosis in the bone marrow, marrow involvement can by patchy and may require serial bone marrow aspirations.[38] In some cases, additional staining of the bone marrow with anti-CD163 antibodies may be helpful. This usually reveals massive expansion of highly activated histiocytes.

In contrast to MAS, the diagnosis of HLH is usually established based on the diagnostic criteria developed by the International Histiocyte Society.[39] The criteria include either:

◆ a molecular diagnosis based on specific mutations found in *PRF1*, *MUNC13–4*, *STX11*, *STXBP2*, *Rab27a*, *SH2D1A*, or *BIRC4*, *or*

◆ a clinical diagnosis based on the clinical criteria listed in Box 168.1.

The definite clinical diagnosis of HLH requires the presence of at least five of the eight criteria listed in Box 168.1.

When applied to SJIA patients with suspected MAS The HLH diagnostic criteria are highly specific but not sufficiently sensitive (sensitivity <30%).[38] Some of the HLH markers, such as lymphadenopathy, splenomegaly, and hyperferritinaemia, are common features of active SJIA itself and, therefore do not distinguish MAS from a conventional SJIA flare. Other HLH criteria, such as cytopenias and hypofibrinogenemia, become evident only at the late stages. This is related to the fact that SJIA patients often have increased white blood cell and platelet counts as well as serum levels

Table 168.1 Comparison of clinical and laboratory features of systemic juvenile idiopathic arthritis (SJIA) and macrophage activation syndrome (MAS)

	SJIA	MAS
Fever pattern	Quotidian	Unremitting
Rash	Evanescent, maculopapular	Petechial or purpuric
Hepatosplenomegaly	+	+
Lymphadenopathy	+	+
Arthritis	+	−
Serositis	+	−
Encephalopathy	±	
WC and neutrophil count	↑↑	↓
Haemoglobin	Normal or ↓	↓
Platelets	↑↑	↓
ESR	↑↑	Normal or sudden ↓
Bilirubin	Normal	Normal or ↑
ALT/AST	Normal or ↑	↑↑
PT	Normal	↑
PTT	Normal	↑
D-dimers	↑	↑↑
Fibrinogen	↑	↓
Ferritin	Normal or ↑	↑↑
SCD25	Normal or ↑	↑↑
CD163	Normal or ↑	↑↑

ALT, alanine aminotransferase; AST, asparate aminotransferase; MAS, macrophage activation syndrome; PT, prothrombin time, PTT, partial thromboplastin time; SJIA, systemic juvenile idiopathic arthritis; WCC, white cell count.

Box 168.1 HLH-2004: revised diagnostic guidelines for HLH[39] The diagnosis of HLH can be established if one of either 1 or 2 below is fulfilled:

1. A molecular diagnosis consistent with HLH (i.e. reported mutations found in either *PRF1* or *MUNC13–4*); *or*

2. Diagnostic criteria for HLH fulfilled (i.e. at least five of the eight criteria listed below present:

   ◆ Persistent fever

   ◆ Splenomegaly

   ◆ Cytopenias (affecting ≥2 of 3 lineages in the peripheral blood):

     – Haemoglobin <90 g/litre (in infants <4 weeks: <100 g/ litre)

     – Platelets $<100 \times 10^9$/ litre

     – Neutrophils $<1.0 \times 10^9$/ litre

   ◆ Hypertriglyceraemia and/or hypofibrinogaenemia:

     – Fasting triglycerides ≥3.0 mmol/litre (i.e. ≥265 mg/dL)

     – Fibrinogen ≤1.5 g/litre

   ◆ Haemophagocytosis in bone marrow* or spleen or lymph nodes, no evidence of malignancy

   ◆ Serum ferritin ≥ 500 µg/litre (i.e. 500 ng/mL)

   ◆ Low or absent NK cell activity (according to local laboratory reference)

   ◆ Increased serum sIL2Rα (according to local laboratory reference)

If haemophagocytic activity is not proven at the time of presentation, further search for haemophagocytic activity is encouraged. If the bone marrow specimen is not conclusive, material may be obtained from other organs.

of fibrinogen as a part of the inflammatory response seen in this disease. Therefore, when they develop MAS, they reach the degree of cytopenias and hypofibrinogenaemia seen in HLH only at the late stages of the syndrome. Attempts to modify the HLH criteria to increase their sensitivity and specificity for the diagnosis of MAS in rheumatic conditions have been initiated.[40] One consideration is that the relative decrease in white blood cell count, platelets, or fibrinogen rather than the low absolute numbers required by the HLH criteria may be more useful in making an early diagnosis. Another problem is that the minimum threshold level for hyperferritinaemia required for the diagnosis of HLH (500 µg/litre) is too low. It is well known that many patients with active SJIA, even in the absence of MAS, have ferritin levels above that threshold while in the acute phase of MAS, ferritin level generally peaks above 5000 µg/litre.

An international collaborative project has been started with the main aim of developing a new set of diagnostic criteria for MAS complicating SJIA.[40] As the first step in this project, the Delphi survey technique was used to identify the clinical features most pertinent to the diagnosis of MAS. The following 9 features were ranked most highly in the 232 respondents: (1) falling platelet count, (2) hyperferritinaemia, (3) presence of haemophagocytosis in the bone marrow, (4) increased liver enzymes, (5) falling leucocyte count, (6) persistent continuous fever of 38 °C or higher, (7) falling ESR, (8) hypofibrinogenaemia, and (9) hypertriglyceridaemia. Questionnaire respondents were intentionally not asked to indicate the threshold level for each laboratory test that they felt would be optimal for early identification of MAS. Instead, the threshold levels will be determined in the second part of the project, which will utilize real data from a large number of patients with and without MAS.

Treatment

MAS is a life-threatening condition still associated with high mortality rates. Therefore, early recognition and of this syndrome and immediate therapeutic intervention to produce a rapid response are critical. No clinical trials have been performed in MAS and treatment has developed mainly from anecdotal experience.

Early diagnosis and appropriate supportive care with corticosteroids will result in control of disease in almost one-half of the patients with MAS (Table 168.2). Most clinicians would start with intravenous methylprednisolone pulse therapy (30 mg/kg for three consecutive days) followed by 2 mg/kg per day in divided doses.

Table 168.2 Suggested management according to risk groups at initial diagnosis

Risk group	Suggested therapy
Low-risk group	
MAS in the absence of high-risk features	Corticosteroids
	IVIG (2 g/kg)
	Supportive care
High-risk group	
CNS involvement	Corticosteroids
Severe bleeding diathesis (DIC)	Ciclosporin, IVIG
Severe renal impairment	IVIG
Multiorgan failure	Consider etoposide
Failure to respond to initial therapy	Supportive care

DIC, disseminated intravascular coagulation; IVIG, intravenous immunoglobulin.

If response to steroids is not evident, addition of ciclosporin (2–7 mg/kg per day) should be considered.[3,16,41] IVIG (2 g/kg in a single dose) should be considered as well.

Intravenous immunoglobulin (IVIG) is a particularly useful agent when the differentiation between sepsis and MAS is uncertain in a clinically ill child. There are reports of effective use of IVIG alone in treatment of MAS, particularly secondary to SJIA or adult-onset Still's disease.[42]

Patients in whom MAS remains active despite the use of corticosteroids and ciclosporin present a serious challenge. In these patients, one might consider using the HLH-2004 treatment protocol developed by the International Histiocyte Society.[39] This protocol in addition to steroids and ciclosporin includes etoposide (or VP16), a podophyllatoxin derivative that inhibits DNA synthesis by forming a complex with topoisomerease II and DNA. Although, successful use of etoposide in MAS has been reported, the potential toxicity of the drug is a major concern, particularly in patients with hepatic impairment. Etoposide is metabolized by the liver, and then both unchanged drug and its metabolites are excreted through the kidneys. Since patients who may require the use of etoposide are very likely to have hepatic and renal involvement, caution should be exercised to adjust the dosage properly and thus limit the extent of potential side effects such as severe bone marrow suppression that may be detrimental. Reports describing deaths caused by severe bone marrow suppression and overwhelming infection have been published. In patients with MAS secondary to HLH it is not required to follow the entire of HLH-2004 protocol for administration of etoposide; if the patient recovers significantly after a few doses of etoposide then ongoing control of disease can be maintained with steroids and ciclosporin. This approach would limit the risks of etoposide such as infection and marrow suppression.

Recently it has been suggested that in patients unresponsive to the combination of steroids and ciclosporin, particularly in those with renal and hepatic impairment, anti-thymocyte globulin (ATG) might be an alternative to etoposide.[43,44] ATG depletes both CD4+ and CD8+ T cells through complement-dependent cell lysis. Mild depletion of monocytes is noted in some patients as well. Although in the reported cases this treatment was well tolerated, one must remember that infusion reactions are frequently reported with the use of ATG and adequate laboratory and supportive medical resources must be readily available if this treatment is used.

The utility of biological drugs in MAS treatment remains unclear. Although TNF inhibitors have been reported to be effective in occasional MAS patients, other reports describe patients in whom MAS developed while they were on TNF inhibitors. Since, at least in SJIA, MAS episodes are often triggered by the disease flare, biologics that neutralize either IL-1 or IL-6, two cytokines that play a pivotal role in SJIA pathogenesis,[45,46] have been tried by many authors. As with TNF inhibitors the results have, however, been conflicting.[47–52] If MAS is driven by EBV infection, one might also consider rituximab, a treatment that would eliminate B lymphocytes harbouring EBV.[53,54] This approach has been successfully used in EBV-induced lymphoproliferative disease.

Prognosis

MAS is a life-threatening condition with significant morbidity and mortality. Due to increasing awareness of this syndrome, early diagnosis and appropriate interventions have resulted in improved outcomes. A proportion of MAS patients may experience recurrent episodes and these patients may require closer monitoring. In future, the use of novel biomarkers to identify the children and adults with rheumatic disease who are at greatest risk of MAS will hopefully lead to better therapies and outcomes.

Multicentric reticulohistiocytosis

Hermann Einsele and Peter J. Maddison

Introduction

Multicentric reticulohistiocytosis (MRH) is a rare systemic disease that is recognized clinically by the combination of typical papular and nodular skin lesions and a severe and destructive polyarthritis, although virtually any organ system of the body can be involved. The term 'multicentric reticulohistiocytosis' was introduced by Goltz and Layman in 1954 to distinguish the disorder from solitary cutaneous nodules, termed reticulohistiocytomas, which have identical histological appearances but are not associated with systemic disease. There are a number of synonyms, including lipoid dermatoarthritis, reticulohistiocytosis, giant-cell reticulohistiocytosis, and normocholesterolaemic xanthomatosis. At one time it was thought to be a lipid storage disease but no consistent abnormality of serum or intracellular lipids has been identified. It is thought generally that the histiocytes and giant cells that characterize the lesions contain a non-specific accumulation of glycoprotein and lipids, and that this disease is a histiocytic granulomatous reaction to an unknown stimulus.[1] However, in one case, type VI collagen inclusions usually found in lymphohistiocytic neoplasms were demonstrated, supporting the concept of a proliferative rather than an inflammatory background for this condition.[2]

Clinical features

MRH is a characterized by mucocutaneous papulonodules and erosive arthritis. The cutaneous lesions consist of multiple reddish-brown papules and nodules, mainly involving the face and distal upper extremities. The arthritis preferentially involves the interphalangeal joints of the hands and can lead to joint destruction and deformities. All of these clinical symptoms are directly caused by the infiltration of reticulohistiocytes, which are histologically characterized by histiocytic multinucleated giant cells with eosinophilic ground-glass cytoplasm.[3]

MRH most commonly affects middle-aged white women. It is about three times more common in women than in men, with a mean age at onset in the fifth decade. MRH classically presents with reddish-brown nodules and papules, 1–2 mm to several centimetres in diameter, distributed acrally. The face (nose and paranasal areas) and hands (dorsum and lateral aspects of fingers and nailfolds) are affected. The ears, forearms, elbows, scalp, and muscosal surfaces can be affected as well. Patients may also present with fever, fatigue, and weight loss.[4] The differential diagnosis includes disseminated Langerhans cell histiocytosis, rheumatoid nodules, tuberous xanthomas, Gottron's papules, gout, progressive nodular histiocytomas, lipogranulomatosis, sarcoidosis, and psoriatic arthritis.[5] In up to 25% of cases, MRH has been found to occur in association with a wide range of underlying internal malignancies, suggesting that the disease may represent a paraneoplastic condition caused by reactive proliferative histiocytes.[6] This association with internal malignancy mandates that patients presenting with MRH should be investigated for an occult neoplastic disease.

The severe destructive arthropathy known as arthritis mutilans occurs in one-half of patients with joint involvement. Approximately 50% of patients with MRH initially develop polyarthritis, 25% initially develop the cutaneous nodules, and another 25% develop both skin and joint manifestations at the same time.[5] Periungual papules arranged around the nailfolds resemble 'coral beads' and have been noted in approximately 40% of cases. An estimated 50% of patients with MRH also develop papules and nodules of the oropharyngeal or nasopharyngeal mucosa; these may occasionally progress to histiocytomas. Rarely, patients develop visceral involvement resulting in serositis, gastric ulceration, and progressive heart failure.[5] Most patients have interphalangeal joint involvement of the hands, but there have also been sporadic cases of involvement of other joints including the knees, shoulders, wrists, hips, ankles, feet, and elbows, in decreasing frequency. The disabling arthritic process progresses rapidly in the early stage and then decreases in intensity to become less active over the ensuing 8–10 years.[1]

Laboratory, imaging, and histology findings

Laboratory results reveal elevated erythrocyte sedimentation rate (ESR) and anaemia in 50% of patients, and hypercholesterolaemia in 30%. The presence of cryoglobulinaemia and cold agglutinins, but not rheumatoid factor, is occasionally seen. The joint lesions of MRH are characterized by sharply circumscribed progressive erosions of the joint surfaces, often with concomitant separation of the bone ends.[5]

The diagnosis of MRH is based on the characteristic histopathological findings, presenting multinucleated giant cells of a foreign-body type, irregular in size and shape, reaching 50–100 μm in diameter. The cytoplasm of the giant cells is slightly eosinophilic and has a finely granulated ground-glass appearance or a foamy, vacuolated appearance. The pathogenesis of MRH is unknown; however, aberrant proliferation of the histiocytic population is postulated in response to monokines, cytokines, and other secretory products that promote macrophage proliferation and phagocytosis.[1] In addition, the biological nature and pathogenetic significance of the ground-glass-like multinucleated giant cells remain largely unknown.

Histochemically, the granular material in histiocytes and giant cells stains with periodic acid–Schiff and Sudan black, indicating the presence of glycolipids and/or glycoproteins and neutral fat.[5] CD68 staining is positive, and S-100 and CD1a are negative.

CD10 was demonstrated[7] to accumulate abundantly in the cytoplasm of ground-glass-like multinucleated giant cells in MRH. The feature was quite specific because in giant-cell tendon sheath tumour, pigmented villonodular synovitis, granuloma annulare, ruptured epidermoid cyst, sarcoidosis, and xanthogranuloma none of the multinucleated giant cells expressed CD10. The biological significance of CD10 in inflammatory and neoplastic disorders is largely unknown.

CD10 is a type 2 cell-surface neutral endopetidase. The CD10 positivity in tumour cells has been reported to correlate significantly with tumour progression and shorter survival in bladder cancer, diffuse large-cell lymphoma, renal pelvis transitional-cell carcinoma, and pancreatic endocrine tumours. The devastating osteolytic process of MRH may be related to the unfavourable biological effects of CD10+ ground-glass-like giant cells. Although the pathogenetic significance remains unknown, the aberrant expression of CD10 is a useful marker of ground-glass-like multinucleated giant cells in MRH and may be a potential target for treating intractable MRH.

Pathophysiology

The characteristic histiocytic proliferation MRH has been shown to result in the release of cytokines, including interleukin (IL)-12, IL-1, IL-6, and tumour necrosis factor alpha (TNFα).[8] Although almost any organ can be involved, the skin of the face and hands, and interphalangeal joints of the hands are most commonly affected. The stimulus for the histiocytic proliferation has not been fully elucidated, although there is an association with internal malignancies and abnormal immunological laboratory findings. Additionally, some patients with MRH are found to have a positive tuberculin skin test. In these patients, MRH will respond to anti-tuberculosis treatment. Additionally, patients with tuberculosis can also present with MRH.[8] This has led to the hypothesis that MRH is a paraneoplastic disease with chronic inflammatory and autoimmune features.

Associated conditions

MRH has been linked to a number of associated conditions, including hyperlipidaemia (30%), systemic vasculitis, tuberous sclerosis, a positive tuberculin test, and internal malignancy. A number of reports have identified a link between MRH and gynaecological malignancies. Two reports in the 1970s first described this

association, with the appearance of MRH preceding the diagnosis of cervical carcinoma[9] and ovarian carcinoma[10] by 2 and 10 months, respectively. From 1980 to 2006, to our knowledge, there have been 20 cases of MRH reported in association with malignancy: 4 of these were associated with ovarian, cervical, or endometrial cancers and 5 were associated with breast cancer. In 4 of the 9 cases, MRH preceded the malignancy diagnosis. In 8 of the 9 cases, MRH followed a parallel course in response to the cancer treatment.[11–13] Breast, ovarian, endometrial, and cervical cancers are among the most commonly reported malignancies linked to MRH.

Diagnosis

The diagnosis is confirmed by skin or synovial biopsy. Solitary reticulohistiocytomas have identical histological findings but there is no evidence of systemic disease.[14] Diseases that may possibly be confused with multicentric reticulohistiocytosis on the basis of clinical or histological findings are:

- Rheumatoid or psoriatic arthritis; chronic gout
- Sarcoid dactylitis—associated with discrete tubercles that lack foam cells or giant cells typical of multicentric reticulohistiocytosis
- Xanthomas
- Fibroxanthoma
- Histiocytosis X—usually presents in childhood and proliferating cells are epidermotropic Langerhans cells rather than of true monocyte–macrophage lineage
- Generalized eruptive histiocytoma—not associated with arthritis and lesions do not exhibit the typical multinucleate giant cells
- Tendon sheath giant-cell tumours—solitary, well-circumscribed nodules in the hands
- Farber's disease—lipogranulomatosis, usually fatal in infancy.

Treatment and course

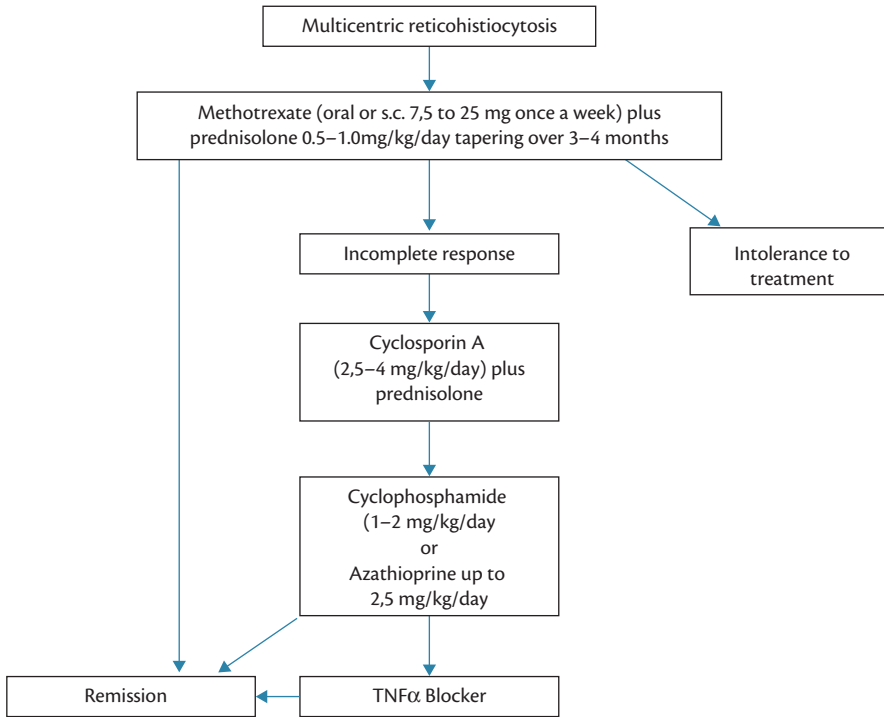
The disease often runs a waxing and waning course and sometimes stabilizes. It is difficult to predict the course in the individual case but as a rule the disease 'burns out' after 5–8 years, with regression of the cutaneous nodules, leaving the patient with severe joint deformities. Occasionally, systemic involvement can be severe enough to be life threatening but otherwise the prognosis is dominated by whether or not there is an associated malignancy. Various drug treatments have been proposed to suppress the condition, including corticosteroids, adrenocorticotropic hormone (ACT), salicylates, anti-malarials, cytotoxic agents, methotrexate (MTX), ciclosporin, and more recently TNFα blockers. There are no controlled trials, as the condition is so rare, and therefore reports of efficacy should be interpreted with caution. Up to 25% of cases have been associated with malignancy. There is no predominant type of cancer seen in this disorder and in most cases MRH does not run a parallel course to neoplasm. These observations have led several authors to avoid labelling MRH as a paraneoplastic disorder.[6,15] Nevertheless, several case reports emphasize the temporal association between MRH and underlying neoplasm, and stress the importance of treating the neoplasm to suppress the manifestations of MRH.[16–18] Regardless of whether MRH is a paraneoplastic disorder, work-up for underlying malignancy cannot be overemphasized.


Fig. 169.1 An algorithm for treating multicentric histiocytosis.

Liang and Granston[19] reported 13 cases of complete or near complete remission. Medications utilized include alkylating agents (mainly cyclophosphamide), MTX, ACTH, hydroxychloroquine (HCQ), and corticosteroids. Cyclophosphamide alone induced complete remission in three patients, MTX in one, and chlorambucil in one. In their opinion the optimal treatment for MRH is oral MTX plus prednisone tapered gradually over 3–4 months. In case of treatment failure or intolerance, the authors recommended cyclophosphamide 0.5–2 mg/kg per day either alone or added to MTX.

Ciclosporin and azathioprine seem to be acceptable alternatives to MTX. MTX and ciclosporin were shown to be effective even after treatment failure with cyclophosphamide,[20–21] and induced (near) complete remission in five patients. Prednisone is always used in combination with other medications and does not usually induce complete remission when used alone. Of interest is the emerging role of TNFα blockers in the treatment of MRH. The presence of TNFα and IL-1β in the synovial tissue of MRH patients has been reported.[15,22–23] Indeed, two case reports of successful treatment of MRH with etanercept have been published.[24–25] In both cases etanercept was used after treatment failure with multiple immunosuppressive agents, including cyclophosphamide. Although no case reports of MRH responding to other biological agents have been identified, probably all biologics could be utilized to treat MRH. Treating MRH with TNFα-neutralizing drugs, one has to keep the possible association with malignancy in 15–30% of cases in mind and these products should thus be used with caution.[26] Recently Goto et al.[27] reported a case of MRH in a 44 year-old Japanese woman that responded to alendronate infusion. Immunohistochemical analysis showed that some of the mononuclear cells in the skin were positive for RANKL. The authors postulated that these cells may induce histiocytes to differentiate into osteoclast-like multinucleated giant cells locally in the skin. Alendronate may directly act

on mononuclear cells, leading to inhibition of histiocyte differentiation and clinical remission. To the best of our knowledge this is the first case that reports a positive response to a bisphosphonate. This treatment modality deserves further study. Based on the above analysis, we propose an approach to the treatment of persistent MRH as shown in Figure 169.1.

CHAPTER 170

Inherited metabolic diseases

Bernhard Manger

Introduction

The term 'lysosomal storage diseases' (LSD) comprises a heterogeneous group of more than 40 hereditary diseases. They are all caused by a dysfunction of lysosomes. Lysosomal enzymes are necessary to metabolize various large molecules. Therefore, a genetic defect of such an enzyme usually leads to an accumulation of a non-degradable metabolite within the cell. The classification of LSD is based on the biochemical nature of this metabolite relevant for the pathogenesis of the disease. The most important subgroups are mucopolysaccharidoses (MPS), mucolipidoses, and sphingolipidoses (Table 170.1).[1] Glycogen storage diseases (except type 2—Pompe's disease) are not considered LSD. The first descriptions of LSD as separate disease entities date back to the late 19th century (Tay–Sachs disease 1881, Gaucher's disease 1882, Fabry's disease 1898). About 50 years later the role of lysosomal dysfunction was recognized and in 1963 the first underlying enzyme deficiency (α-glucosidase in Pompe's disease) was characterized. Most LSD are autosomal recessive disorders; the only exceptions are Fabry's disease and MPS type II (Hunter's disease) with an X-linked inheritance pattern.[2] The individual disease entities are very rare, most of them with a prevalence of less than 1 in 100 000. Considered as a group, however, one LSD occurs in about 8000 live births. The real prevalence might even be higher, because mild attenuated forms tend to be easily overlooked.[3] Enzyme replacement therapies (ERT) are currently available for Gaucher's, Fabry's, and Pompe's diseases as well as for several types of MPS.

Mucopolysaccharidoses

Pathogenesis

MPS are genetic, metabolic disorders caused by a deficiency of enzymes necessary for the degradation of glycosaminoglycans, such as dermatan, heparan, keratan, or chondroitin sulphates. Depending on the type of enzyme deficiency, the MPS are grouped into seven types (Table 170.1). The presenting symptoms of the various types, especially with respect to the musculoskeletal system, are fairly similar. The degree of the enzyme deficiency is responsible for the severity of the resulting disease. It can range from disability in early childhood with severe somatic and neurological manifestations to mild, attenuated forms with normal development and intelligence, which are frequently not diagnosed until adolescence or adulthood.

This is most evident in MPS I, the most frequent disorder in this group with an incidence of about 1 in 100 000. One of more than 100 known mutations of the gene for the enzyme α-L-iduronidase, located on chromosome 4, leads to an accumulation of heparan and dermatan sulphates in the lysosomes of various organs. Most involved are connective tissues, bone, airways, heart, kidneys, and in severe forms the central nervous system (CNS). The most severe manifestation is MPS I type Hurler, first described in 1919,[3] which presents within the first months of life with the typical phenotype (macrocephaly, broad nasal bridge, enlarged tongue and lips) and marked mental retardation. Without therapy these patients have a short life expectancy and will usually not be seen by a rheumatologist primarily.

A clinical presentation with much milder symptoms, MPS I type Scheie, is named after the ophthalmologist who first described this phenotype.[4] These patients have normal facial features and normal intellectual development, and may reach adulthood without having been diagnosed. Musculoskeletal and ocular symptoms are usually the reasons for the first consultation of a specialist. In 302 patients with MPS I type Scheie the diagnosis was made at a mean age of 9.3 years with a mean delay of 1.5 years after onset of symptoms.[5]

Between these two phenotypic presentations of MPS I exists a wide range of intermediate phenotypes, designated 'attenuated MPS I' or type Hurler/Scheie. The underlying genetic enzyme deficiencies of other MPS are summarized in Table 170.1.

Clinical manifestations

The musculoskeletal symptoms of MPS I, II, VI, and VII have many similar features and will be described together. They are frequently the first manifestation of the disease, especially in attenuated forms, and therefore the rheumatologist should be able to recognize them.[6,7] Joint stiffness or contractures are present in more than 80% of patients.[8] This is caused by a glycosaminoglycan (GAG) deposition in intra- and periarticular structures and is most prominent in the hands ('claw hands') (Figure 170.1), feet, and shoulders, but may involve any other joint. This reduced range of motion can cause considerable disability and a reduced quality of life. In contrast to other rheumatic disorders, which can cause reduced joint mobility, any signs of local or systemic inflammation are typically lacking in MPS.

Another frequent symptom is carpal tunnel syndrome, observed in 62% of MPS I type Scheie patients with a mean age of 12 years.[9] Since the overall frequency of carpal tunnel syndrome in children

Table 170.1 Lysosomal storage diseases

Disease	OMIM[a]	Enzyme deficiency
Mucopolysaccharidoses (MPS)		
MPS I		α-L-Iduronidase
Type Hurler	607014	
Type Scheie	607016	
Type Hurler/Scheie	607016	
MPS II (Hunter's syndrome)	309900	Iduronate sulphate sulphatase
MPS III (Sanfilippo's syndrome)		
Type III-A	252900	Heparan-S-sulphate-sulphaminidase
Type III-B	252920	N-Acetyl-D-glucosaminidase
Type III-C	252930	Acetyl-CoA-glucosaminide-N-acetyltransferase
Type III-D	252940	N-Acetylglucosaminine-6-sulphate-sulphatase
MPS IV (Morquio's syndrome)		
Type IV-A	253000	Galactosamine-6-sulphate-sulphatase
Type IV-B	253010	β-galactosidase
MPS VI (Maroteaux–Lamy syndrome)	253200	Arylsulfatase B
MPS VII (Sly's syndrome)	253220	β-Glucuronidase
MPS IX (Hyaluronidase deficiency)	601492	Hyaluronidase
Mucolipidoses (ML)		
ML II (I-cell disease)	252500	N-Acetylglucosaminyl-1-phosphotransferase
ML-III (Pseudo-Hurler's syndrome)		N-Acetylglucosaminyl-1-phosphotransferase
Type III-A	252600	
Type III-C	252605	
Sphingolipidoses		
GM1 Gangliosidosis		Ganglioside-β-galactosidase
Type I	230500	
Type II	230600	
Type III	230650	
GM2 Gangliosidosis		
Type I (Tay–Sachs disease)	272800	β-Hexosaminidase A
Type II (Sandhoff's disease)	268800	β-Hexosaminidase B
Type III (juvenile type)		β-Hexosaminidase A
GM2 activator protein deficiency	272750	GM2 activator protein
Niemann–Pick disease		Sphingomyelinase
Type A	257200	
Type B	607616	
Gaucher's disease		β-Glucocerebrosidase
Type I (adult form)	230800	
Type II (infantile form)	230900	
Type III (juvenile form)	231000	

Table 170.1 (Continued)

Lipogranulomatose (Farber's disease)	228000	Ceramidase
Fabry's disease	301500	α-Galactosidase A
Metachromatic leucodystrophy	250100	Arylsulpgatase A
Mucosulfatidosis	272200	Sulphatase-modifying factor 1
Krabbe's disease	245200	Galactosylceramide-β-galactosidase
Sphingolipid activatating protein deficiency	176801	Prosaposin, saposin B

is much lower than in adults, this symptom should raise the level of suspicion. More than one-half of all cases of carpal tunnel syndrome in children are caused by MPS.[10] Trigger fingers in MPS can be caused by glycosaminoglycan deposits within tendon sheaths.[11]

The characteristic bone involvement in MPS is described as dysostosis multiplex. This comprises skeletal abnormalities such as macrocephaly, odontoid hypoplasia, flattened vertebral bodies, thoracolumbar kyphosis, and thickening of ribs, clavicles, and phalanges. Lower limb abnormalities include flattened acetabula (Figure 170.2), dysplasia of femoral heads, coxa valga, and genu valgum. Growth retardation can be present but is usually not the leading symptom in attenuated MPS.

In contrast to the other variants, MPS type IV is characterized by significant joint hypermobility resulting from ligamentous laxity and bone hypoplasia or deformity. It is most obvious in hands and wrists and contrasts with proximal stiffness. MPS type III is mainly a neurological disorder with few or no musculoskeletal manifestations and for type IX there are only very few cases reported in the literature, with normal joint mobility.

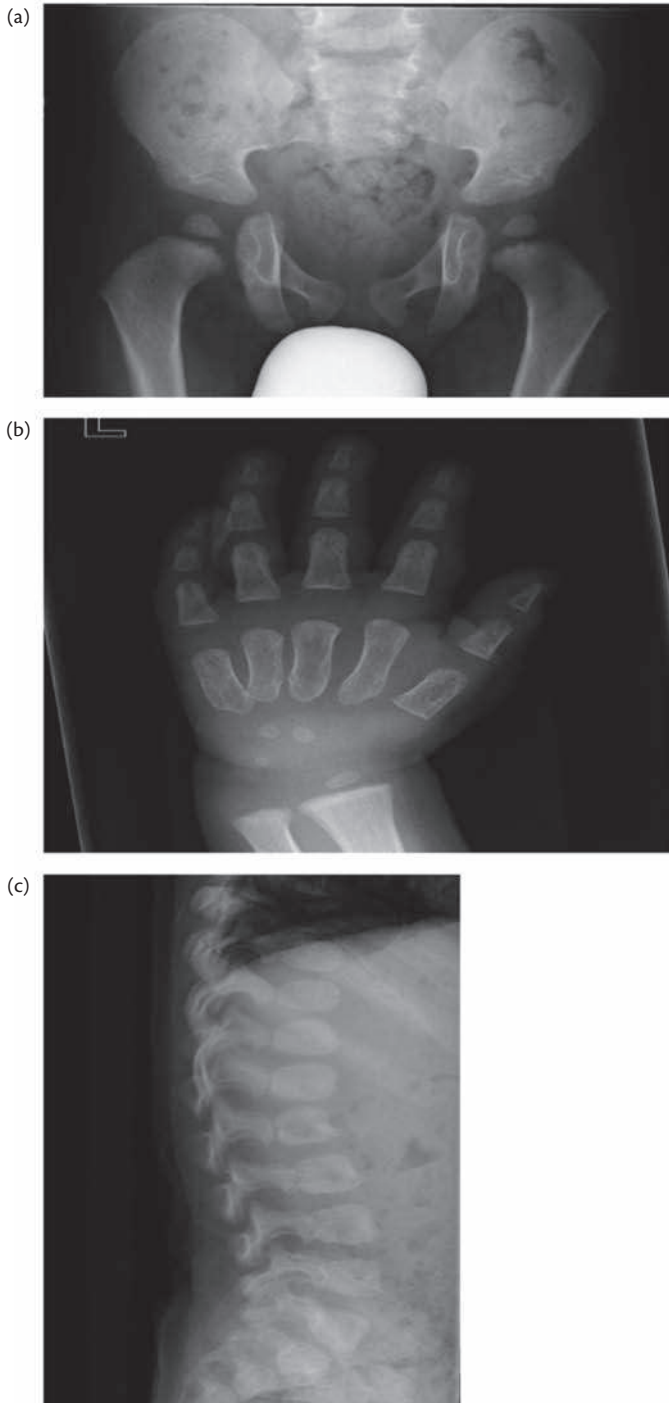
Besides bone and joint manifestations, patients with attenuated forms of MPS frequently develop corneal clouding and thickening with dysfunction of mitral and aortic valves as leading symptoms. Other typical symptoms include frequent pulmonary and ear infections, obstructive sleep apnoea, hearing loss, abdominal hernias, hepatosplenomegaly, and spinal cord compression.[3]


Fig. 170.2 Dysostosis multiplex. A 2 year old boy with Hunter's syndrome (MPS II): (A) Radiograph of the pelvis showing flared iliac bones with flattened acetabula. (B) Radiograph of the left hand showing bullet-shaped phalanges and short metacarpals with proximal pointing. Diagnosis

A recently published algorithm recommends a quantitative and qualitative analysis of GAG excretion in a specialized laboratory for all patients with joint contractures without clinical or laboratory signs of inflammation. Measuring an elevated GAG concentration in the urine is very suggestive for MPS, but a negative test does not rule out this diagnosis. The determination of specific enzyme activities in plasma or in cultured fibroblasts or leucocytes is the diagnostic gold standard for defined MPS disorders. Gene sequencing can then identify the underlying mutation.[8]

Therapy

The optimal treatment of all the comorbidities of MPS requires a multidisciplinary approach involving physiotherapists, cardiologists, otorhinolaryngologists, pneumologists, rheumatologists, neurosurgeons, and orthopaedic surgeons.[12]

Treatment of the underlying enzyme deficiency is possible by two different principles: haematopoietic stem cell transplantation and ERT. Haematopoietic stem cell transplantation within the first 2 years of life is indicated for severe MPS forms with neurological involvement, because stem cells can engraft and differentiate in the CNS. In contrast, infused enzymes are too large to cross the blood–brain barrier. Therefore, ERT is the treatment of choice for non-neurological types and attenuated forms of MPS. ERT with recombinant form of the deficient enzymes has been approved for MPS I (laronidase), MPS II (idursulfase), and MPS VI (galsulfase), a therapy for MPS IV and VII, is in development. An improvement of hepatomegaly, walking ability, shoulder mobility, and enhanced quality of life has been demonstrated with ERT.[13,14]

Fabry's disease

Pathogenesis

Fabry's disease is a hereditary, X-linked LSD, caused by a reduced or absent activity of α-galactosidase A. More than 60 mutations of the gene for this enzyme, located on the long arm of the X chromosome, have been described. The reduced enzyme activity leads to an accumulation of the glycosphingolipid globotriaosylceramide in the lysosomes particularly of endothelial cells. The characteristic skin manifestations were first described in 1898, independently by two dermatologists, J. Fabry and W. Anderson.[12] The prevalence of the disease is about 1 in 40 000 males. Heterozygous women can also develop a form of Fabry's disease, but this is usually milder due to random X-chromosomal inactivation. The mean delay between the onset of symptoms and diagnosis is 14 years in men with Fabry's disease, in women even more than 16 years.[15]

Clinical manifestations

Normally, the first symptoms appear in schoolchildren or young adults. These consist of attacks of intense burning pain and paresthesias in the extremities (acroparesthesia). These attacks can be triggered by physical exercise, stress, rapid temperature changes, or infection. Such a disease flare itself can cause fever, adynamia, and elevation of inflammatory markers. For that reason, the pain in hands, wrists, feet, and ankles is sometimes misinterpreted as a symptom of juvenile idiopathic arthritis or rheumatic fever. The pathogenetic basis of these symptoms is a C-fibre neuropathy caused by globotriaosylceramide deposits in vasa nervorum, neurons, and spinal ganglia.[16] Crucial diagnostic information can be obtained from the medical history. Frequently patients report heat or exercise intolerance and the inability to sweat (hypohidrosis). When the patient reaches adulthood, the acroparesthesias slowly subside and symptoms from other organ systems arise. An early manifestation is also the appearance of non-blanching angiokeratomas at thighs, buttocks, and around the umbilicus (Figure 170.3). These

Fig. 170.3 Non-blanching angiokeratomas around the umbilicus in a patient with Fabry's disease.

are characteristic tiny, dark red, painless papules with a characteristic histology. Therefore, the initial diagnosis of Fabry's disease is frequently established by a dermatologist ('angiokeratoma corporis diffusum Fabry'). Another symptom is corneal clouding with a typical linear pattern of whorled opacities within the cornea (cornea verticillata). This finding is so characteristic on slit-lamp examination that the ophthalmologist also plays a key role in the diagnostic process. The only differential diagnoses of these corneal opacities are drug-induced alterations (e.g. amiodarone, chloroquine).

In adulthood, untreated Fabry's disease leads to various visceral manifestations: kidney involvement initially leads to proteinuria and slow loss of function progressing over the years to endstage renal failure. Typical cardiac manifestations are valvular abnormalities (most frequently mitral regurgitation), ventricular hypertrophy, congestive heart failure, atrial fibrillation, and other arrhythmias. Cerebrovascular symptoms include dizziness, tinnitus, hearing loss, transient ischaemic attacks, white matter lesions, and early stroke. Gastrointestinal involvement presents as diarrhoea, nausea, malabsorption, and abdominal pain. Affected women may experience acroparesthesias in adolescence and cardiac symptoms in adulthood, but a progression to endstage renal disease is very rare.

Diagnosis

The most important diagnostic clue is a detailed family history with a focus on renal, cardiac, or cerebrovascular disorders at a relatively young age in (male) relatives. In Fabry registers more than 90% of all patients had at least one diseased relative.[17] In males with the classic phenotype, the diagnosis is easily confirmed by measuring a reduced α-galactosidase A activity in plasma or leukocytes. In females the enzyme activity can be in the low normal range, so the direct detection of a mutation in at least one allele of the α-galactosidase A gene may be required.

Therapy

The infusion of α-galactosidase A can reverse globotriaosylceramide depositions in involved tissues and inhibit disease progression. Therefore, ERT is indicated in all affected men once the diagnosis is established. Women with substantial disease manifestations and children with severe acroparesthesia, fatigue, and exercise and heat intolerance should also receive this treatment. Two compounds have been approved for the treatment of Fabry's disease: a gene-activated

human α-galactosidase A (agalsidase α) and a recombinant human α-galactosidase A (agalsidase β). Despite slight differences in glycosylation patterns the specific activity and immunogenicity of both products appears similar, and infusion reactions caused by IgG antibodies to the protein moiety of the molecules can occur. The approved dosages are 0.2 mg/kg body weight for agalsidase α and 1 mg/kg body weight for agalsidase β as biweekly infusions.[18,19] After prolonged treatment with agalsidase β, a clearance of globotriaosylceramide deposits has been demonstrated histologically in kidneys, heart, and skin.[20]

Gaucher's disease

Pathogenesis

Gaucher's disease was initially described in 1882 and is considered the most frequent LSD with a prevalence of 1 in 60 000 live births. It is caused by a defect of the enzyme β-glucocerebrosidase encoded on chromosome 1. Because there are more than 200 described mutations the phenotype can be very heterogeneous. Of interest for the rheumatologist is mainly the non-neuronopathic type I of Gaucher's disease (about 85% of all cases). The underlying enzyme deficiency causes an accumulation of glucocerebrosides in tissue macrophages, causing them to increase in volume ('Gaucher cells') which leads to bone marrow replacement and hepatosplenomegaly. In addition, those macrophages become activated and influence the production of proinflammatory cytokines and immunoregulatory functions of B lymphocytes and neutrophils.[2,7]

Clinical manifestations

The musculoskeletal symptoms are mainly caused by the bone marrow infiltration and expansion by Gaucher cells. Vessel occlusions and elevated intraosseous pressure in combination with cytokine release lead to an increased bone turnover and defective bone remodelling. Consequences are osteopenia, bone pain, avascular necrosis, osteolytic lesions, pathologic fractures, and deformities (Figure 170.4). If these pathologies are located close to a joint, they
Fig. 170.4 T1 (left)- and T2 (right)-weighted MRI obtained from the lower femur and upper tibia of a 30 year old woman with non-neuronopathic Gaucher's disease experiencing pain due to acute avascular necrosis of bone.

Table 170.2 Clinical and laboratory features of lysosomal storage diseases relevant for the rheumatologist

Disease	Musculoskeletal symptoms	General/visceral symptoms	Laboratory tests	Musculoskeletal imaging	Differential diagnosis
Mucopoly-saccharidoses	Joint contractures, carpal tunnel syndrome, trigger finger, dysostosis multiplex, hip dysplasia, spinal cord compression *In type IV*: ligamentous laxity/joint hypermobility	Corneal clouding, glaucoma, valvular heart disease, hernias, hepatosplenomegaly, pulmonary and ear infections, growth retardation	Inflammatory parameters normal, glucosaminoglycane excretion in urine ↑ (altered patterns of GAG excretion), enzyme activities in leukocytes ↓	Dysostosis multiplex, hip dysplasia, kyphosis, scoliosis, gibbus formation	Other causes for carpal tunnel syndrome, tenosynovitis, JIA, spondyloarthritis, fibromatoses
Fabry's disease	Painful attacks of acroparesthesia in hands and feet	Heat intolerance, hypohidrosis, fever, adynamia, cornea verticillata, angiokeratomas, proteinuria, renal failure, cardiac arrhythmias, ventricular hypertrophy, cardiomyopathy, cerebrovascular events, nausea, diarrhoea, malabsorption, abdominal pain	Inflammatory parameters ↑ (during flares), α-galactosidase in plasma or leucocytes ↓ or genotyping, *later*: creatinine ↑, proteinuria	Normal	Polyneuropathies, JIA, adult-onset Still's disease, autoinflammatory diseases, collagen vascular diseases, vasculitides, amyloidosis, 'growing pains'
Gaucher's disease	Bone pain, bone deformity, pathologic fracture, AVN	Splenomegaly, hepatomegaly, haemorrhagic diathesis, growth retardation	Pancytopenia, inflammatory parameters ↑, chitotriosidase ↑, β-glucocerebrosidase ↓	Osteopenia, osteolytic lesions, bone infarctions, AVN, bone marrow infiltration (MRI)	Other causes for AVN, oligoarthritis, autoinflammatory diseases, multiple myeloma, sickle cell anaemia, osteomyelitis

AVN, avascular necrosis; GAG, glycosaminoglycan, JIA, juvenile idiopathic arthritis.

can cause effusions and immobility. Because of the local and systemic inflammatory character a misinterpretation of the symptoms as chronic rheumatic condition is not uncommon.[21] The symptoms frequently present as flares or 'bone crises', therefore sickle cell anaemia or osteomyelitis also have to be considered in the differential diagnostic process. All symptomatic patients with Gaucher's disease present with splenomegaly and usually also hepatomegaly. The volume of the spleen can increase enormously and lead to pain, infarction, and replacement of abdominal or pelvic organs. The resulting hypersplenism results in anaemia, thrombocytopenia, and thus fatigue and bleeding diathesis. Less frequent organ manifestations are interstitial lung disease and pulmonary hypertension.

Diagnosis

In most cases, the bony deformities, osteolytic lesions, fractures, or avascular necroses are initially detected by conventional radiographs. In contrast, MRI is able to detect the underlying bone marrow infiltration already in early stages of the disease. Frequently, the initial diagnosis of Gaucher's disease is established when a bone marrow biopsy is performed because of cytopenias and the typical macrophages are found.

Confirmation of the diagnosis requires measurement of a reduced β-glucocerebrosidase activity in leucocytes. A helpful, but less specific test is the determination of plasma chitotriosidase activity. This parameter is markedly elevated in most Gaucher patients and can also be used for therapy monitoring.

Therapy

ERT is the treatment of choice in non-neuronopathic Gaucher's disease. Recombinant human glucocerebrosidase (imiglucerase,

velaglucerase α) is give as infusions of up to 60 U/kg body weight at 2 week intervals. Regular follow-up visits are required for dose adaptations depending on clinical and laboratory parameters. This treatment not only leads to a normalization of haematological parameters and reduction of liver and spleen size, but also an improvement of acute and chronic bone symptoms.[22]

Conclusion

LSD can cause a variety of musculoskeletal symptoms (Table 170.2). These are frequently the initial reason why children and young adults with these disorders seek medical advice. Because effective treatments are available for several of these disorders (MPS I, II, VI, Fabry's and Gaucher's disease), an early diagnosis has become crucial for the preservation of organ functions and quality of life. The rheumatologist may play a key role in the diagnostic process and should therefore be familiar with the typical clinical manifestations of these diseases.

Rheumatological manifestations of endocrine disorders

Sanjeev Sharma and Gerry Rayman

Introduction

Involvement of the musculoskeletal and connective tissue systems is common in endocrine disorders, with many patients initially presenting to the rheumatologist. On the other hand patients, with established endocrine disease may later develop musculoskeletal-related complications. Therefore, to ensure that the associated condition is not missed or the diagnosis not delayed, both endocrinologists and rheumatologists need to be aware of these associations.

Endocrine disorders can involve a variety of tissues including bones, muscles, nerves, and joints. This chapter considers these associations from a rheumatologist's point of view and presents them in four categories: endocrine conditions that involve bones, joints, muscle, and supporting adnexa. A tabular classification of endocrine disorders with rheumatological complications has also been provided to complete the description from the endocrine perspective.

Disorders of bones

A large number of endocrine disorders can affect the skeletal system. The common skeletal disorders arising from or associated with endocrinopathies as now described.

Osteoporosis and osteomalacia

Osteoporosis results from bone loss due to age-related changes in bone remodelling as well as extrinsic and intrinsic factors that exaggerate this process, of which endocrinopathies constitute an important aggravating factor.[1] In contrast, osteomalacia refers to abnormal bone because of abnormal mineralization of the bone matrix. The following endocrine disorders are associated with these states.

Parathyroid disorders

Both hyperparathyroidism and hypoparathyroidism can worsen osteoporosis although the former is more commonly encountered in the clinical setting. Primary hyperparathyroidism (PHPT) results

from parathyroid adenomas or hyperplasia of the parathyroids and is characterized by high levels of both calcium and parathyroid hormone (PTH; Table 171.1) or hypercalcaemia in the presence of detectable rather than suppressed PTH levels. It preferentially affects cortical bone as opposed to trabecular bone and therefore forearm bone mineral density (BMD) in comparison with vertebral BMD is helpful when assessing the extent of the involvement. Osteoporosis is one of the indications for parathyroidectomy. Silverberg et al.,[2] in a 10 year old prospective study, showed improvement of BMD and normalization of biochemical markers following surgical treatment of PHPT. Medical management of PHPT includes use of bisphosphonates and correction of vitamin D deficiency.

Secondary hyperparathyroidism (SHPT) is encountered commonly in calcium and vitamin D deficiency and also in advanced chronic kidney disease. Rarely long-standing and untreated SHPT leads to autonomous activity of the parathyroid glands causing tertiary hyperparathyroidism (THPT).

Hypoparathyroidism is a relatively rare disorder, most commonly encountered following parathyroid and thyroid surgeries. Less common is primary hypoparathyroidism due to autoimmune destruction and very rarely hypoparathyroidism can follow neck radiation. Hypoparathyroidism is characterized by low calcium and high phosphate levels in the presence of a low PTH level. Rheumatological symptoms include bone pain, muscle cramps, and paraesthesiae. Untreated hypoparathyroidism can lead to entheseal

Table 171.1 Types of hyperparathyroidism

Type	Calcium	PTH	Management
Primary	↑	↑ (or normal)	Medical/surgical
Secondary	↓ (or normal)	↑	Correction of vitamin D deficiency, calcitriol, phosphate binders
Tertiary	↑	↑	Parathyroidectomy

PTH, parathyroid hormone.

and ligamentous ossifications. Replacement therapy with calcium and calcitriol is the cornerstone of treatment but care should be taken to prevent hypercalciuria since these patients are susceptible to nephrocalcinosis and urinary stone disease.

Hyperthyroidism

Hypothyroidism is defined as a state of excess circulatory thyroid hormones most commonly related to either overactivity of the thyroid gland (diffuse or nodular disease) or iatrogenic due to over-replacement of thyroid hormones. Hyperthyroidism leads to increased bone loss mainly affecting cortical than trabecular bone. Baqi et al.[3] showed that BMD and markers of bone turnover were significantly better when thyroid-stimulating hormone (TSH) was maintained between 0.35 mU/litre and 6.3 mU/litre compared to women with a TSH lower than 0.3 mU/;itre. While correction of the hyperthyroid state remains the cornerstone of management, use of bisphophonates can help to prevent bone loss in those in whom the hyperthyroid state is difficult to control[4] and in those who have already developed osteoporosis.

Vitamin D deficiency

In the United Kingdom, the prevalence of vitamin D deficiency in all adults is around 14.5%, but may be more than 30% in those over 65 years old, and as high as 94% in otherwise healthy South Asian adults.[5] UVB radiation mediates the majority of vitamin D production in the body by converting cutaneous 7-dehydrocholesterol to cholecalciferol (vitamin D_3), but this can be supplemented by ingestion of fatty fish (cod, salmon) and plant ergocalciferol (vitamin D_2).

Rickets, which is classically seen in children prior to the fusion of the epiphyses, is now uncommon in the developed world. Poor mineralization of bones leads to bowing of tibia, swelling of rib cartilages ('rachitic rosary'), widening of epiphyseal joints, and also causes developmental delay. Older people with reduced exposure to sunlight are susceptible to osteomalacia. Apart from bone pain, vitamin D deficiency may also cause proximal myopathy resulting in further restriction of daily activities. The Endocrine Society[6] recommends using the serum circulating 25-hydroxyvitamin D (25(OH) D) level, measured by a reliable assay, to evaluate vitamin D status in patients who are at risk of vitamin D deficiency.

Vitamin D *deficiency* is defined as a 25(OH) D level below 20 ng/mL (50 nmol/litre) and vitamin D *insufficiency* as a 25(OH) D of 21–29 ng/mL (50–72.5 nmol/litre). The Endocrine Practice Guidelines[6] recommended dietary intakes for patients at risk as given in (Table 171.2).

Table 171.2 Recommended intake of vitamin D[6]

Age group (years)		Daily requirement (IU)
Children	1–8	600–1000
Males	9–18	600–1000
	>19	1500–2000
Females	9–18	600–1000
	>19	1500–2000
Pregnancy		1500–2000
Lactation		1500–2000

Cushing's syndrome and use of glucocorticoids

Cushing's syndrome is caused by excessive endogenous production of steroids related to adrenal conditions (adenoma, hyperplasia, or malignancy) or less commonly due to a pituitary adenoma (Cushing's disease). The same phenotypical features of centripetal obesity, easy bruising, ecchymosis, and hypertension can also be caused iatrogenically by the use of glucocorticoid medications to treat other medical conditions. The rheumatological effects of glucocorticoid excess include increased bone resorption and acceleration of osteoporosis leading to increased risk of fractures, more in trabecular than cortical bone. In a study by Chiodiniet al.,[7] subclinical hypercortisolaemia was found in 4.8% among patients with osteoporosis.

All patients with Cushing's syndrome or on glucocorticoid therapy equivalent to 5 mg or more of prednisolone/day for 3 months should have modification of risk factors and BMD measured at baseline.[8] If the T-score is less than −1, then consider bone protection by treatment with bisphophonates along with calcium (total 1500 mg/day) and vitamin D (400–800 IU/day).[8]

Hyperprolactinaemia

Hyperprolactinaemia is the commonest of the pituitary disorders and can result from a variety of disorders that cause oversecretion of the peptide hormone prolactin by the lactotroph cells of the anterior pituitary gland. These are summarized in Box 171.1. Hyperprolactaemia commonly presents with one or a combination of galactorrhoea, amenorrhea, infertility, and loss of libido. Sustained elevation of prolactin levels results in hypoestrogenism with subsequent accelerated bone loss and osteoporotic fractures.[9] Hyperprolactinaemic patients should be screened for osteoporosis and treated on standard lines. Similarly, young patients with osteoporosis and amenorrhoea should be screened for hyperprolactinaemia.

Hypogonadal states

Age-related changes in skeletal architecture leading to osteoporosis in both sexes are due to diminution of sex steroids. The relationship of the female menopause with osteoporosis is well recognized, but male age-related osteoporosis is less well recognized; it is defined as the occurrence of osteoporosis in men over 70 years of age without any other known cause.[9] The rate of decline of both cortical and trabecular bone is similar in both sexes but men have a reduced fracture rate due to attainment of a higher peak bone density and unlike women, do not have the equivalent of a period of accelerated bone turnover as occurs during the perimenopausal period. While hypogonadal levels of total testosterone are clearly associated with osteoporosis and increased hip fractures,[10] across the testosterone range reduction of BMD has only been shown to be directly related to bioavailable testosterone and not total testosterone—the latter does not necessarily reflect bioactive testosterone, being influenced by the level of sex hormone binding globulin.[11]

Classical hypogonadal conditions such as Klinefelter's syndrome, Kallman's syndrome, and idiopathic hypogonadotrophic hypogonadism as well as secondary hypogonadism (e.g. pituitary adenomas, following hypophysectomy) are commonly associated with osteoporosis. Indeed, it is not unusual for these conditions to be discovered when the patient presents with a fragility fracture. Testosterone treatment in hypogonadal men is very effective and will increase BMD by approximately 7.5% in the lumbar region (L2–4) and by 5% in the femoral trochanteric area.[12] Such replacement

has to be carefully instituted and the patient and spouse/partner counselled, as behavioural changes and increased libido can cause significant emotional and psychological distress to the patient and the relationship.

Hyperparathyroidism

Skeletal manifestations of hyperparathyroidism were common in the past but with increased awareness and earlier detection of asymptomatic cases, the overall incidence of skeletal-related compliactions is declining.

Osteitis fibrosa cystica

Osteitis fibrosa cystica (OFC), a distinctive feature of hyperparathyroidism, is now rare with a reported incidence of 3–4% in PHPT and 1.5% in SHPT in some series.[13] It is due to exaggerated osteoclast-mediated bony resorption with replacement of marrow and cellular elements with fibrosis. A classic example of OFC is the brown tumour commonly seen in the mandible and maxilla, but it can also involve ribs, clavicle and pelvis. Clinically, these are benign, soft, and painless but can lead to disfigurement. There is no specific treatment other than managing the hyperparathyroidism. Other associations of OFC include thinning of cortical bone leading to a 'salt-and-pepper' appearance and disappearance of lamina dura from the root of teeth.

'Rugger jersey' spine

This classic feature of SHPT associated with chronic renal failure (CRF) is characterized by alternate sclerotic bands on the upper and lower vertebral body margins sandwiching areas of lucency in the body, giving the striped appearance of a traditional rugby jersey. Some studies have reported an incidence as high as 27% in patients with CRF on haemodialysis.[14]

Subperiosteal resorption

This is now the commonest radiological feature of hyperparathyroidism. Resorption along the shaft of phalanges gives a 'sawtooth' appearance but can also affect the humerus, clavicles, and sacroiliac joints, leading to pseudo-widening of joints. Acroosteolysis is an extreme form of resorption of the tufts of terminal phalanges seen in radiographs of the hand.

Fragility fractures

One-half or more of patients with hyperparathyroidism are asymptomatic and diagnosed when screened for complications including fragility fractures, osteoporosis, and renal calculus. Although cortical bones are more affected, leading to involvement of the appendicular skeleton, the incidence of vertebral fractures is also increased. Involvement of sacroiliac joint causes deformities of the pelvic skeleton and gait problems.

Disorders of joints

Endocrine-associated arthropathies constitute an important differential in the diagnosis of arthritis associated with systemic disorders. Not uncommonly, the endocrine diagnosis only comes to light as a result of the investigations undertaken to evaluate the arthritic complaint.

Diabetes mellitus

This is the commonest of the endocrine conditions. In 2009, the estimated worldwide prevalence of diabetes was 285 million and this is expected to increase to 438 million by 2030.[15] In England in 2012, 2.9 million people have been diagnosed with diabetes with another 800 000 undiagnosed. It has been estimated that by 2025 there will be more than 4 million people with diabetes in the United Kingdom.[16] Broadly, type 1 diabetes is caused by absolute insulin deficiency mediated by an autoimmune destruction of the pancreatic beta cells, while type 2 diabetes is due to insulin resistance and relative insulin deficiency. Characterization of rheumatological manifestations in diabetes is mostly based on observational data,[17,18] although some conditions are classically seen in diabetes (Box 171.2).

Box 171.2 Rheumatological manifestations in diabetes mellitus

Manifestations specific to diabetes

- Diabetes muscle infarction (rare)

Manifestations more common in diabetes

- Limited joint mobility/diabetes cheiroarthropathy
- Charcot's osteoarthropathy
- Carpel tunnel syndrome
- Tarsal tunnel syndrome
- Dupuytren's disease
- Stenosing flexor tenosynovitis (trigger finger)
- Adhesive capsulitis of the shoulder (frozen shoulder syndrome)
- Calcific shoulder periarthritis
- Plantar faciitis
- Achilles tendonitis

Manifestations sharing risk factors of diabetes

- Diffuse idiopathic skeletal hypersostosis
- Crystal-induced arthropathies (gout and pseudogout)

Adapted from Lebiedz-Odrobina and Kay.[19]

Diabetes cheiroarthropathy (limited joint mobility)

First described by Lundbaek in 1957,[20] diabetes cheiroarthropathy is not a classical joint disorder since there is more involvement of periarticular structures. Different series have quoted its prevalence as 30–58% in type 1 diabetes and 45–76% in type 2 diabetes,[21] but common determinants in both groups include increased duration of diabetes and presence of microvascular complications including retinopathy and nephropathy.[22,23]

It is characterized by thick, tight, waxy skin on the dorsal aspect of the fingers and metacarpophalangeal joints and sclerosis of tendon sheaths resulting in limited joint mobility and characteristic flexion contractures (inability to fully flex or extend the fingers). The characteristic clinical finding is the so called 'prayer sign'—the inability to completely appose the palms without a gap remaining between opposed palms and fingers. The underlying cause is thought to be multifactorial and related to increased glycosylation of collagen in the skin and periarticular tissue. There is no specific therapy apart from physiotherapy and efforts to improve glycaemic control.

Charcot's osteoarthropathy

Although neuropathic osteoarthropathy was first described in 1868 by Jean-Martin Charcot as a complication of neurosyphilis,[24] diabetes is now its commonest cause, with an estimated prevalence of 0.15% which increases to 13% in specialized foot clinics. Pathophysiologically, its development is believed to be related to a combination of repetitive trauma or injury in an insensate foot *(neurotraumatic theory)* and autonomic neuropathy causing increased blood flow *(neurovascular theory)* leading to increased recruitment of osteoclasts causing release of proinflammatory cytokines which cause bone resorption and destruction. More recent evidence

implicates the RANK/RANK-ligand/osteoprotegerin (OPG) system in the pathogenesis of the osteoclastic resorption and osteopaenia.[25] Although almost invariably associated with chronic painless diabetic neuropathy, acute Charcot's osteoarthropathy is often painful, but the degree of pain may be less than expected in relationship to the severity of the clinical and radiological findings, and indeed pain is frequently absent. The foot is the most commonly affected region, with a predilection to involve the ankle mortise, tarsometatarsal, metatarsophalangeal, and interphalageal joints. The area is characteristically warm, with overlying skin erythema and diffuse swelling. The diagnosis is mainly based on clinical features aided by radiological investigations (Figure 171.1) including MRI and indium-111-leucocyte (^{111}In-WBC); but even then distinction from osteomyelitis can remain difficult.

Immobilization with total contact cast for up to 12 months to support the joint and prevent further trauma is the cornerstone of treatment. Intravenous bisphophonates are commonly used as adjuvant therapy to inhibit osteoclast-mediated bone destruction but the evidence for their use is limited.[26]

Diffuse idiopathic skeletal hyperostosis—Forestier's disease

Diffuse idiopathic skeletal hyperostosis (DISH) was described in 1950 by Forestier and Rotes-Querol as an age-dependent condition characterized by calcification and ossification of ligament, tendon, and joint capsule (enthesial) insertions. The anterior and posterior longitudinal ligaments are commonly involved, resulting in restriction of a range of spinal movements. Its association with diabetes is probably related to hyperinsulinaemia as evidenced by prevalence

Fig. 171.1 Standing plain radiograph of knee showing early osteoarthritic changes and an increase in joint space

(13–40%)[27] when compared to the general population. Raised insulin and insulin-like growth factor (IGF)-1 levels have been postulated as contributory to accelerated ossification in DISH,[28] although this association has not been seen in patients with impaired glucose tolerance.[29]

Treatment is supportive with analgesia, local corticosteroid injections, and spinal physiotherapy.

Crystal-induced arthritis

Gout

Obesity, insulin resistance, and risk for type 2 diabetes as components of the metabolic syndrome have now been well documented in many population studies. Analysis of the NHANES III data showed that the prevalence of the metabolic syndrome increases substantially with increasing levels of serum urate.[30] After adjusting for age, gender, and risk factors for development of the metabolic syndrome, i.e. diabetes, hypertension, and body mass index (BMI), the likelihood of having the metabolic syndrome was found to be threefold greater if gout was present.[31] However the association between hyperuricaemia and diabetes remains an epidemiological observation and relative contributions of uric acid underexcretion and uric acid overproduction to the hyperuricemia of patients with the metabolic syndrome remain to be determined.

Pseudogout

The association between chondrocalcinosis (CC), i.e. deposition of calcium pyrophosphate dehydrate (CPP) crystals in hyaline and fibrous cartilage, remains debatable in the absence of any large population studies. In a study by Silveri and colleagues[32] no statistical difference was observed between the prevalence of diabetes mellitus and impaired glucose tolerance in CC patients vs controls.

Adhesive capsulitis of the shoulder (frozen shoulder syndrome)

Frozen shoulder syndrome is characterized by restricted shoulder joint movement especially affecting external rotation and abduction. It is more common in people with diabetes, with an estimated prevalence of around 10% in type 1 diabetes and 20% in type 2 diabetes.[33] There is no association with either glycaemic control or disease duration but it occurs more frequently in those with autonomic neuropathy and limited joint mobility.[34]

Pathophysiologically, it is believed to be related to increased expression of fibrogenic growth factors and proinflammatory cytokines including interleukin (IL)-1β and tumour necrosis factor (TNF)α and β leading to excessive accumulation of collagenous tissue. Analgesics, physiotherapy, and intra-articular corticosteroid injections form the cornerstone of treatment. The latter is very likely to cause deterioration in glycaemic control. It is therefore important to inform patients so that they can make appropriate changes to their diabetes medications or seek advice if they are not self-adjusting.

Acromegaly

Arthropathy is one of the most common complications of acromegaly affecting up to 75% of patients.[35] The condition is a relatively rare, insidious in onset, progressive, and potentially life-threatening endocrinopathy characterized by excessive and uncontrolled secretion of growth hormone (GH) and most commonly caused by a GH-secreting pituitary tumour. Other causes, all very rare, include increased growth hormone releasing hormone (GHRH)

from hypothalamic tumours, ectopic GHRH from non-endocrine tumours, and ectopic GH secretion by non-endocrine tumours. Annual new patient incidence is estimated to be 3–4 cases per million population per year, with a mean age at presentation being 40–45 years. Excessive GH secretion leads to raised IGF-1 levels which act as the primary mediator of growth-promoting effects of GH. The pathogenesis of the arthropathy is a combination of early metabolic effects and subsequent mechanical changes. The direct effect of GH leads to growth of soft tissue and fibroblasts, causing excessive proliferation of connective tissue. Early treatment of the GH excess may reverse these changes, but if allowed to persist, altered joint geometry results in repeated intra-articular trauma resulting in scar, cyst, and osteophyte formation worsening the joint geometry. Box 171.3 provides a list of rheumatological manifestations of acromegaly.

Acromegalic arthropathy

Articular manifestations constitute an important and often presenting feature of acromegaly. Excessive and sustained GH levels, mediated by IGF-1, lead to proliferation of articular cartilage and periarticular supporting structures resulting in cartilage thickening and reduction of joint space. Initial changes including widening of joint spaces and periarticular soft tissue hypertrophy are partially reversible but continued GH secretion leads to irreversible changes which include and which in turn reduce joint mobility, laxity of joints and degenerative joint disease (Figure 171.2).[36]

Clinical features of acromegalic arthropathy include back pain due to involvement of the axial skeleton, especially the lumbar area. Large joints like hip, knee, and shoulder are also affected in 60–70% of patients. Permanent articular changes cause a considerable reduction of quality of life, which persists despite adequate medical or surgical treatment of the condition.

Box 171.3 Rheumatological manifestations of acromegaly

Phenotypical changes

- Prognathism
- Acral enlargement
- Macroglossia
- Acne
- Greasy skin
- Skin tags
- Gigantism (in childhood)

Musculoskeletal changes

- Arthralgia
- Arthropathy

Neurological changes

- Carpal tunnel syndrome
- Ulnar nerve compression
- Spinal stenosis

Fig. 171.2 Plain radiograph of ankle showing disrupted ankle mortise and midfoot due to a neuropathic joint.

Alterations of bone mineral density in acromegaly

There is conflicting data on whether acromegaly is a risk factor for osteoporosis. GH increase osteoblastic activity, an anabolic effect that is reflected in an increase in osteocalcin levels and an elevated BMD levels in cortical bone. When associated with reduced BMD this is related to the secondary hypogonadal state that is common in at least 50% of patients with acromegaly.[37] Importantly, the overall risk of fracture is not increased in acromegalics when compared with normal controls.[38]

Neuropathies

Acromegaly is also commonly associated with a variety of entrapment neuropathies which may present with classical symptoms such as paraesthesiae in the distribution of the median nerve in the hand, but not uncommonly non-classical features, e.g. aching in the forearm as in carpal tunnel syndrome. Spinal stenosis is a well-recognized complication of acromegaly and may present with lower back pain or lower limb ache and not necessarily as the classical intermittent claudication. Chronic GH and IGF-1 excess cause endochondral, marginal, and subligamentous growth of vertebral bone with resulting vertebral enlargement, and osteophyte formation and narrowing of the spinal canal. Early diagnosis and treatment are important in preventing this complication, which can progress to severely impair quality of life.

Endocrine conditions associated with calcium pyrophosphate deposition disease

Deposition of CPP crystals in found in a number of endocrine conditions, especially diabetes, hypothyroidism, and hyperparathyroidism.

It can lead to acute flare-ups of synovitis (pseudogout) or chronic degenerative disease (chondrocalcinosis).

Hyperparathyrodism

There is a strong association (18–25%) between CPP deposition disease and hyperparathyroidism,[39] and this was found to be a presenting feature in 7.5% of patients presenting with hyperparathyroidism for the first time.[40] Acute pseudogout attacks commonly involve the knees but can also involve the metacarpophalageal joints. This association could be due to the aggravating effects of sustained hypercalcaemia on age-related degenerative joint disease.

Hypothyroidism

There is a slightly increased prevalence of CC in hypothyroidism (odds ratio 1.94) but the mechanism is unclear. The joints commonly involved include knee, wrists, and metacarpals.

Disorders of muscles

Involvement of the muscular system is common in many endocrinopathies although their presentation can be non-specific. There are, however, some conditions such as diabetes muscle infarction (DMI) and diabetic amyotrophy that are specific to the endocrinopathy.

Diabetes muscle infarction

DMI is an unusual disorder of type 1 and type 2 diabetes patients with advanced microvascular damage including nephropathy. First described in Angervall in 1965,[41] more than 120 cases can be found in the literature,[42] and increasing awareness has led to prompt recognition of this previously underdiagnosed condition. Typically, acute presentation with atraumatic painful swelling, notably of the quadriceps or thigh muscles, is found in diabetic subjects with known microvascular complications including retinopathy and nephropathy. Laboratory investigations generally show high erythrocyte sedimentation rate (ESR), normal white cell count, and normal or mild elevation of creatine phosphokinase. MRI findings are invariably characterized by increased signal intensity of the diffusely enlarged muscle groups on T2-weighted sequences and gadolinium-enhanced images. Muscle biopsy is not necessary for diagnosis and should be reserved for patients with atypical presentations and lack of improvement. The disease is generally believed to be self-limiting, although recurrence occurs in one-half of the cases.[43] Treatment is usually supportive and consists of anti-inflammatory and anti-platelet agents.

Diabetic amyotrophy

Also known as proximal diabetic neuropathy, femoral neuropathy, or lumbosacral radioplexus neuropathy, this is due to an acute peripheral neuropathy usually affecting the thighs but occasionally the hips and buttocks. It is characterized by muscle pain with wasting and weakness and may present to the rheumatologist as pain in and around the hip with weakness. The cause is unclear but it is very commonly associated with symmetrical distal diabetic peripheral neuropathy. Characteristically it is accompanied by sudden weight loss and its resolution is accompanied by a return to former weight. It usually resolves after 6–12 months without specific treatment except supportive therapy, pain control, and maintaining good glycaemic control.

Myopathy

Myopathies are a group of conditions related to abnormal skeletal muscle state and present as muscle weakness, pain, cramps, muscle tenderness, and spasms in varying degrees. Although the exact pathophysiology remains incompletely understood, postulated mechanisms include disturbances in the function of the muscle fibres due to increased mitochondrial respiration, accelerated protein degradation, lipid oxidation and enhanced beta-adrenergic sensitivity to hormonal excess.[44] Common endocrinopathies that cause myopathies are the following:

- **Thyroid dysfunction**: both hypothyroidism and hyperthyroidism may cause a proximal myopathy.

- **Steroid myopathy**: Cushing's disease or the use of glucocorticoids may be associated with a proximal myopathy.

- **Parathyroid dysfunction**: both hyperparathyroidism and hypoparathyroidism, as previously described, can cause myopathy.

- **Hypoadrenalism and pituitary dysfunction:** when associated with secondary hypoadrenalism these may cause a variety of myopathic symptoms, but predominantly muscle weakness and symptoms of 'chronic fatigue'.

Disorders of supporting adnexa (ligaments, tendons, capsule, and retinacula)

Several important rheumatological manifestations of the adnexa are associated with endocrinopathies.

Carpal tunnel syndrome

Carpal tunnel syndrome (CTS) is an increasingly recognized neuromuscular disorder that has a prevalence of around 3.8% in the general population.[45] It is caused by entrapment of the median nerve within the carpal tunnel as it traverses the flexor retinaculum in the wrist, leading to pain and paraesthesia along the distribution of the median nerve in the hand. However, rheumatologists and other physicians should be aware of its increased occurrence in various endocrine disorders which include hypothyroidism (5–10%), acromegaly (30–50%), and diabetes mellitus (11–21%).

Dupuytren's disease

Dupuytren's disease (DD) is more common in diabetes (prevalence 16–42%) than in the general population (prevalence 7%).[46] It is a progressive but painless condition caused by hyperplastic contractures of the palmar aponeurosis (or palmar fascia). The ring and little finger are the fingers most commonly affected. The middle finger may be affected in advanced cases, but the index finger and the thumb are nearly always spared. Similar to diabetic cheiroarthropathy, the prevalence of DD among the diabetic population increases with age and duration of diabetes but is not associated with glycaemic control.[47]

Stenosing flexor tenosynovitis (trigger finger)

Compared to a prevalence of 2% in the general population, trigger finger is considerably commoner in the diabetic population with reported figures of 5–36%.[48] It is characterized by fixed flexion or extension contractures of the fingers due to fibrosis and thickening of the long flexor tendon sheaths. Similar to DD, it is more common in diabetics with a longer duration of disease and effects.

Lupus-like syndrome associated with anti-thyroid medications

Carbimazole and propylthiuracil are thionamide derivaties that are commonly used in the medical management of hyperthyroidism. Agranulocytosis is an uncommon but well-documented adverse effect of these drugs. Rarely, they have also been associated with lupus-like clinical states including rash, arthralgia, and positive

Table 171.3 Rheumatological manifestations of endocrine disorders

Endocrinopathy	Rheumatological manifestations affecting			
	Skeletal system	**Joints**	**Muscles**	**Supporting adnexa**

antinuclear antibodies in 10–53% of patients.[49] However, they do not fulfil the diagnostic criteria for drug-induced systemic lupus erythematosus.[50]

Conclusion

Endocrine disorders are associated with a wide variety of conditions affecting the musculoskeletal system and as such the first presenting symptom may be rheumatological in nature. It is therefore important that general practitioners and rheumatologists are aware of these possible associations. Similarly, endocrinologists need to be aware of the rheumatological complications that may result from the endocrine disorder such as spinal stenosis in acromegaly and lupus-type syndrome complicating anti-thyroid therapy.

Table 171.3 provides a summary list of the various endocrinopathies and associated rheumatological manifestations.

CHAPTER 172

Haemoglobinopathies

David Rees

Introduction

The haemoglobinopathies are a group of inherited disorders caused by mutations in one or more of the globin genes. They are the commonest single-gene disorders in the world, reaching polymorphic frequencies in most ethnic groups, apart from northern Europeans and the native populations of the Americas and Australia.[1] There are two main clinical syndromes caused by these mutations: thalassaemias and sickle cell disease. Other rarer phenotypes include haemolytic anaemia due to unstable haemoglobins, methaemoglobinaemia, and polycythaemia caused by mutations causing high oxygen affinity; none of these have significant rheumatological manifestations.

Thalassaemia syndromes

Thalassaemia is caused by a reduction in the rate of synthesis of one of the globin chains. The two main types are α thalassaemia and β thalassaemia.

α Thalassaemia

The α thalassaemias have relatively few rheumatological implications and are not considered in detail here. There are normally four functioning α globin genes, and α thalassaemia is usually caused by large deletions removing one or more of these, causing the following syndromes:

- **α Thalassaemia trait**: two or three functioning α globin genes cause this asymptomatic condition, associated with a reduction in the size and haemoglobin content of red cells.

- **Haemoglobin H disease**: if there is only one functioning α globin gene, mild to moderate haemolytic anaemia results, with the haemoglobin usually 70–100 g/L. Moderate splenomegaly is common and frequent blood transfusions rarely necessary. There is moderate erythroid bone marrow expansion, which is likely to result in some degree of osteopenia although this is rarely clinically significant.

- **Haemoglobin Bart's hydrops fetalis**: in this condition there are no functioning α globin genes, which causes severe fetal anaemia with almost inevitable fetal death in the third trimester.

β Thalassaemia

β Thalassaemia is caused by mutations in one or both of the β globin genes; these are typically point mutations or small deletions. There are more than 400 different β thalassaemia mutations, resulting in a full spectrum of clinical conditions from asymptomatic to transfusion dependence. Unlike α globin, β globin is not expressed in the fetus, and so the homozygous condition does not cause symptoms until three months of age at the earliest. The following syndromes occur:

- **β Thalassaemia trait**: inheriting one β thalassaemia allele causes mild, asymptomatic anaemia.

- **β Thalassaemia intermedia**: this condition involves significant anaemia and splenomegaly, which does not necessitate regular blood transfusions. Children are typically well for the first few years of life, but develop symptoms and require intermittent blood transfusions. It is caused by many different genotypes, most often when two mild β thalassaemia mutations are inherited.

- **β Thalassaemia major**: this occurs when two severe β thalassaemia mutations are inherited. Severe anaemia, failure to thrive, bony distortion, and massive splenomegaly occur in the first year of life; death occurs without the instigation of regular blood transfusions to maintain the haemoglobin above 95 g/L. These transfusions results in inevitable iron overload and chelation is started after about 12 transfusions, to prevent endocrinopathy and fatal cardiomyopathy. Haematopoietic stem cell transplantation is potentially curative if a suitable sibling donor is available.

Rheumatological complications of thalassaemia

Osteopenia

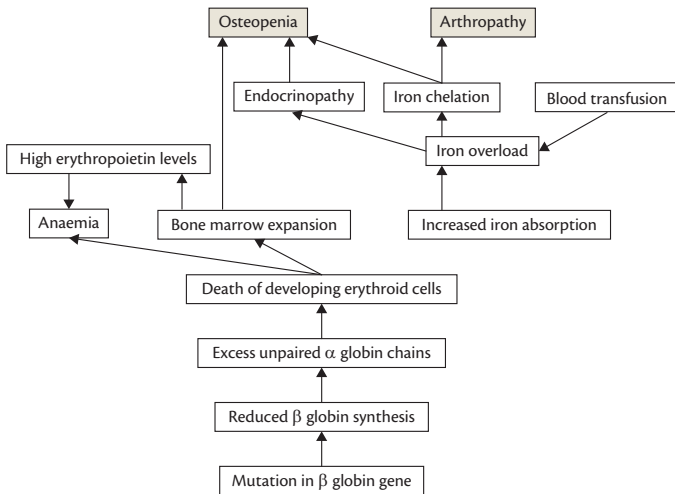
About 50% of adult patients with optimally treated thalassaemia major have severe reductions in bone mass with a Z-score of less than −2.5, with most of the remainder showing low bone mass, with a Z-score of −1 to −2.5.[2] This is multifactorial. Erythroid bone marrow expansion physically reduces the volume of bone cortex. Excess iron is directly deposited in bone, which impairs osteoid formation. Iron also causes endocrinopathy with low levels of sex hormones and delayed puberty. Iron chelators, particularly desferrioxamine, inhibit osteoblasts and collagen formation, and vitamin D deficiency is common in many non-tropical countries (Figure 172.1). Additionally, patients often have reduced levels of physical activity due to coexistent illness. About 40% thalassaemia major patients in the United States report a history of bone fracture, and the risk of fracture seems to increase with increasing endocrinopathy.[3] Bone


Fig. 172.1 Pathophysiology of osteopenia and arthropathy in β thalassaemia major.

pain is similarly a common symptom in thalassaemia major, often related to osteoporosis.

Management of osteopenia in thalassaemia major involves being aware of the risk and organising regular bone mineral density measurement from the age of about 10 years. Children and adults should be encouraged to be physically active, and vitamin D levels maintained in the optimal range with appropriate supplementation. Blood transfusion should be optimized to maintain the pre-transfusion haemoglobin above 95 g/L with the aim of limiting bone marrow expansion. Endocrinopathy should be prevented, by starting chelation early before significant iron accumulation occurs, usually after 10–12 transfusions. Overchelation can also cause bone damage, and care is needed once the serum ferritin is below 1000 µg/L. Several small studies suggest that bisphosphonates can reverse significant osteopenia, and this is probably the treatment of choice.[4]

Osteopenia is also a feature of thalassaemia intermedia, predominantly related to massive erythroid expansion. Significant osteopenia and pathological fractures suggest that regular blood transfusions should be started, although bone loss may then occur for other reasons. Bisphosphonates are also thought to be of therapeutic benefit.

Arthropathy

Before effective iron chelation was available, thalassaemia major patients with marked haemosiderosis sometimes developed osteoarthropathy, particularly affecting the ankles. It was probably related to hypoparathyroidism, bone marrow expansion, and iron deposition in the joints. Modern iron chelation has now made this rare in most countries.

About 15% patients using the oral iron chelator deferiprone (previously called L1) develop characteristic arthropathy as a side effect of the drug. This is often fairly mild and spontaneously recovers, although can result in severe and progressive joint damage, particularly in South Asian populations. The knees are most often affected, with joint effusions, irregularity of the subchondral bones, and cartilage damage on MRI.[5]

Other rheumatological complications

Massive erythroid expansion is seen in thalassaemia intermedia and undertransfused thalassaemia major, and results in the characteristic 'hair-on-end' appearance of skull radiograph. Related to this, thalassaemic facies can occur, with expansion of the maxillary bones and skull vault. Severe iron overload and chelation with desferrioxamine can result in calcification of intervertebral discs, which may contribute to back pain. Scoliosis and paraspinal extramedullary haematopoiesis are also fairly common.

Sickle cell disease

The term sickle cell disease (SCD) refers to a group of conditions, caused by the inheritance of mutated β globin, in which the sixth amino acid is changed from glutamic acid to valine. This sickle haemoglobin (HbS) forms polymers when deoxygenated, which damage the erythrocyte. Sickle cell anaemia (SCA) is the most common and severe form of the condition, in which HbS is inherited from both parents, although other compound heterozygous states cause similar syndromes (Table 172.1).[6] Pathological processes are complicated, involving an interrelated network, which starts with vaso-occlusion and includes infarction, vasculopathy, inflammation, haemolysis, reperfusion injury, nitric oxide deficiency, hypoxaemia, and hypercoagulability (Figure 172.2). It is a multisystem disorder with almost every tissue and organ involved, and rheumatological manifestations are common.

Clinical features include periods of apparent good health interspersed with unpredictable episodes of acute illness, usually involving acute pain and sometimes referred to as 'crises'. Acute lung complications and infection are also prevalent. These acute problems occur on a background of vasculopathy and progressive organ damage, resulting in an increased incidence of stroke, pulmonary hypertension, restrictive lung defects, retinopathy, renal impairment, cholelithiasis, priapism, leg ulcers, arthropathy, and bone damage. SCA is the commonest cause of paediatric stroke in the world.

Most complications are treated symptomatically. Penicillin prophylaxis in children has been shown to reduce morbidity and mortality from pneumococcal infection, and is recommended from about the age of 3 months in most countries. Randomized controlled trials have demonstrated that hydroxycarbamide improves the natural history of the condition; it reduces the frequency of acute pain and acute chest syndrome, and may delay organ damage and death.[6] Regular blood transfusions are used if there is evidence of severe, progressive vasculopathy, such as cerebrovascular disease. Haematopoietic stem cell transplantation is the only curative option, and the donor currently has to be an HLA-matched sibling; toxicity is still a significant issue, and only a minority of severely affected patients currently undergo this procedure.

Median life expectancy for SCA is probably about 50 years in the northern hemisphere, but considerably less in sub-Saharan Africa where most patients live, and the majority die in childhood. This increased mortality is probably primarily due to infections, including pneumococcus and malaria.[7]

Rheumatological complications of sickle cell disease

Acute bone pain

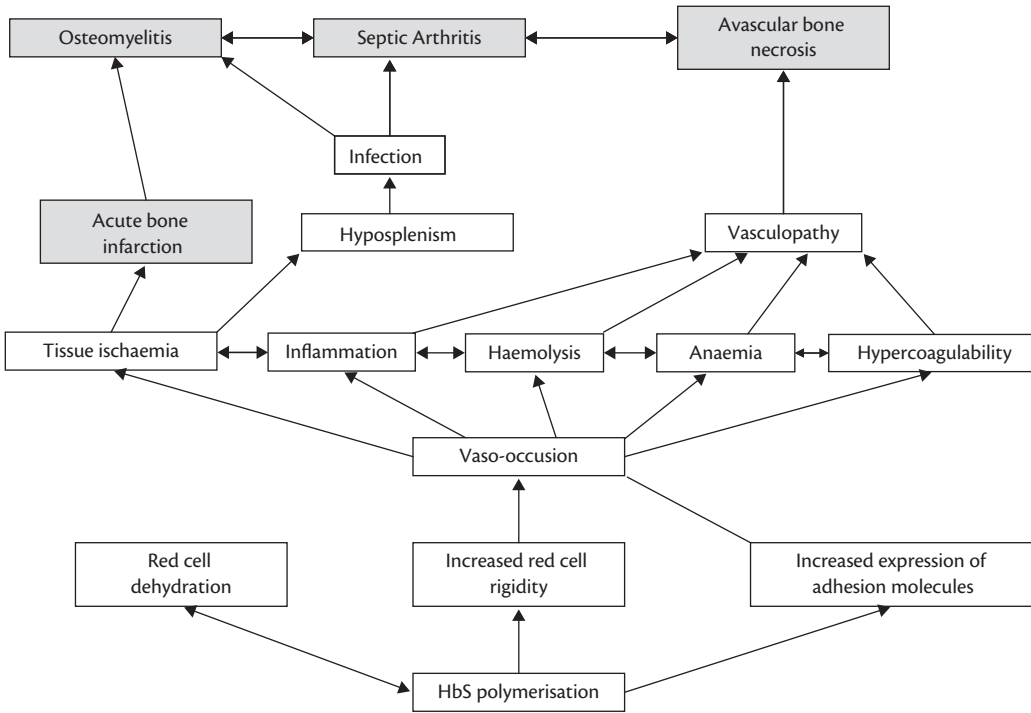
Acute bone pain is the commonest symptom in SCD, with severe episodes occurring on average about once per year, although this varies widely between individuals. The pain is thought to be due to vaso-occlusion of postcapillary venules, with infarction of the bone and subsequent inflammation. Most episodes are idiopathic,


Fig. 172.2 Pathophysiology of rheumatological problems in sickle cell disease.

Table 172.1 Commoner types of sickle cell disease with ethnic distribution

Severe SCD	
HbS/S	SCA, the commonest form of SCD
HbS/β^0thalassaemia	Most common in India, southern Europe
Severe HbS/β^+thalassaemia	Most common in India, southern Europe
HbS/O^{Arab}	Rare but found in Middle East and Balkans
Moderate SCD	
HbS/C	25–30% cases of SCD in African populations
Moderate HbS/β^+ thalassaemia	Most cases in Greece, Turkey. 6–15% HbA present
HbS/D$^{Punjab\ a}$	Found in India, Middle East but occurs all over the world
Mild SCD	
Mild HbS/β^{++} thalassaemia	Mostly in people of African origin
HbS/E	HbE centred in South-East Asia and so HbSE uncommon, although increasing
HbS/hereditary persistence of fetal haemoglobin	High HbF levels protect against serious complications. Commonest in West Africa

SCA, sickle cell anaemia; SCD, sickle cell disease.
[a]HbD^{Punjab} is also called HbD$^{Los\ Angeles}$.

although cold or windy weather, infection, dehydration, and stress may precipitate episodes. Pain typically involves the limbs and is often multifocal. The pain is described as deep-seated, like toothache, and the infarcted bones may be tender. Swelling of affected areas is common, particularly over the tibia.[8] In infants dactylitis, sometimes referred to as hand–foot syndrome, is the commonest

manifestation of bone infarction, in which painful swelling of the hands and feet occur for a few days (Figure 172.3).

There are no specific diagnostic tests. Plain radiographs are typically normal and should not be done unless to exclude fracture if there is a history of trauma; MRI may show evidence of bone infarction, although the appearances are not specific. Blood tests sometimes show neutrophilia, increased anaemia and increased bilirubin. C-reactive protein (CRP) and other inflammatory markers may be raised, although very high levels suggest coexistent infection. The erythrocyte sedimentation rate (ESR) is uninterpretable in SCD because of anaemia and the failure of sickle cells to form rouleaux.

There are no specific treatments for acute pain in SCD. Many episodes can be managed at home with paracetamol and non-steroidal anti-inflammatory drugs (NSAIDs), but severe pain requires hospital admission for treatment with opioids. These can be effective orally, although parenteral administration with nurse- or

Fig. 172.3 Dactylitis of the right hand in a young child with sickle cell anaemia.

patient-controlled analgesia is sometimes necessary. Sedation levels should be monitored closely, as oversedation is one of the main causes of death during acute pain. Massage, distraction, and warmth are often helpful. Fluid balance should be monitored carefully, and intravenous hydration should only be used if the patient is unable to drink adequately. Antibiotics are usually given if the temperature is more than 38 °C.

Typical episodes of severe pain last several days before gradually resolving, although shorter episodes lasting only a few minutes also occur. Full recovery may take over a week and permanent bone or joint damage does not result from these acute episodes.

Osteomyelitis

Bone infarction and hyposplenism predispose people with SCD towards osteomyelitis. Approximately 10% patients with SCD develop this at some point, with the peak incidence in children and young adults. Salmonella and *Staphylococcus aureus* are most commonly isolated, but many other organisms have been implicated, including Gram-negative bacilli, tuberculosis, Klebsiella, and *Streptococcus pneumonia*. Any bone can be affected.

In the early stages, it is difficult to distinguish osteomyelitis from acute bony vaso-occlusion, although the latter is much more common. The diagnosis of osteomyelitis is suggested by high fevers, greater than 38.5 °C, marked bony swelling, and extreme tenderness, although all these can also be features of bone infarction. Very high CRP and other inflammatory markers also suggest osteomyelitis, but again are not diagnostic. Radiographs, MRI and bone scintigraphy cannot reliably distinguish infarction from infection for about the first week after onset. Ultrasound scans can be used to identify subperiosteal fluid, with larger volumes suggesting osteomyelitis.[9] Growth of organisms such as salmonella, together with a suggestive clinical picture, is usually sufficient to make the diagnosis. Definitive diagnosis relies on isolation of pus or bacteria from the affected bone, and is probably best achieved by early use of ultrasound, with drainage and culture of significant collections of periosteal fluid.

Treatment typically involves 6 weeks of antibiotics selected according to sensitivities of isolated bacteria. In general there is a trend to over diagnose osteomyelitis in SCD, and treatment should not be started unless an organism has been isolated, or there is a very strong index of clinical suspicion. If empirical antibiotics are started, they should cover salmonella and *S. aureus*; ceftriaxone or ciprofloxacin are often used, depending on local sensitivities. Surgery may be important to drain large collections of fluid. Incomplete or late diagnosis can result in chronic osteomyelitis requiring repeated surgery and course of antibiotics over many years.

Septic arthritis

As for osteomyelitis, septic arthritis is hard to distinguish from acute vaso-occlusion. It is much rarer than vaso-occlusion, and usually occurs as a consequence of infarction at the end of a long bone. Diagnosis relies on aspiration of synovial fluid when infection is suspected, and Salmonella and *S. aureus* are isolated most frequently. Treatment requires a prolonged course of antibiotics.

Avascular necrosis

Avascular necrosis (AVN) of the femoral and humeral heads is common in SCD, although the exact prevalence is uncertain and depends on methods of detection. Plain radiographs show changes of osteonecrosis of the femoral head in 10–15% of adults, whereas MRI changes are seen in about 40% of adults and 25% of children. AVN of the humeral head is present in about 10% of adults with SCD, although it often causes few symptoms. Typically AVN causes chronic pain of the affected joint with exacerbations, which can be difficult to distinguish from acute vaso-occlusive pain. There is no good evidence on how best to manage this condition. In children rest and simple analgesia can lead to a complete resolution of symptoms. Established osteonecrosis of the femoral head in SCD has been treated with osteotomy, core decompression, and autologous bone grafting, although there is not much evidence that any of these are better than physiotherapy.[10] Once AVN is established, collapse of the femoral head is almost inevitable, and hip replacement arthroplasty is necessary to relieve pain. As this often occurs in adolescents and young adults, repeat hip replacements are likely, and technically challenging. AVN of a wide range of other bones has been described in SCD, including the knee, skull, face, mandible, ribs, spine, and pelvis.

Coincidental rheumatological illness in sickle cell disease

SCD is a common condition and inevitably coincidental rheumatological disease occurs in some adults and children. Many patients with SCD in industrialized countries are now surviving into old age, with increasing numbers affected by degenerative diseases. Diagnosis of these conditions is often delayed because of the tendency to attribute all symptoms to SCD, and management is complicated by potential interactions between the different diseases and their medications. In particular, there is anecdotal evidence that long-term use of corticosteroids may increase the risk of complications in SCD, including severe acute pain, increased sepsis and stroke[11]; on this basis, it is probably sensible to start hydroxycarbamide or even long-term blood transfusions if rheumatological disease is also present which is likely to need long-term treatment with corticosteroids.

Systemic lupus erythematosus (SLE) is a particular problem in SCD. It is approximately five times more common in women of African origin living in Europe compared to native Europeans, making it relatively prevalent in SCD patients. Many of the symptoms overlap with SCD, including musculoskeletal pain, neurological and renal complications. Diagnosing SLE can therefore be difficult, as can identifying the cause of particular symptoms when both conditions are known to coexist. As mentioned earlier, corticosteroids can be problematic in SCD, and other immunosuppressive treatments increase infective complications. However, in general SLE treatment should be prioritized, with hydroxycarbamide or regular blood transfusions started if serious sickle complications occur.

Haemochromatosis

Graeme J. Carroll, WIlliam H. Breidahl, and John K. Olynyk

Introduction and history

Hereditary haemochromatosis (HH) is a common inherited metabolic disorder characterized by systemic iron overload.[1–2] HH affects approximately 1 in 200 people and is most common in persons of northern European origin. Organ damage in the pancreas, liver, heart, endocrine glands, skin, and joints has been described in HH. There is evidence that the frequency and extent of organ damage may be changing with time, perhaps due to earlier diagnosis and treatment.[3] In persons of northern European origin, homozygosity for the C282Y mutation in the *HFE* gene found on chromosome 6 is present in over 90% of patients with HH,[4] whereas in southern Europe as many as 30% of cases may be heterozygous or wild type for this mutation.[5] Individuals homozygous for the C282Y mutation in the *HFE* gene product have up to a 30% chance of developing significant disease as a result of iron overload.[1]

The clinical manifestations of the disorder were reviewed by Sheldon in 1935, but in his description an arthropathy is not recorded.[6] It was not until Schumacher described two cases and reported a peripheral arthritis in 5 of 23 hospital cases of idiopathic haemochromatosis in 1964 that arthropathy was identified in haemochromatosis.[7] Subsequent studies have confirmed the presence of a clinically recognizable arthropathy.[8–17] Although clinically and radiologically characteristic, the arthropathy is not specific for haemochromatosis, since it cannot be differentiated from monoarticular osteoarthritis in the same target joints or from the form of polyarticular osteoarthritis classified as type 2 polyarticular osteoarthritis (T2POA).[18,19] Moreover, differentiation from pyrophosphate deposition disease, diabetes with metacarpophalangeal (MCP) joint involvement and even rheumatoid arthritis (RA) can sometimes be difficult.[8,20,21]

Characteristics of the arthropathy

Frequency of arthropathy

Arthropathy in HH has been reported to range from 24% to 81% as can be seen in Table 173.1. The association observed between this arthropathy, homozygosity for C282Y, and total body iron burden determined by baseline ferritin concentrations, suggests that iron load is a major determinant of arthropathy in HH and more

important than occupational factors.[16] Valenti et al. and others have also reported that arthropathy in HH is strongly associated with iron load.[15,17]

Considerable variation in the frequency of chondrocalcinosis has been reported, with estimates ranging from 5% to 49% of study participants as shown in Table 173.1.[9–11,13–15,17] Chondrocalcinosis is considered to be a late manifestation of the disease and by inference linked to disease chronicity. In one study, the incidence of chondrocalcinosis increased from 39% to 72% in 18 patients with known arthropathy who were undergoing regular venesection over a period of 10 years.[22] In no patient was diminution in size or disappearance of the chondrocalcinosis observed.

Joints affected—topography and course

The arthropathy of haemochromatosis is chronic and progressive. The index and middle finger metacarpophalangeal (MCP2,3) joints are most commonly affected. Importantly, from a pathogenetic perspective, these joints are also involved in some patients with juvenile HH, which has a different genetic basis.[23] The involvement of the MCP2,3 joints can be appreciated on clinical examination. Lack of flexion in these joints accounts for the 'iron fist' sign, an example of which is shown in Figure 173.1.[24]

Other joints in the hands can be affected in HH, but usually in association with the MCP2,3 joints. Coexistent interphalangeal (IP) joint disease due to osteoarthritis (OA) is not more frequent in HH than in population controls. Furthermore, primary idiopathic OA in the IP joints (type 1 polyarticular OA or T1POA) is also no more frequent in HH than in community controls.[17] A trend toward more frequent involvement of the triscaphe (scaphoid–trapezoid–trapezium) joint was noted by Valenti et al.[15] Occasionally the wrist and intercarpal joints can be affected as illustrated in the sentinel report by Schumacher[7] and the studies reported by Valenti et al.[15] However, in none of these other joints is there specificity for HH and even in the case of the MCP2,3 joints, there is a lack of disease specificity. Where chondrocalcinosis is present in either articular cartilage or fibrocartilage in association with a compatible MCP2,3 arthropathy, the specificity for the arthropathy of HH may be high, but to our knowledge this hypothesis has not been formally tested. The large joints such as the hip, ankle, radiocarpal, elbow, shoulder, and knee are also recognized sites in which the arthropathy of

Table 173.1 The frequency of arthropathy and chondrocalcinosis in reported series of patients with haemochromatosis and arthropathy

Study	Reference	Arthropathy [% frequency] (number studied)	Chondrocalcinosis % frequency (% of those with arthropathy)	% male in study
Dymock et al. 1970	9	57.4 (of 54 males)	49.2 (64.0)	93.1
Edwards et al. 1980	10	37.1 (n = 35)	17.1 (46.2)	60.0
Huaux et al. 1986	11	56.0 (n = 25)	20.0 (28) [n = 20]	72.0
Schumacher et al. 1988[b]	12	81.1 (n = 159)	NA	64.2
Faraawi et al. 1993	13	64 (n = 25)	36 [NA]	72.0
Sinigaglia et al. 1997	14	81.3 (n = 32)[a]	6.3 [NA]	
Valenti et al. 2007	15	36% for MCP disease (n = 88)	11% (100) [n = 10]	80.7
Richette et al. 2010	16	51% (OA in any of 7 regions) (n = 306)	NA	52.6
Carroll et al. 2011	17	24.4%[c] (n = 41)	4.9% (100%) [n = 2]	43.9

[a]31.2% had disease-specific arthropathy.

HH may manifest.[8,9,11,13,15] Joints such as the ankle and radiocarpal joints, which are usually spared in idiopathic or primary OA, may be involved in the arthropathy of HH. So far, no clinical criteria based on topography alone have been tested for diagnostic sensitivity and specificity for the arthropathy of HH.

Is the arthropathy inflammatory or non-inflammatory?

The arthropathy of HH is generally considered to be non-inflammatory. Despite the frequency of chondrocalcinosis, pseudogout presentations are uncommon. Case series draw attention to occasional cases where impressive clinical signs of synovitis have been observed and occasionally aspirates disclose numerous inflammatory cells and/or calcium pyrophosphate dihydrate (CPPD) crystals, but synovial fluids (SF) are mostly non-inflammatory. The observation that ferritin concentrations in the SF are higher in patients with OA who have *HFE* gene mutations raises the possibility that

Fig. 173.1 Iron fist sign in hereditary haemochromatosis.

SF ferritin may be a marker for an inflammatory component in the arthropathy of HH.[25]

Radiological findings in the arthropathy of hereditary haemochromatosis

The radiological features of the arthropathy of HH are similar to those in idiopathic osteoarthritis.[26,27] Subchondral sclerosis and joint space narrowing are typical. The latter can be rapidly progressive, with substantial deterioration within a matter of months.[11] More often however, the rate of progression is slow. Osteophytes may be present and can be prominent. In the MCP2,3 joints, hook-like osteophytes on the radial side of the metacarpal heads are characteristically seen. In one study, they were present in 17% of 41 definite or probable HH cases. The patients with hook-like osteophytes were all homozygous for the C282Y mutation.[17] Although regarded as a characteristic radiological feature of the arthropathy of HH, hook-like osteophytes do occur sometimes in OA and are thus not disease specific. The frequency with which subchondral lucencies, or geodes, are found in joints affected by the arthropathy accompanying HH is high, but has not been quantified. Dymock et al. described a strong correlation between subchondral lucencies and focal or eccentric chondral resorption and noted that cartilage loss occurred only occasionally in the absence of lucencies.[9] Lucencies may be prominent in the hip joint as depicted in Figure 173.2.[28] Erosions such as those seen in RA are not present, although infraction of marginal subchondral lucencies may be difficult to discriminate from rheumatoid erosions.

Pathology and aetiopathogenesis of arthropathy in hereditary haemochromatosis

Most of the information concerning joint pathology in HH has been obtained from surgical specimens derived at the time of joint
Fig. 173.2 MRI of the hip showing lucencies within the acetabulum and the femoral head.

replacement surgery and is therefore representative of advanced disease. Thinning or erosion of articular cartilage with exposure of eburnated bone is commonly described, but other findings such as iron deposition in cartilage, chondrocalcinosis, primary and secondary osteonecrosis, and articular cartilage avulsion at the tidemark in hip cartilage have been observed.[29,30] Cartilage avulsion is a very unusual finding in primary OA.[29] It is possible that dysregulated uptake of ferritin by osteocytes or chondrocytes may contribute to osteonecrosis and/or chondral damage.

In the synovium, deposits of iron have been observed, particularly in the synovial lining cells.[6,7,31–33] Indeed, deposition here as opposed to the sublining layers or synovial stroma is considered to be a point of differentiation between HH and secondary forms of haemochromatosis, such as occurs in thalassaemia major.[34] In the latter, sublining deposition is more marked.[31] Heiland et al. examined synovial tissue obtained from joint replacement specimens in patients with RA, OA, and HH,[32] and report many common features and very few differences overall. Importantly, haemosiderin deposits were found only in HH synovium and not in patients with RA or OA. Macrophage and neutrophil infiltration within the synovium was correlated with the extent of iron haemosiderin deposition. Interestingly, haemosiderin was still present in HH patients who had undergone regular venesection. In contrast, RA was easily distinguished from both OA and HH. The authors emphasize that HH arthropathy can be clearly differentiated from OA by the infiltration of cells of the innate immune response (macrophages, neutrophils) and also from RA by the lack of infiltrating specific immune cells (B cells, T cells). Thus in a number of respects the pathology of the arthropathy of HH is distinguishable and could perhaps be classified as 'intermediate' between that of RA and OA (Figure 173.3).

How iron is deposited and accumulates in the synovium in patients with HH is unclear, but the predominance of iron in the synovial lining layer raises the possibility that iron may be 'captured' from the synovial fluid as a result of persistently high serum ferritin concentrations and the phagocytic actions of synovial fibroblasts. Deposition may be effectively irreversible and accompanied by slowly progressive chondral resorption even in subjects who undergo regular venesection.[12,32] Iron deposition may of itself be seriously detrimental to the joint. Ferritin has recently been shown to act as a proinflammatory cytokine and could contribute directly to joint injury.[35] Importantly, in hepatic stellate cells, at nanomolar concentrations similar to those observed by one of the authors
Fig. 173.3 Immunohistochemistry of synovium from RA, OA and hereditary haemochromatosis. Hereditary haemochromatosis can be differentiated from OA by the infiltration of cells of the innate immune response (macrophages, neutrophils) and also from RA by the lack of infiltrating specific immune cells (B cells, T cells).

(GJC) in SF in HH, ferritin was found to be a potent and rapid inducer of IL-1 gene expression.[35]

How excess iron contributes to the development of calcium pyrophosphate production and chondrocalcinosis is not well understood. In-vitro studies show that iron inhibits pyrophosphatase, suggesting that excess iron may promote pyrophosphate deposition in synovium or cartilage.[36] Additionally, accumulation of calcium pyrophosphate may be facilitated by reduced clearance in the setting of synovial siderosis.[37] While both ferric and ferrous iron influence CPPD formation, to date chondrocalcinosis has not been definitively linked to the level of iron overload.[38,39,40]

Osteoporosis in hereditary haemochromatosis

Osteoporosis (OP) is also a recognized feature of HH with a frequency estimated to range from 25% to 35%.[16,41,42] Indeed in a questionnaire-based study in which the frequency of OP in HH patients was compared to that in 'healthy blood donors', the odds ratio (OR) for OP was found to be 1.9 (confidence interval 1.1–3.5). The mechanism responsible for OP in HH is unknown. Possible contributory factors include reduced bone formation secondary to iron-mediated suppression of osteoblast activity[43–45] and increased bone resorption due to hypogonadism[45]; however, the latter is

uncommon in HH and would not explain the relatively high preva-
lence of OP in HH.

Prognosis and treatment

Arthropathy in HH may predate other manifestations of the dis-
ease and is sometimes the manifestation which leads directly to
diagnosis. There is conjecture as to whether iron depletion has
any effect on arthralgia, other symptoms of the arthropathy, or
its course. There are anecdotal descriptions of symptom relief fol-
lowing phlebotomy and in one survey about one-third of patients
indicated that they experienced improvement in musculoskeletal
symptoms following iron depletion.[7,46,47] Most authorities doubt
that phlebotomy produces any substantial relief of arthralgias
or other joint symptoms, but Harty et al. have described a mean
reduction in arthralgia of 46% in those who reported arthralgia
in response to a questionnaire survey.[8–12,31,46,48] It is generally
accepted that 'de-ironing' has no effect on structural progression
of the joint disease, although this has not been rigorously evalu-
ated. In contrast, other manifestations of HH are clearly responsive
to iron depletion, so much so that arthropathy is now considered
to be the main cause of morbidity and reduced quality of life in
treated disease. Whether 'tight control of iron metabolism' from
an early age in those considered likely to manifest clinically overt
HH or aggressive treatment to target approaches with phlebotomy
could attenuate or prevent arthropathy or at least produce better
outcomes is still unknown.

Other forms of medical treatment for the arthropathy of HH
have been utilized. Analgesics, non-steroidal anti-inflammatory
drugs (NSAIDs) and cyclooxygenase-2 inhibitors can produce
symptomatic relief, but are not thought to have any disease-mod-
ifying effects, although no formal studies have been undertaken.
Intra-articular steroids may be useful temporarily, but are gener-
ally unpredictable. In an open study, two patients with HH and
in particular painful and disabling hand arthropathy responded
temporarily to Anakinra 100 mg SC administered daily for 5 days
and then regressed to baseline over the next 3 months.[49] Whether
continuous treatment of HH with this or other IL-1 antagonists will
provide sustained benefit remains to be determined. There is scope
for major benefit from surgical interventions in HH arthropathy,
not least from joint arthroplasties.

Conclusion

The arthropathy of haemochromatosis is relatively common even
in patients with HH recruited from the community. It is a chronic,
progressive arthropathy with a level of inflammatory activity that is
both clinically and histopathologically intermediate between that of
RA and OA. There is a predilection for the finger MCP joints and it
is variably, but not commonly, accompanied by chondrocalcinosis.
The precise mechanism responsible for tissue damage in affected
joints remains unknown; however, there is growing evidence that
iron load is a major determinant of the arthropathy. HH arthropa-
thy is variably responsive to phlebotomy. Whether earlier diagnosis
and treatment targeted to achieve tight control of iron metabolism
from an early age or as soon as possible after diagnosis could pro-
duce better outcomes remains to be determined. Novel and more
effective approaches to management with a view to prevention of
structural joint damage still need to be developed.
